Contents

	<i>Contributors</i>	<i>ix</i>
	<i>Additional contributors and acknowledgements</i>	<i>xiii</i>
	<i>Foreword</i>	<i>xv</i>
	<i>Preface</i>	<i>xvi</i>
	<i>About the companion website</i>	<i>xvii</i>
PART 1	General topics	1
SECTION 1	Dietetic practice	3
1.1	Professional practice	5
1.2	Dietary modification	20
1.3	Changing health behaviour	25
SECTION 2	Nutritional status	39
2.1	Dietary reference values	41
2.2	Assessment of nutritional status	47
2.3	Dietary assessment	61
2.4	Food composition tables and databases	67
SECTION 3	Nutrition in specific groups	73
3.1	Women's health	75
	3.1.1 Polycystic ovary syndrome	75
	3.1.2 Premenstrual syndrome	78
	3.1.3 Menopause	81
3.2	Preconception and pregnancy	84
3.3	Older adults	92
3.4	People in low income groups	104
3.5	Dietary patterns of black and minority ethnic groups	112
3.6	Vegetarianism and vegan diets	129
3.7	People with learning disabilities	141
3.8	Paediatric clinical dietetics and childhood nutrition	159
	3.8.1 Introduction	159
	3.8.2 Growth, nutritional assessment and nutritional requirements	160
	3.8.3 Growth faltering	170
	3.8.4 Nutritional care of the preterm infant	176
	3.8.5 Community paediatrics	178
	3.8.6 Autism	179
	3.8.7 Special needs	181
	3.8.8 Paediatric general medicine	182
	3.8.9 Paediatric oral nutritional support	183
	3.8.10 Paediatric enteral tube nutrition	184
	3.8.11 Paediatric parenteral nutrition	188
	3.8.12 Paediatric gastroenterology	191

3.8.13	Cystic fibrosis	193
3.8.14	Paediatric liver disease	195
3.8.15	Paediatric nephrology	196
3.8.16	Neurology and the ketogenic diet	198
3.8.17	Inherited metabolic disorders	199
3.8.18	Paediatric food hypersensitivity	201
3.8.19	Paediatric human immunodeficiency virus	203
3.8.20	Paediatric diabetes	204
3.8.21	Cardiology	206
3.8.22	Paediatric cancers	208
3.8.23	Paediatric haematopoietic stem cell and bone marrow transplantation	210
3.8.24	Nutrition support in the critically ill child	211
3.8.25	Neurosurgery	214
3.8.26	Burns	216
3.8.27	General surgery	219
SECTION 4	Specific areas of dietetic practice	221
4.1	Freelance dietetics	223
4.2	Public health nutrition	231
4.3	Sports nutrition	252
4.4	Food service	260
	4.4.1 Hospitals and institutions	260
	4.4.2 Prisons	269
	4.4.3 Armed forces	271
4.5	Food law and labelling	273
SECTION 5	Other topics relevant to practice	285
5.1	Genetics and nutritional genomics	287
5.2	Functional foods	295
5.3	Drug–nutrient interactions	299
5.4	Alternative and complementary therapies	305
PART 2	Clinical dietetic practice	313
SECTION 6	Nutrition support	315
6.1	Nutritional requirements in clinical practice	317
6.2	Malnutrition	325
6.3	Oral nutritional support	336
6.4	Enteral nutrition	344
6.5	Parenteral nutrition	357
6.6	Fluids and electrolytes	365
SECTION 7	Clinical dietetic practice	373
7.1	Respiratory disease	375
7.2	Dental disorders	385
7.3	Dysphagia	391
7.4	Gastrointestinal disorders	400
	7.4.1 Disorders of the upper aerodigestive tract	400
	7.4.2 Orofacial granulomatosis	401

7.4.3	Disorders of the stomach and duodenum	406
7.4.4	Gastroparesis	409
7.4.5	Disorders of the pancreas	415
7.4.6	Malabsorption	420
7.4.7	Coeliac disease	426
7.4.8	Inflammatory bowel disease	442
7.4.9	Intestinal failure and intestinal resection	450
7.4.10	Irritable bowel syndrome	460
7.4.11	Disorders of the colon and rectum	467
7.4.12	Liver and biliary disease	474
7.4.13	Cystic fibrosis	502
7.5	Renal disorders	515
7.5.1	Acute and chronic kidney disease	515
7.5.2	Renal stones	539
7.6	Neurological disease	549
7.6.1	Parkinson's disease	549
7.6.2	Motor neurone disease	555
7.6.3	Rare neurological conditions	563
7.6.4	Multiple sclerosis	570
7.6.5	Chronic fatigue syndrome/myalgic encephalomyelitis	576
7.6.6	Neurorehabilitation	581
7.7	Refsum's disease	589
7.8	Inherited metabolic disorders in adults	594
7.9	Musculoskeletal disorders	605
7.9.1	Osteoporosis	605
7.9.2	Arthritis	615
7.9.3	Gout	622
7.10	Mental health	626
7.10.1	Eating disorders	626
7.10.2	Dementias	637
7.10.3	Nutrition and mental health	644
7.11	Immunology and immune disease	656
7.11.1	Nutrition and immunity	656
7.11.2	Food hypersensitivity	663
7.11.3	HIV and AIDS	696
7.12	Diabetes mellitus	711
7.13	Obesity	727
7.13.1	General aspects and prevention	727
7.13.2	Management of obesity and overweight in adults	735
7.13.3	Bariatric surgery	746
7.13.4	Childhood obesity	750
7.14	Cardiovascular disease	756
7.14.1	General aspects	756
7.14.2	Coronary heart disease	765
7.14.3	Dyslipidaemia	777
7.14.4	Hypertension	788
7.14.5	Stroke	796
7.15	Cancer	805
7.15.1	General aspects	805
7.15.2	Head and neck cancer	815
7.15.3	Cancer of the gastrointestinal tract	826
7.15.4	Breast cancer	834
7.15.5	Lung cancer	838
7.15.6	Gynaecological cancers	841

	7.15.7 Prostate cancer	844
	7.15.8 Haematological cancers and high dose therapy	849
	7.15.9 Cancer cachexia	855
7.16	Palliative care and terminal illness	859
7.17	Trauma and critical care	865
	7.17.1 Critical care	865
	7.17.2 Traumatic brain injury	880
	7.17.3 Spinal cord injury	890
	7.17.4 Burn injury	898
	7.17.5 Surgery	905
	7.17.6 Wound healing, tissue viability and pressure sores	914

Appendices

Appendix A1	Generic framework for critical appraisal	921
Appendix A2	Micronutrients	922
Appendix A3	Dietary reference values	931
Appendix A4	Weights and measures	934
Appendix A5	Dietary data	938
Appendix A6	Body mass index (BMI)	943
Appendix A7	Anthropometric data	945
Appendix A8	Predicting energy requirements	948
Appendix A9	Clinical chemistry	949
Appendix A10	Nutritional supplements and enteral feeds	954
Appendix A11	Nutrition screening tools	971
	<i>Index</i>	977

Foreword

Good nutritional care has never been so important and, as the British Dietetic Association (BDA) has said, registered dietitians (RDs) are the only '*qualified health professionals that assess, diagnose and treat diet and nutrition problems at an individual and wider public health level*'. Dietitians have, therefore, many crucial roles to play in improving care standards in the new emerging NHS and beyond in improving the health of our nation.

This edition of the *Manual of Dietetic Practice* is an outstanding source of information for both qualified and student dietitians. It takes an exemplary systems approach in its clinical sections, which focus on dietetic practice, beginning with nutritional support and followed by chapters dedicated to specialist areas such as gastroenterology and oncology. It also covers the breadth of dietetic specialties outside healthcare. Dr Joan Gandy should be congratulated for her excellent contribution in managing, collating and editing this leading edge reference work, and clear praise and acknowledgement must also be given to the many authors of the individual chapters without whom the manual could not have been produced.

Providing good nutritional care for all is a matter of quality. During my many years involved with clinical nutrition, including periods chairing the group that developed the National Institute for Health and Care Excellence (NICE) Quality Nutrition Support Standards (2006) as well as the British Association of Parenteral and Enteral Nutrition (BAPEN), I have had the privilege of working with visionary, highly committed and enthusiastic dietitians who make a real difference. This manual should help to guide many more individuals to pursue such dietetic excellence and I hope that for many it will also lead to a commitment to join cross disciplinary efforts to improve the nutritional care delivered to patients, their carers and the public. Only then will we attain unprecedented levels of excellence.

Dr Mike Stroud

*Consultant Gastroenterologist, Southampton
University Hospitals NHS Trust
Senior Lecturer in Medicine and Nutrition,
Southampton University*

Preface

This book, the fifth edition of the *Manual of Dietetic Practice*, is intended to be part of a spectrum of resources available to dietitians, dietetic students and others. The spectrum now includes an increasing number of specialist dietetic texts and this edition of the manual is written, as far as possible, to complement these texts; both published works and books currently being prepared, e.g. *Diet and Nutrition for Gastrointestinal Disease*. Inevitably, some specialisms are too small to warrant a separate text and are therefore included in this manual. This edition of the manual is aimed mainly at non-specialist dietitians and dietetic students, and is intended for use as a standard textbook in dietetic departments.

Dietetics is a dynamic profession, which means that knowledge and practice change rapidly and dietitians are working in more diverse areas. Therefore, this edition of the manual includes new topics such as genetics and nutrigenomics, and immunology and health. Areas of interest to dietitians continue to expand and dietitians are specialising in areas such as respiratory medicine that were previously considered as general rather than specialist; another new chapter. Medical advances have resulted in conditions that once resulted in early death being managed differently, with longer survivorship. An example of this is the dietetic management of inherited metabolic disorders. Most people with these conditions now survive well into adulthood and therefore present fresh challenges in management; as a result, this topic has been included in this edition.

Many of the chapters have been totally rewritten, often by pairs or groups of people and with many more involved in reviewing the texts; dietitians of every level of experience have been involved, from students through to professors. The approach of the manual has also changed and is in line with the specialisms of the British Dietetic Association (BDA) specialist groups and other dietetics groups and networks.

However, as this is a text on dietetic practice, general chapters on the nutrients have been removed, although an appendix has been created to provide a ready reference on micronutrients. The *Manual of Dietetic Practice*

is constructed to be cohesive and as such there is considerable cross referencing between chapters. It is divided into two parts encompassing seven sections with appendices:

Part 1. General topics

Section 1 – Dietetic practice

Section 2 – Nutritional status

Section 3 – Nutrition in specific groups

Section 4 – Specific areas of dietetic practice

Section 5 – Other topics relevant to dietetic practice

Part 2. Clinical dietetic practice

Section 6 – Nutrition support

Section 7 – Clinical dietetic practice

The area of paediatric dietetics is always challenging, as well as interesting, and this area has been completely revised in this edition to provide an appropriate level of knowledge for non-paediatric dietitians who work with children in general settings. Working with the BDA's Specialist Paediatric Group and Vanessa Shaw, editor of *Clinical Paediatric Dietetics*, the chapters on developmental stages have been edited and consolidated into one extended chapter, with an introduction to topics in clinical paediatric practice. Hopefully, dietitians will find this useful and student dietitians will be introduced to another exciting and satisfying area of practice.

Another innovation is the inclusion on the Wiley Blackwell Internet site of additional resources, including case study discussion papers and slides of the figures and tables that can be downloaded. In addition, this edition will be available as an electronic book. As the field of dietetic practice has expanded so too has the *Manual of Dietetic Practice* and I suspect that the next edition will be presented in a different, if not multiple, format.

While editing the MDP has been a challenge, the level of support has been overwhelming and inspiring. I am indebted to the many people who have written or revised the chapters, and the many reviewers and other contributors.

Joan Gandy

PART 1

General topics

SECTION 1

Dietetic practice

1.1

Professional practice

Najia Qureshi, Sue Kellie, Ingrid Darnley, Julie Farmer, Judy Lawrence and Joan Gandy

Key points

- In the UK dietitians must be graduates of an approved programme of education and registered with the Health and Care Professions Council.
- The British Dietetic Association is a professional association that aims to inform, protect, represent and support its members.
- Dietitians are autonomous practitioners who work within an ethical framework of conduct.
- The nutrition and dietetic process is central to dietetic practice.
- Dietetics is an evidence based profession with research and outcome evaluation at its core.
- Dietitians engage in continuing professional development throughout their careers to ensure that their practice is robust, efficacious and innovative.

Dietetics is a well respected and established profession, albeit a relatively new profession. The first UK dietitian, Ruth Pybus, a nursing sister, was appointed in 1924 at the Royal Infirmary in Edinburgh. She initially sought to demonstrate that a dietetic outpatient clinic could significantly reduce the number of admissions and therefore benefit the hospital. She was successful; after a 6-month trial, her appointment as a dietitian was confirmed. The development of other dietetic departments quickly followed, especially in London, and in 1928 the first non-nursing dietitians were appointed. From these early days dietetics has been a science based profession and in the 1980s became the first of the allied health professions (AHPs) to become a graduate profession.

In 1936 the British Dietetic Association (BDA) was founded as the professional association for registered dietitians in Great Britain and Northern Ireland. The BDA aims to inform, protect, represent, and support its members.

Dietetics is both an art and a science that requires the application of safe and evidence based practice, reflective practice and systematic clinical reasoning. A dietitian needs to combine these skills with knowledge and experience, together with intuition, insight and understanding of the individual (or specific) circumstance in order to maintain and improve practice. Following several public enquiries at the end of the last century it was recognised that there needed to be greater priority given to non-clinical aspects of care, such as skills in communicating with colleagues and service users, management, develop-

ment of teamwork, shared learning across professional boundaries, audit, reflective practice and leadership. Subsequent legislative changes were implemented with the establishment of the Health and Care Professions Council (HCPC).

Dietetics as a profession

An occupation or trade becomes a profession '*through the development of formal qualifications based upon education, apprenticeship, and examinations, the emergence of regulatory bodies with powers to admit and discipline members, and some degree of monopoly rights on the knowledge base*' (Bullock & Trombley, 1999, p. 689). A degree of responsibility and expectation comes with being a professional. A member of any profession, including dietetics, must, within their practice, agree to be governed by a code of ethics, uphold high standards of performance and competence, behave with integrity and morality, and be altruistic in the promotion of the public good (Cruess *et al.*, 2004). Furthermore, these commitments form the basis of an understanding, or social contract, that results in professions, and their members, being accountable to service users and to society.

Professional regulation

To practise as a dietitian, and to use the title of dietitian, it is mandatory to have completed an approved

programme of education and be registered with the HCPC. The HCPC was set up in 2001 to protect the health and wellbeing of people using the services of the health professionals registered with them. It aims to:

- Maintain and publish a public register of properly qualified members of the professions.
- Approve and uphold high standards of education and training and continuing good practice.
- Investigate complaints and take appropriate action.
- Work in partnership with the public and other groups, including professional bodies.

To remain on the HCPC register, dietitians must continue to meet the standards that are set for the profession. The professional standards are:

- Good character of health professionals.
- Health.
- Proficiency (dietetics).
- Conduct performance and ethics.
- Continuing professional development (CPD).
- Education and training.

The HCPC use these standards to determine if a registrant is fit to practise. If the HCPC finds that there are concerns about a dietitian's ability to practise safely and effectively, and therefore fitness to practise is impaired, it has the legal right to take action. This may mean that the registrant is not allowed to practise or that they are limited in what they are allowed to do. The HCPC can legally take appropriate action to enforce this (HCPC, 2010).

The British Dietetic Association as a professional body

The distinction between a regulatory body (HCPC) and a professional body (BDA) is often misunderstood. It is important that dietitians are fully aware of the differences from the beginning of professional training. Much like the HCPC, the BDA is committed to protecting the public and service users. However, the two organisations achieve this in very different ways (Table 1.1.1). The HCPC has the ultimate sanction to prevent a dietitian from practising if, following investigation, they are deemed to be unsafe or untrustworthy. However, the BDA provides guidance, advice, learning and networking opportunities, and professional indemnity insurance cover, all with the aim of supporting the development of safe and effective practitioners. This ultimately helps protect the public and service users. The BDA also provides a trade union function and supports members throughout their working life on issues such as pay and conditions, equal opportunities, maternity rights and health and safety.

Autonomy

Autonomy can be defined as the right of self governance and as independent practitioners, who practice autonomously, dietitians are personally accountable for their

Table 1.1.1 Remit of the Health and Care Professions Council (regulatory body) and the British Dietetic Association (professional body)

Health and Care Professions Council	British Dietetic Association
Protect the public and service users	Protect the public and service users
Set professional standards of practice	Membership support
Approve education programmes that train and educate graduates to meet these standards	Advance the science and practice of dietetics
Register graduates of these programmes	Promote education and training in the science and practice of dietetics
Ensure registrants meet professional standards	Regulate the relationship between dietitians and their employer through the trade union
Sanction registrants who do not meet these standards	Provide professional indemnity insurance

practice (BDA, 2008a). This means they are answerable for their actions and omissions, regardless of advice or directions from another health professional. Dietitians have a duty of care for their service users and clients who are entitled to receive safe and competent care or service.

The HCPC states that as autonomous and accountable professionals, dietitians, '*... need to make informed and reasonable decisions about their practice. This might include getting advice and support from education providers, employers, professional bodies, colleagues and other people to make sure that you protect the wellbeing of service users at all times.*' (Health and Care Professions Council, 2008).

It is important that dietitians are aware of the boundaries of their autonomy, which will never be limitless but will always be confined to their scope of practice. As with all health professionals, dietitians must never practise in isolation. Up to date knowledge skills and experience are the cornerstone of safe and effective practice, and as such dietitians should always have access to a support network of leaning, development and peer review. In the National Health Service (NHS) setting, the system for learning and development is usually already established via internal processes, e.g. supervision, appraisal, local training programmes, library services and journal clubs. Outside of the NHS these processes are not automatically in place and it is essential that every healthcare professional actively establishes a network of support and learning to match their scope of practice, e.g. freelance practice (see Chapter 4.1).

Scope of practice

Identifying individual scope of practice is not easy as the boundaries will be different for each practitioner and will

Table 1.1.2 Factors that define dietetic scope of practice

Factor	Example
Occupational role	Clinician, researcher, educator, writer, consultant
Sector	Private practice, industry, higher education, commercial
Environment	Acute, community, GP practice, industry, media
Client group	Children, elderly, people with learning difficulties, public, supermarket
Speciality	Diabetes, public health, obesity, product development
Approaches	Behavioural therapy, group education, anthropometry, cook and eat session
Types of cases for referral elsewhere	Other dietitians or other healthcare professionals, social services

evolve over time (BDA, 2009a). The description of a dietitian's scope of practice is often broad and may describe some or all of the factors shown in Table 1.1.2.

A much more specific scope of practice is described in relation to specific service users. When presented with a service user, the dietitian should undertake a personal risk assessment as part of the overall assessment, asking key questions before proceeding. These questions include:

- Is the service user safe?
- Am I safe?
- Can I justify the decision I have made during the assessment (e.g. has the research, evidence, standards and guidance been considered)?
- Can I identify the most appropriate approach for the service user group?
- Do I have the correct balance of skills, knowledge and experience to be competent in my chosen approach?

Extended scope of practice

The extended roles dietetic practitioner undertake are those outside their core and specialist roles. They are usually (but not exclusively) roles traditionally carried out by other health professionals either as a core duty or role extension. Additional skills and knowledge are acquired through formal training. The extended role practitioner must advance dietetic practice and contribute to improving outcomes. Examples of extended roles include:

- Replacing gastrostomy tubes in the community.
- Inserting peripheral midlines for intravenous feeding.
- Advising on appropriate exercise regimens.

Whatever role a dietitian commits to, extended or otherwise, they must constantly be aware of their individual scope of practice, and practice within this.

Ethics and conduct

Conduct is the manner in which a person behaves, especially in a particular place or situation, while ethics are moral principles that govern a person's or group's behaviour. However, it is essential to put these definitions into context for them to have any meaning. In professional practice, professional ethical conduct is paramount. Outside of their professional role, dietitians have the right to behave how they choose, within the limits of the law, and this will be limited only by personal ethical boundaries. In professional practice, it is the professional codes of conduct that provide the framework for, and the benchmark by which, ethical conduct will be measured.

A major function of a code of conduct is to enable professionals to make informed choices when faced with an ethical dilemma. For the dietetic workforce the key guidance is laid out in the HCPC Standards of Conduct, Performance and Ethics (2008) and Guidance on Conduct and Ethics for Students (2009). These standards are written in broad terms so as to apply to all registrants as far as possible, and are designed not to be overly prescriptive, thereby undermining professional judgement and stifling progress and innovation.

The BDA Code of Professional Conduct (2008a) builds on the generic standards of the HCPC, with more dietetic specific guidance. They apply to the whole dietetic workforce from unregulated students and support workers to qualified dietitians. In practice, however, there will be numerous occasions where, despite guidance, there is no right or wrong answer to everyday dilemmas in practice. The HCPC (2008, p. 5) states that in such situations *'If you make informed, reasonable and professional judgements about your practice, with the best interests of your service users as your prime concern, and you can justify your decisions if you are asked to, it is very unlikely that you will not meet our standards.'*

Through HCPC mandated continuing professional development, a dietitian can ensure they have the technical knowledge, with the right skills and competencies, to be able to function in their role. As an autonomous professional, it is equally important to be an ethically competent practitioner to ensure trust between the professional and user. In addition, this trust is not confined to the individual practitioner but to the profession itself. Interpretation of ethical competence allows the distinction between skill and expertise or technical competence, and professionalism (Friedman, 2007). Friedman describes the acquisition of ethical competence in five stages as shown in Figure 1.1.1.

Model and Process for Nutrition and Dietetic Practice

The primary purpose of the practice of dietetics is to optimise the nutritional health of the service users, be they an individual, group or community, or population. By optimising the nutritional health of the service users the dietitian expects to positively influence health outcomes. In the practice of dietetics it is common for the dietitian to seek to influence or change other aspects of

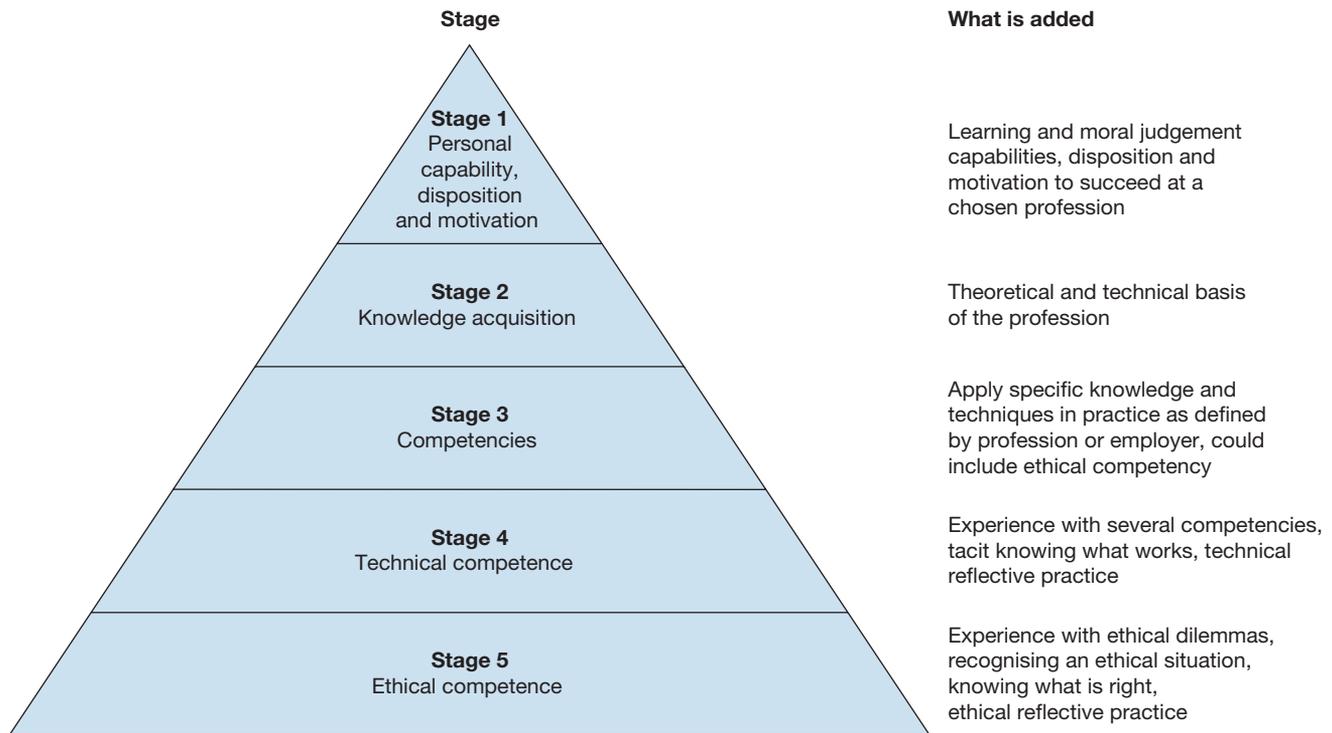

Figure 1.1.1 Stages in the acquisition of ethical competence (adapted from Friedman, 2007)

care or treatment, e.g. medication or the psychological wellbeing of the service user. However, the primary purpose of the dietitian is to identify and take action to improve the nutritional status of the service user and to improve those symptoms that are amenable to dietetic intervention.

Any single consultation or professional activity is incredibly complex and involves a number of different and varied strands of knowledge from biological and social sciences to food and medicine, alongside communication and clinical decision making skills and attributes such as empathy and respect. These are applied within professional and legal frameworks and boundaries and within organisational and social norms and standards. Most of this thought process is invisible to other professionals and often to the user as it takes place rapidly within the dietitian. The model of dietetic practice (MDP) seeks to make this explicit and visible. The BDA's Model and Process for Nutrition and Dietetic Practice (2012) is shown in Figure 1.1.2.

The model for dietetic practice brings together all of these aspects in a single framework that describes dietetic practice whether with individuals, groups or communities. The purpose of the MDP and the nutrition and dietetic process (NDP), which is the key aspect within it, is to help the profession provide safe, effective and consistent services and evidence of this.

Nutrition and dietetic process

At the centre of the NDP is the relationship between the service user and the dietitian. This relationship is key and

influences how all the other aspects of the process function. The service user is at the centre of all professional practice and is most often the most important decision maker in any situation. User (person or patient) centred care has been demonstrated to lead to improved outcomes and to improved satisfaction with care (Robinson *et al.*, 2008). There are many and varied definitions, but the Institute of Medicine (2001) definition, '*Providing care that is respectful of, and responsive to individual patient preferences, needs and values and ensuring that patient values guide all clinical decisions*' encompasses all the concepts.

This definition ensures that the dietitian recognises that the service user's values and preferences will influence how the dietetic intervention is received and therefore how the intervention is delivered. This could be as simple as the level of information and choice the service user requests within the consultation or as complex as decisions about which aspects of the possible dietetic intervention plan to participate in or how to receive the service. The NDP developed by the BDA (2012) is shown in Figure 1.1.3.

This core relationship is at the centre of the NDP and is surrounded by other factors that will influence how the dietitian delivers the intervention and how the service user receives it. The inner rings describe what the dietitian, as a professional, brings to the relationship. This includes:

- Ethical frameworks such as the HCPC Code of Conduct, Performance and Ethics and the BDA Code of Professional Practice.

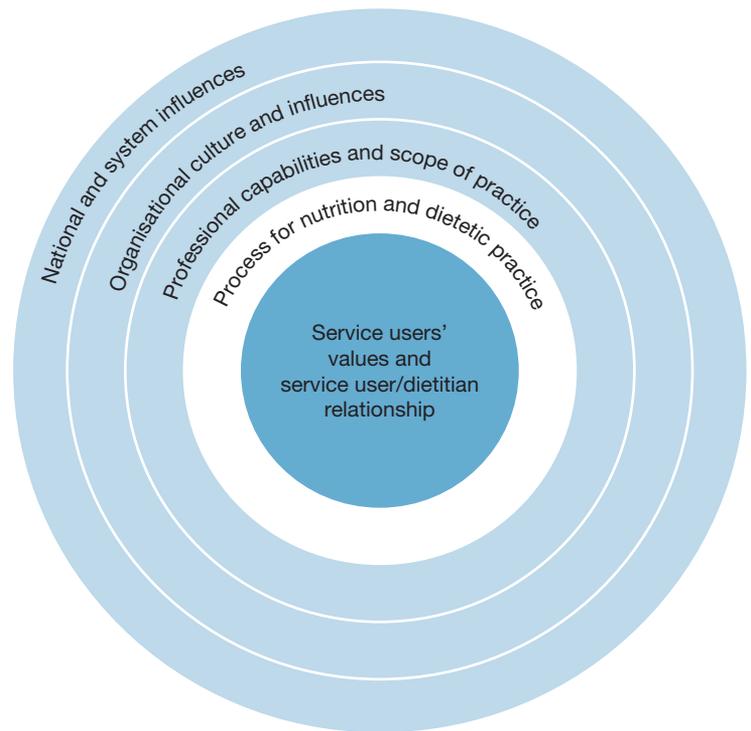

Figure 1.1.2 Model of Nutrition and Dietetic Practice [source: The British Dietetic Association 2013. Reproduced with permission of the British Dietetic Association (www.bda.uk.com)]

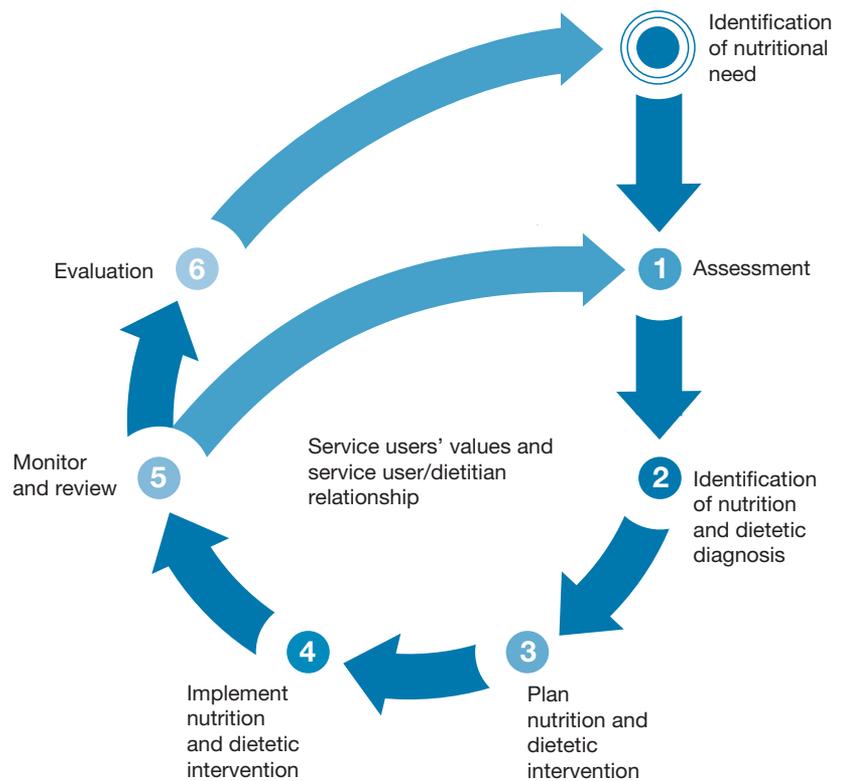

Figure 1.1.3 Nutrition and Dietetic Process [source: The British Dietetic Association 2013. Reproduced with permission of the British Dietetic Association (www.bda.uk.com)]

- Dietitian's scope of practice and professional capabilities.
- Evidence base for professional practice and the dietitian's continuing professional development.

This is surrounded by the organisational, social and environmental influences on practice. An organisation providing health services will require the dietitian to practise within their governance systems that are designed to provide safe and effective practice. There will be health needs and economic analysis, which will determine what services are required to meet the health needs of the local population and where the care is provided, and these can influence how the dietetic service is delivered.

The BDA Model and Process for Nutrition and Dietetic Practice (2012) provides the framework for a nutritional or dietetic intervention and describes the actions of the dietitian, together with the knowledge skills and critical thinking that a dietitian brings to all interventions. The dietitian places decision making skills and the service user's needs at the centre of the intervention. This process supports the implementation of a standard quality of care that is then personalised to the service user. By using the process, the dietitian moves from experience based practice to evidence based practice, explicitly applying the science and social science evidence base to critical decision making; essentially they are influenced by the service users preferences, need and values (Lacey & Pritchett, 2003). The BDA nutrition and dietetic process consists of five steps (Table 1.1.3):

1. Assessment.
2. Nutrition and dietetic diagnosis.
3. Formulation and planning of the intervention.
4. Implementation of the intervention.
5. Monitoring and evaluation.

Dietetic diagnosis

As previously stated, a dietitian is an autonomous professional and therefore responsible for their actions. One of the ways in which a dietitian demonstrates this autonomy is the identification of a nutritional and dietetic diagnosis. The diagnosis step may be considered the most important step in the NDP but it is often the step that is missed. In making a diagnosis the dietitian uses critical reasoning skills to evaluate the assessment information and to make judgements as to the risks to the service user(s) of taking action, or not. The dietitian will prioritise the nutritional issues identified and make a judgement as to whether taking action on these issues will make a difference to the health and outcomes for the service user.

In developing the diagnosis, the dietitian identifies the relevant aspects of the assessment and clearly states the nutritional problems that they and the service user have prioritised and the nutritional issues the dietitian can influence, and by doing so, the impact the nutritional and dietetic intervention will have on the service user's health. The benefits from making a nutritional and dietetic diagnosis include:

- Sharing with others involved with the service user the nutritional issue(s) that the dietitian and service user have prioritised.
- Identifying the specific nutritional issue(s) that the dietitian can influence.
- Identifying the indicators in the assessment process that will form the basis of monitoring and evaluation.
- Demonstrating the thoroughness of the assessment process and clearly communicating this to other professionals.

The diagnostic statement should clearly record for all service providers the problem, its cause (aetiology) and why the dietitian considers that it is a problem (symptoms). This statement also forms the basis of the monitoring and evaluation step as the dietitian will also have identified the most important indicators from their description of the symptoms.

Recording and information management

Another fundamental aspect of professionalism is the accurate recording of the nutrition and dietetic process. The HCPC (2007) Standards of Proficiency require dietitians to be able to maintain records appropriately. The information in records, including dietetic records, is used for many different purposes. Most importantly, it provides a permanent account of the dietetic process, especially the intervention, and a means of communication between all professionals and others involved, including the service user.

Information contained within records is also used for a number of other purposes, including demonstrating the overall effectiveness of the dietetic service and, possibly, organisation, quality monitoring and service improvement, research and public health purposes. While the increasing use of electronic health records will require more systematic record keeping, there is evidence that using a systematic format in any record, paper or electronic, improves the quality of care and service user outcomes (Mann & Williams, 2003). It is therefore important that the information in professional records is recorded accurately, systematically and consistently.

Quality improvement

Quality (Donabedian, 1980) has many dimensions. In the health service, patients, the public and carers expect safe, effective and consistent high quality care and treatment (NHS Scotland, 2003). For the individual dietitian this is a requirement of registration with the HCPC. Quality improvement involves a series of activities undertaken to reduce the gap between current practice and desired practice.

As a result of the need to account for its management and clinical efficiency, effectiveness and value for money, the NHS developed the concept of clinical governance. Clinical governance is defined as, *'the system through which NHS organisations are accountable for continuously improving the quality of their services and safe-*

Table 1.1.3 Definitions of the steps in the Model and Process for Nutrition and Dietetic Practice

Step	Definition
Assessment	<p>A systematic process of collecting and interpreting information to make decisions about the nature and cause of nutrition-related health issues in an individual, a group or a population</p> <p>Its purpose is to obtain adequate and relevant information to identify nutrition related problems and to inform the development and monitoring of the intervention</p> <p>It is initiated by the identification of need, e.g. screening, referral by a health professional, self referral, high level public health data, epidemiological data or other similar process</p>
Identification of nutritional and dietetic diagnosis	<p>Identification of nutritional problems that impact on the physical, mental and/or social wellbeing where the dietitian is responsible for action</p> <p><i>Individual</i></p> <p>It requires therapeutic or educational action as determined by the dietitian and service user</p> <p>Based on scientific evaluation of physical and psychological signs, symptoms, dietary and medical history, procedures and test results and the priorities of the service user</p> <p><i>Groups</i></p> <p>In a therapeutic group there will be a diagnosis for the individuals in the group (as individuals). In a public health group the diagnosis step will be the same as for the population</p> <p><i>Populations</i></p> <p>Within a public health needs assessment framework the nutritional diagnosis is defined as assessing a nutritional health priority for action. It involves choosing (for action) the nutritional health conditions and determinant factors with the most significant size, impact and severity</p> <p>At all levels it includes the identification and categorisation of the occurrence, risk or potential for the development of a nutritional problem that the dietitian will be responsible for treating independently or of leading the strategy to manage</p>
Plan intervention	<p>A set of activities and associated resources that are used to address the identified nutritional and dietetic diagnosis designed with the intent of changing nutrition related behaviours, risk factors, environmental factors or aspect of physical or psychological health or nutritional status of the individual, group or population. All interventions are planned with the communities, service users and carers who are the recipients of the intervention. This client centred approach is a key element in developing a realistic plan that has a high probability of positively influencing the outcome. This will usually involve describing:</p> <ul style="list-style-type: none"> • Overall measurable and specific outcomes • Intermediate goals, which will achieve the outcomes, determined by the diagnosis statement and assessment information • Plan designed to meet the goals and outcomes – interventions, provision of food, provision of nutritional support, education package, counselling, coordination of care, social marketing campaigns, food availability, food shopping and cooking skills • Roles and responsibilities of individuals, professionals and organisations in delivering the plan
Implementation	<p>The action phase of the nutrition and dietetic process. Dietitians may carry out the intervention, delegate or coordinate to another health or social care professional; patient, client or carer; voluntary organisation or member of the nutrition and dietetic team</p>
Monitoring	<p>The review and measurement of the client, group or population's nutritional status at planned intervals with regard to the nutritional diagnosis, intervention plan, goals and outcomes. It includes monitoring the implementation processes of the plan</p>
Evaluation	<p>The systematic comparison of current findings against previous status, intervention goals and outcomes or a reference standard, and usually takes place at the end of the process</p>

guarding high standards of care, by creating an environment in which clinical excellence will flourish' (Sally & Donaldson, 1998, p. 61). The principles of clinical governance are embedded within the organisation and encompass:

- Clinical audit.
- Evidence based practice.
- Information governance (including record keeping).
- Patient and public involvement.
- Patient safety.
- Revalidation and performance.
- Risk management and medicolegal issues.

Latterly, the term clinical effectiveness was developed as a response to demands to provide evidence of effectiveness. Health professionals have developed measures to report on the quality of clinical services and assess the effectiveness of medical interventions. These include:

- Clinical or medical audit.
- Outcome measures.
- Evidence based practice.
- Guidelines.

Clinical audit is carried out locally and nationally, and provides a method for systematically evaluating, reflecting

upon and reviewing practice against evidence based standards.

Dietetic outcome measurement

The provision of safe, effective and good quality care, or intervention, is fundamental to dietetic practice and is a HCPC registration requirement. A dietitian needs to know that an intervention is evidence based and effective, i.e. that it achieves the predicted outcome and makes effective use of the available resources. To demonstrate this, the dietitian needs to be able to systematically and consistently identify and predict what the desired outcome of their intervention will be, the timescale involved and to what extent this has been achieved from the viewpoint of both the dietitian and the recipient.

Outcome measurement should use SMART principles (systematic, measurable, achievable, realistic and timely). Much of the information needed will already have been collected and is readily available. Putting the patient at the centre of care is a central feature of health policy across the UK, so measuring the patient experience has to be a key component of outcome measurement. The BDA (2011a) outcomes model is a useful starting point for measuring dietetic outcomes, i.e. capturing the unique contribution of the dietitian.

Measurement of outcomes can take place at the individual, service, multidisciplinary team, organisational or national level. Measuring healthcare outcomes is a developing field and no single methodology is universally applicable to all situations. Patient reported outcome measures (PROMs) are a national, validated and mandated approach to collecting outcome information from the patient's perspective for a small number of elective surgical procedures. This approach is being expanded to cover more situations. The use and development of validated outcome measures is an emerging methodology; however, no single outcome measure will capture every dimension of care. The BDA (2011a) outcomes model provides an introduction and steps for developing dietetic outcome models.

Evidence based practice

Evidence based practice has been defined as, '*. . . the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients*' (Sacket *et al.*, 1996). While evidence based practice was developed in clinical practice, it can be applied to any dietetic discipline or setting and is an essential part of professional practice. The International Confederation of Dietetic Associations (2010) defines evidence based dietetics practice as being, '*. . . about asking questions, systematically finding research evidence, and assessing the validity, applicability and importance of that evidence. This evidence-based information is then combined with the dietitian's expertise and judgement and the client's or community's unique values and circumstances to guide decision-making in dietetics.*'

Evidence based practice is not a 'one off' activity but must be continuous throughout a dietitian's professional career. It is an essential part of being a professional and an essential element in the nutrition and dietetic process. Evidence based practice can be broken down into five key stages which are:

- Formulating the question.
- Finding the evidence.
- Critical appraisal.
- Using and acting on evidence.
- Evaluation and reflection.

At the end of this process it should be possible to identify areas within practice that require evidence; this should be the stimulus to conduct research to fill this gap. Measuring outcomes and audit are essential elements of evidence based practice.

Formulating the question

The first step in evidence based practice is recognising that there is a need for new information. This may be recognised from practice, reading or research. Recognition of need for new information must be converted into an answerable question. This can be broken into four stages that are collectively known as the PICO principle (Glasziou *et al.*, 2003).

The PICO principle

PICO is an acronym that stands for:

- Patients, or population, to which the question applies.
- Intervention being considered in relation to these patients/population.
- Comparison(s) to be made between those receiving the intervention and another group who do not receive the intervention.
- Outcome(s) to be used to establish the size of any effect caused by the intervention.

It is a framework that helps to focus the literature search by clarifying the question, identifying the information needed to be able to answer the question, translating the question into searchable terms and helping to develop and refine the search approach. In research this will be the research question or hypothesis.

Finding the evidence

Choosing the right evidence is of fundamental importance; therefore, it is essential to use PICO to identify search terms, search for evidence systematically and critically appraise the evidence.

Literature searching

A literature search is a systematic approach to retrieving information, i.e. a detailed and organised stepwise search for all the material available on a topic. Choosing the right evidence is of fundamental importance to answering the research question. There are several literature databases available and each has different criteria for the inclusion

Table 1.1.4 Levels of evidence [from Evidence Based Nursing Practice Hierarchy of Evidence (2008)]

Level	Description	Example
1	Strong evidence from at least one systematic review of well designed randomised controlled trials (RCTs)	Meta analyses The Cochrane Collaboration publications
2	Evidence from at least one properly designed RCT of appropriate size	Articles published in peer reviewed journals
3	Evidence from well designed trials without randomisation, e.g. cohort, time series or matched case controlled studies	Articles published in peer reviewed journals
4	Evidence from well designed non-experimental studies from more than one centre or research group	Articles published in peer reviewed journals
5	Opinions from respected authorities, based on clinical evidence, descriptive studies or reports from committees	NICE guidelines Evidence based local procedures and care pathways
6	Views of colleagues/peers	Members of the multidisciplinary team

of articles. The databases include PubMed (MedLine), CINAHL and Web of Science. NHS Evidence, managed by The National Institute for Health and Care Excellence (NICE), provides access to selected quality health and social care evidence and best practice.

Levels of evidence

There are different systems in use to grade evidence, but they all reflect the methodological rigour of studies. A study assigned as level 1 (or A) evidence (a systematic review or meta analysis that has been conducted using Cochrane Library methodology) is considered the most rigorous and least susceptible to bias. A study deemed to be level 4 evidence is considered the least rigorous and more susceptible to bias (Table 1.1.4). Level 1 evidence is limited for dietetic practice due to the ethical constraints of performing the studies.

When searching for evidence it is necessary to identify the best available evidence, which may include evidence from qualitative, observational studies or professional consensus (expert) opinion. Qualitative methods can help to provide answers to the kinds of questions that are not easily answerable by experimental methods (Swift & Tischler, 2010).

Critical appraisal

Each year thousands of articles are published in peer reviewed journals; however, many will not be well written, report robust studies or be relevant to practice. Therefore, it is essential to evaluate the rigour of an article and whether or not it is relevant to practice by critically appraising it. Critical appraisal is the systematic approach to the evaluation and interpretation of a publication in terms of its validity, results and relevance to an individual's practice or further research. It is essential that the approach is systematic so that the entire article is assessed; strengths and weaknesses of the study design, as well as biases within the study design or writing, need to be identified if effective change is to be made to practice. Critical appraisal will also enhance skills in understanding the research and audit process, while being an important CPD activity. The principle of critical appraisal should be used when evaluating any publication.

How to critically appraise an article

There are many examples available of how to do critical analysis; however, with experience, specific study design tools should be used. Recognised tools are available from NHS Solutions for Public Health (www.sph.nhs.uk) or the Scottish Intercollegiate Guidelines Network (SIGN) (www.sign.ac.uk). A generic framework for critical appraisal is shown in Appendix A1.

Using and acting on evidence

Research and evidence is of limited use if it is not translated into effective clinical practice. Dissemination and utilisation of evidence in decision making in healthcare is the key to the provision of quality care. Clinical experience, based on personal observation, reflection and judgement, is also needed to translate scientific results into treatment of an individual service user. After appraising the evidence and deciding that it is sound, it is essential to put it into context. Evidence must be combined with a dietitian's own expertise, experience and knowledge within their own setting before changes are implemented. The benefits and risks of implementing change must be weighed against the benefits and risks of not using alternative approaches. The decision to implement change should be made in collaboration with other members of the team or department, or patient. Involving all stakeholders will ensure that changes are implemented.

Evaluation and reflection

Evidence based practice is a continuing activity, and evaluation and reflection are a fundamental part of practice. This enables dietitians to identify gaps in their knowledge, areas that require further research and continuously to question practise. Any changes must be evaluated by either audit or service evaluation using appropriate outcome measures. To evaluate the effect of change it is essential that baseline information is collected.

Once a sufficient body of evidence is available, practice recommendations, guidelines and their associated standards can be generated. Clinical guidelines are recommendations on the appropriate treatment and care of patients

with specific diseases and conditions. Guidelines can be generated at an international level, e.g. The World Health Organization, or nationally by organisations such as NICE or SIGN in the UK, or by other clinical specialist organisations and professional bodies, e.g. BDA, Royal College of Physicians, and associated clinical working groups, e.g. Intercollegiate Stroke Working Group. Some, such as those developed by NICE, also consider cost effectiveness. Guidelines can also be produced at a regional or local level. Evidence can be used to improve the quality and outcomes of care by informing structural changes at national and regional levels, such as Managed Clinical Networks in Scotland and the Regional Cancer Networks.

Practice based evidence in nutrition (PEN) (www.pennutrition.com/bda) is a dynamic knowledge translation subscription service that is based on knowledge pathways providing evidence based answers for food, nutrition and dietetic practice questions. The content is developed by systematically reviewing the evidence base.

Routine activities that aid practitioners include keeping a portfolio and reading and evaluating new evidence. A portfolio is vital evidence of CPD and should be used to reflect and evaluate practice and the effect of any change. Simple electronic tools are available to provide information on new evidence. These include:

- *Application software (Apps)* – these include EBM toolkits from publishers, e.g. BMJ books, journals, searchable databases, e.g. PubMed, and critical appraisal tools.
- *Electronic table of contents (eTOC)* from appropriate journals – current contents pages are sent to subscribers (this is usually a free service).
- *Alerts, updates and newsletters* from professional bodies and organisations, e.g. Bandolier and Centre for Reviews and Dissemination (CRD) York.

Most of these services are available as email alerts or Really Simple Syndication (RSS) Feeds; once set up they are automatic.

Research, audit and service evaluation

The skills required to conduct research can also be applied to conduct audit and service evaluation. However, research is used to generate new evidence whilst audit and service evaluation evaluate care. It is important to remember that a survey conducted in clinical care cannot be called an audit unless the results are compared with a standard; standards are generated by research. An important distinction between research, audit and service evaluation is that research requires ethical approval from the appropriate research ethics committee while audit and service evaluation do not. Within the NHS they all require review and approval by the appropriate department, i.e. research and development or clinical governance. Table 1.1.5 gives a brief summary of the key differences between the categories of studies. If the categorisation of the study is unclear, it is important to consult the appropriate department or committee before commencement.

Research can be defined as the, ‘*original investigation undertaken in order to gain knowledge and understanding*’ (Research Assessment Exercise, 2001). It underpins evidence practice and is a vital component of a dietitian’s professional role. The HCPC (2008) requires that dietitians must be able to conduct research and audit and that they continue to use and develop research skills throughout their careers. The essential nature of research and audit as part of professional practice is embedded within both the BDA’s Code of Professional Practice (BDA, 2008a) and the Curriculum Framework for the Pre-registration Education and Training for Pre-registration Dietitians (BDA, 2008b). The BDA (2009b) defines four stages of research involvement and details the skills required at each stage. On qualification all dietitians should have the necessary skills to understand, interpret and apply research. If dietitians maintain and build upon these basic skills, some will eventually lead research and supervise others (Whelan, 2007).

The research process

Research consists of three phases: planning, conducting research and disseminating the results (Hickson, 2008), as shown in Table 1.1.6. The phases may overlap, e.g. dissemination may be planned during the planning stage or an application for funding may require a dissemination plan.

Research governance and ethics

Research governance encompasses regulations, standards and principles of good research practice, therefore ensuring that research is conducted to high ethical and scientific standards. It applies to everyone involved in the research process, including researchers at all levels, employers and support staff. In a clinical setting this will include care providers. Every organisation that conducts research or in which research is conducted should have a research governance framework or guide to good research practice, e.g. Department of Health (2005) Research Governance Framework for Health and Social Care; Medical Research Council (2000) Good Research Practice. Such frameworks and guides protect everyone involved in research, including the researcher. The framework or guide should include:

- Principles of good research, including the research culture.
- Responsibilities and accountability of researchers at all levels, institutions and carers if applicable.
- Processes including approval.
- Finance.
- Ethics.
- Gathering, handling and storing data.
- Result reporting.
- Monitoring procedures.

Ethical approval from an appropriate committee is essential for any research involving humans, clinical data, human organs or tissues; it is a legal requirement in the NHS. Informed consent and confidentiality are central to ethical research. The review process will vary depending

Table 1.1.5 The differences between research, audit and service evaluation (source: NHS National Patient Safety Agency 2008. Reproduced with permission)

Research	Clinical audit	Service evaluation
Attempts to derive new knowledge; studies may aim to generate hypotheses or to test them	Designed and conducted to produce information to inform delivery of best care	Designed and conducted solely to define and judge current care
Quantitative research – designed to test a hypothesis	Designed to answer the question: 'Does this service reach a predetermined standard?'	Designed to answer: 'What standard does this service achieve?'
Qualitative research – identifies/explores themes following established methodology		
Addresses clearly defined questions, aims and objectives	Measures against a standard	Measures current service without reference to a standard
Quantitative research – may involve evaluation or comparing interventions, particularly new ones	Involves an intervention in use ONLY (the choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)	Involves an intervention in use ONLY (the choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)
Qualitative research – usually involves studying how interventions and relationships are experienced		
Usually involves collecting data that are additional to those for routine care, but may include data collected routinely. May involve treatments, samples or investigations additional to routine care	Usually involves analysis of existing data, but may include administration of a simple interview or questionnaire	Usually involves analysis of existing data, but may include administration of a simple interview or questionnaire
Quantitative research – study design may involve allocating patients to an intervention group	No allocation to intervention groups; the healthcare professional and patient have chosen intervention before clinical audit	No allocation to intervention groups; the healthcare professional and patient have chosen intervention before service evaluation
Qualitative research uses a clearly defined sampling framework underpinned by conceptual or theoretical justifications		
May involve randomisation	No randomisation	No randomisation

Table 1.1.6 The research process

Phase	Step
Plan research	Develop a research question Use the literature to research the background Choose an appropriate methodology Write a research proposal Formulate aims and objectives If necessary, obtain funding Obtain ethical and institutional approval
Conduct research	Prepare for data collection and management Recruitment and consent participants Collate and analyse data
Dissemination of results	Develop dissemination plan Present findings at a scientific conference Write and submit a manuscript for a peer reviewed journal

on the organisation. Within the NHS the National Research Ethics Service offers a central and consistent service, including the Integrated Research Application System (IRAS) (www.myresearchproject.org.uk). This is a single system of applying for permissions and approvals for health and social care and community research in the UK without unnecessary duplication. Each university will have its own system for ethical approval.

How to do research

This section gives a brief overview of research; more detailed information can be found in Hickson (2008). Further resources are listed at the end of the chapter.

Planning research

The first step in research is developing the question and the PICO principle can be used to generate a concise question. The aims and objectives of the research should relate directly to the research question; the methodology will be determined by the aims and objectives; and when disseminating the results of the research, the discussion and conclusion of a paper or abstract should relate to the question and aims and objectives. The research question may arise from clinical practice or from the literature. A research question will lead to a hypothesis.

Table 1.1.7 Research methodologies

Descriptive	Cross sectional survey Qualitative, e.g. grounded theory, discourse analysis, ethnography, narrative research and phenomenology	
Empirical	Experimental	Randomised parallel groups Randomised cross over
	Observational	Cohort Cross sectional Case control

The research question plays a crucial role in reviewing the literature for the project. The literature review may stem from the aims and objectives or serve to formulate the aims and objectives. The research aim is usually a broad statement outlining the goal and objectives are more detailed statements of how the aim will be achieved. Each objective should be simple, straightforward and achievable. Well thought out objectives suggest a methodology and thus help determine the methodology.

The actual method is how the study will be carried out and includes details such as where the research will take place, who will be involved, how the participants will be recruited, the actual data collection and how the data will be analysed. It is quite acceptable to include both quantitative and qualitative methodologies in a study, but often such a study will be divided into two stages with one stage informing the other. Table 1.1.7 gives an overview of research methodologies.

It is essential to write a research protocol when planning the project and include details of the study rationale, aims and objectives, methods with specific measurable outcomes, statistical analysis, dissemination plans and timeline. The protocol can be used when applying for governance and ethical approval, and funding and will form the basis of the eventual dissemination. When using questionnaires, or other instruments to measure variables, it is important to consider the population for which they are validated and how the results obtained from them will be analysed. If results require statistical analysis, it is sensible to consult a statistician at this stage so that any necessary modifications can be made to the planned data collection.

Conducting research

This stage of the research process is usually constrained by time and money. A Gantt chart detailing delivery dates and deadlines is a useful organisational tool. Difficulties obtaining ethical approval or with recruitment of research staff and participants often delay projects, so sufficient time should be built in at the planning stage to avoid missing deadlines later. Communication is the key to keeping the research process on track, e.g. if recruitment

is slower than anticipated, it is helpful to let funders know before deadlines are missed; funding bodies often have a wealth of research experience and can be a source of help and advice if necessary. Meticulous record keeping will also help the research process to run smoothly. Data collection sheets that are easy to complete will be less likely to contain errors. Data collection methods should be piloted and necessary changes made. Research logs or diaries can act as a cross check to reference dates and times that certain activities took place. Keeping a research diary may be a requirement of an organisation.

Data analysis will probably involve transferring data into a software analysis program and particular care should be taken at this stage to avoid introducing errors. If possible, double data entry should be used where two people enter quantitative data on separate spreadsheets and compare them for differences. Qualitative data often need to be transcribed. This time consuming task can be delegated to professional transcribers, although this step can be a valuable part of the process of becoming familiar with the data.

Dissemination

It is essential that dietitians disseminate all the evidence generated, including research, audit and service evaluation. There are vehicles for every type and size of study; small and negative studies are valuable as they add to the evidence base and may inform others of potential difficulties. Dissemination can occur internally, within the department or institution, or externally at conferences and in peer reviewed journals. Conferences are the best way to disseminate small studies and initial findings. The most important way to disseminate work is as a manuscript published in a peer reviewed journal. Guidance on how to write a conference abstract or a manuscript for publication can be found at www.bda.uk.com/conference/research. Publication guidelines, e.g. CONSORT (Consolidated Standards of Reporting Trials) have been produced in order to improve the quality of research reporting and are available from the Equator Network (www.equator.org.uk).

Continuing professional development

Professional practice develops over time and individual professionals must strive, and expect, to develop and improve their practice so that services and the outcomes for their service users improve. This process is known as continuing professional development (CPD). Continuing professional development is an active process by which every day and more formal experiences are critically reflected upon to identify learning points which are then recorded in a useful format. The BDA (2008c) defines CPD as, '... a systematic on-going process which allows individuals to maintain, update and enhance their knowledge and expertise in order to ensure that they are able to carry out work safely and effectively.'

A dietitian has a responsibility to meet the HCPC Standards for CPD (2011). The HCPC states that, '... CPD is the way health professionals continue to learn and

develop throughout their careers so they keep their skills and knowledge up to date and are able to work safely, legally and effectively. Dietitians, like other HCPC registrants, are required to reregister every two years and each profession is audited. A random sample of dietitians is required to submit their CPD portfolios for audit. It is not a review of the standard of the CPD activities themselves, but of how the individual meets the HCPC standards for CPD. Registrants must demonstrate a variety of CPD activities and how the activities were used to improve their practice. Further guidance on this process is available both from the BDA and the HCPC.

Continuing professional development activities

An individual's CPD should reflect a wide range of learning activities and be relevant to their current or developing scope of practice. CPD activities may be self directed, work based, professional activities or formal/educational activities. Further examples of CPD are shown in Table 1.1.8. Dietitians working within the NHS may be required to link to the NHS Knowledge and Skills Framework (Department of Health, 2004; NHS Employers, 2010). However, as an individual practitioner, a dietitian should organise and undertake CPD for their own development.

Reflective practice

Reflective practice has been defined as, '*... the capacity to reflect on action so as to engage in a process of continuous learning*' (Schon, 1991) and is essential to the development of professional practice in dietetics. The purpose of reflection is to enable a practitioner to use experience to develop practice through a systematic process of analysing experience to learn from it. Reflective practice is the method by which dietitians make sense of practice by analysing a situation or experience, knowledge and skills used, and their reaction to the experience, and by exploring learning, which can be applied in the

future. During the process further learning needs are often identified. This reflection on practice is also one method by which a professional may identify new theories of practice and so integrate the technical science basis and the practice and art of dietetics.

Reflection is a skill that requires development and practice. It requires the individual to be open to their feelings and to what they can learn from the experience. There are a number of models that provide a structured process to aid the process of reflection and building a portfolio (Gibbs, 1988; Rolfe *et al.*, 2001).

Practice supervision

A dietitian should also seek practice supervision throughout their professional training and career. Supervision is the process of professional learning and support involving a range of activities. It enables individuals to develop knowledge and competence, assume responsibility for their own practice and enhance service user protection, quality and safety of care (BDA, 2011b). The supervision process can directly influence CPD, providing a structured process of professional support that facilitates life long learning and personal development, and highlights training needs. Practice supervision is integral to delivering a quality service and should be included within working practices where work based scenarios are explored, reflection upon practice takes place and evidence of CPD is gathered. This process of supervision will start as a student in practice education and continue throughout working life. Examining performance, identifying strengths and weaknesses and seeking to improve are key attributes of a professional.

Preceptorship

Professionals in the first year of practice, particularly within the NHS, should work within a structured development programme called preceptorship. The aim of preceptorship is to enhance the competence and confidence

Table 1.1.8 Examples of continuing professional development (CPD) activities

Workbased learning	Professional activity	Formal / educational	Self directed learning
Learning by doing	Involvement in a professional body	Courses	Reading journals/articles
Case studies	Membership of a specialist interest group	Further education	Reviewing books or articles
Reflective practice	Lecturing or teaching	Research	Keeping a file of progress
Clinical audit	Mentoring	Attending conferences or seminars	
Discussions with colleagues	Being an examiner or tutor	Writing articles or papers	
Gaining, and learning from, experience	Organising journal clubs or other specialist groups	Distance learning	
Work shadowing	Membership of other professional bodies or groups	Planning or running a course	
Secondments	Presenting at conferences		
Job rotation	Supervising research		
Journal club	Being promoted		
In-service training			
Supervising staff or students			
Analysing significant events			
Project work or project management			

of newly registered practitioners as autonomous professionals (Department of Health, 2010). During this time, the new practitioner, supported by a preceptor, will develop their skills, behaviour and attitude to become a more confident practitioner. It is likely to be a structured programme with a mix of theory and guided reflection with a preceptor. Further guidance is available from a number of different sources including the BDA (2011b).

Recording continuing professional development

Dietitians have a responsibility to maintain an accurate, continuous and up to date record or portfolio of CPD activities (HCPC, 2009). The BDA provides tools to support the development of a portfolio and proformas to record CPD, based on the framework for reflective practice of Rolfe *et al.* (2001) which uses the following questions:

- What?
- So what?
- Now what?

These enable the dietitian to describe the CPD activity, explain what is learnt and reflect on the benefits to the service user alongside the use of new skills, as well as investigating any areas for development or improvement.

Conclusion

Dietetics has a proud tradition of upholding safe, effective, evidence based nutritional expertise, and this is fundamentally a result of the professionals who work within the discipline. The profession's commitment to constantly be innovative, whilst striving for the highest standards of technical and ethical competence, have seen it evolve into the internationally respected profession it is today.

1.2

Dietary modification

Annemarie Knight and Katherine Law

Key points

- Dietary modification is defined as the elimination, manipulation or introduction of dietary components to achieve dietary goals.
- Skillful assessment is required to identify all the factors that may influence the success of dietary intervention.
- Dietary modification requires the use of a range of dietetic skills, including communication skills and the skills to change health behaviour.
- A total diet approach should be adopted and dietary advice should be given in terms of food choice not nutrients.

Dietary modification is a cornerstone of dietetic practice and employs a range of dietetic skills. When undertaking dietary modification, dietitians need in depth knowledge of food composition, food availability and factors that determine what people eat. It is well acknowledged that dietary interventions are more likely to be effective when they are based on a sound understanding of the factors influencing the food choice of individuals or communities, not on the principles of changing health behaviour alone. An integrated approach to dietary counselling that considers all the relevant factors can improve compliance, satisfaction and clinical outcomes (Fine, 2006). The emphasis that these factors have on developing the most effective dietary intervention strategies will vary depending on the situation.

In the assessment phase of the nutrition and dietetic care process, the dietitian uses skills in nutritional, dietary and clinical assessment in order to decide the goals of dietary intervention (BDA, 2012) (see Chapter 1.1). Key to deciding how best to achieve these goals is an assessment of the interaction between the individual, or community, and their social situation. This assessment can also aid the identification of potential barriers that may impact the effectiveness of the intervention. Service users can and should be actively involved in their own health-care, and the dietitian's role is to advise and help facilitate negotiated patient centred goals. When monitoring and evaluating the effectiveness of any dietary intervention, ongoing reassessment of the factors contributing to the achievement of dietary goals will be necessary.

Principles of dietary modification

Dietary modification can be defined as the elimination, manipulation or introduction of dietary components to achieve dietary goals. Dietary interventions are aimed at individuals, groups or communities and vary greatly in complexity. Modifications that are considered simple, e.g. increasing the fruit and vegetable intake of a community, may in fact be very difficult to achieve and require significant dietetic input. Similarly, those considered more complex, e.g. meeting an individual's nutritional requirements via the parenteral route, might be more straightforward to achieve.

Whether total or partial control of an individual's nutritional intake is required, challenges will almost certainly arise. A detailed knowledge of food and its composition is vital, together with an excellent knowledge of the tools and resources to reach achievable results. Once the requirement for dietary modification is highlighted and the level of regulation has been determined, four key factors should be considered to achieve the required result: knowledge, achievability, motivation and communication.

Knowledge

In order for dietary modification to be effective, both the dietitian and service user (and any other health-care professionals, or supporting individuals) must be knowledgeable regarding the rationale for the changes

proposed. It is part of the dietitian's role to ensure that all those involved understand why change is necessary and how the proposed dietary modification will contribute to achieving treatment goals. From a service user's perspective, this can encourage compliance and also empower individuals to take some responsibility (Department of Health, 2001) for their own health and lifestyle. This process can be demonstrated through programmes such as Dose Adjustment for Normal Eating (DAFNE) and Diabetes Education and Self-Management for Ongoing and Newly Diagnosed (DESMOND), which focus primarily on the education and empowerment of the patient to allow for ongoing dietary modification that complements individual lifestyles (see Chapter 7.12).

Thomas (1994) identified a reaction to the development of knowledge, including the development of skills, confidence in one's ability to make dietary changes and response to situational cues; all impacted positively on the service user's ability to take ownership of their diet. It is part of the dietitian's role to be the source of knowledge for the service user, facilitating and promoting dietary change and providing support and encouragement to the empowered individual.

Achievability

It is the dietitian's responsibility to ensure that goals set for diet modification are achievable, both from the clinical and service user's perspectives. The provision of practical, tailored advice and support are useful in this process. Excellent communication and, in some cases, counselling skills are required to assess the service user's lifestyle and level of understanding, to ensure that goals set are appropriate (see Chapter 1.3). Within a clinical or institutional setting, dietary modification is arguably more achievable due to a more controlled environment. Meals are generally provided and nutritionally regulated, so more specific guidance is easily accessible. There may however be barriers to ensuring an individualised approach to dietary modification in an institutional setting. With regard to artificial enteral and parenteral nutrition, a prescribed regimen is normally provided and amended as required, usually resulting in greater compliance.

Working alongside service users in outpatient or community settings can pose different challenges. Dietary interventions may be targeted at individuals or groups and in both cases, the optimum duration and frequency of contact needed to build effective relationships will need to be considered. More frequent or longer consultations may be necessary to ensure that the dietitian can provide adequate support.

Motivation

As is evident within many areas of dietetic practice, the motivation of both the service user and the dietitian is key to success. The Transtheoretical Model (Stages of Change Model) (Prochaska & DiClemente, 1986) demonstrates this process, highlighting those stages where successful dietary modification may be optimised. Identifying

that individual service users will differ in terms of their motivation to adopt potential dietary modifications is also key, and in all cases targeting and tailoring of advice will probably increase effectiveness (Thomas, 1994). It may be appropriate to make smaller dietary changes first, allowing additional time and support for the adoption of more substantial dietary changes. The dietitian can use skills such as rapport building, motivational interviewing, reflective listening and problem solving to assess and increase motivation to change (Fine, 2006; Gable, 1997; Hunt & Pearson, 2001).

Communication

Effective, clear communication underpins successful dietetic practice. The way in which dietary advice is communicated can have an important impact on its effectiveness. An individualised approach should be adopted to ensure messages are tailored to the individual or group and that the most effective communication strategies are adopted. Recognising that dietary choices are mostly made on the basis of foods rather than nutrients and communicating actions using food terms enables the individual to take control of their dietary changes. When communicating dietary strategies to individuals, groups or communities, the dietitian may use written, verbal, audiovisual, electronic or interactive forms of communication, although often a combination of these will be used. Knowledge of tools such as dietary exchange systems and resources can also facilitate the communication of dietary modifications. Skills in changing health behaviour and effective communication are central to successful dietary modification (see Chapter 1.3).

Types of dietary modification

Modifying dietary intake can provide a methodical and practical solution to wider health issues, and encourage an individualised and problem solving approach. This can range from the elimination of nutrients through to the reintroduction of dietary components, and can also include the manipulation of foods (Table 1.2.1).

Manipulation of dietary components

Dietary components can be manipulated in the following ways:

Texture

The texture or consistency of the diet may be modified, e.g. in the management of swallowing disorders.

Composition

It may be necessary to alter the chemical composition of the diet in the management of conditions such as food hypersensitivity. Modification may require the use of dietary products whose macronutrient composition has been manipulated, e.g. amino acid or medium chain triglyceride based formulae.

Table 1.2.1 Approaches to dietary intervention

	Dietary intervention	Example of dietary modification to achieve dietary goals
Elimination	Weight management	Eliminate energy dense foods
	Food hypersensitivity	Eliminate foods containing allergen Eliminate foods causing intolerance
Manipulation	Weight management	Manipulation of portion size
	Oral nutritional support	Substitute foods to increase energy density
	Texture modification	As per the Dysphagia Diet Food Texture Descriptors (NPSA Dysphagia Expert Reference Group, April 2011)
	Artificial nutritional support	Manipulation of chemical composition of dietary components, e.g. elemental feed
Introduction or reintroduction	Restrict nutrients	Low fat diet, electrolyte restriction in renal disease, metabolic disorders
	Healthy balanced diet	Ensuring intake is balanced, including all food groups
	Elimination diet	Foods are eliminated and reintroduced slowly, assessing symptoms (e.g. LOFFLEX diet, suspected allergies)
	Weight management	Introduce substitutions for high energy density foods
	Oral nutritional support	Introduce substitutions for low energy density foods

Quantity

When modifying the quantity of a dietary component, it is necessary to consider the frequency of consumption, portion size and any appropriate food substitutions that can be made in the diet to achieve dietary goals.

Elimination of dietary components

Where possible, dietary interventions should always take a total diet approach and focus on the overall pattern of foods eaten rather than on specific foods or nutrients (American Dietetic Association, 2002). In the majority of cases, the elimination of individual foods will not be necessary; instead, modifying the quantity of the food consumed alongside the frequency of consumption will be sufficient to achieve dietary goals. The elimination of dietary components will be necessary in some conditions, e.g. inborn errors of metabolism. Where dietary components are excluded it is important to assess the role they play in the individual's diet and what substitute foods need to be recommended to ensure nutritional requirements are met.

Introduction and reintroduction of dietary components

A starting point for dietary modification is often to base recommendations on an individual's current dietary intake, although achieving dietary goals will involve the introduction of new foods. The introduction of dietary components will range from simple to complex recommendations, all of which should meet individual requirements. Where foods have been eliminated from the diet it will be necessary to plan their reintroduction, e.g. a food challenge with an identified allergen in the management of food hypersensitivity (see Chapter 7.11.2).

Process of dietary modification

Rationale

The first step in dietary modification is to ascertain the purpose of the modification based on a comprehensive assessment and the identification of the nutritional problem. The aim of dietary modification may be to:

- Achieve a nutrient profile that offers greater health benefits.
- Meet dietary needs in a safer way.
- Correct a dietary deficiency or surplus.
- Avoid the consumption of a particular dietary component.
- Achieve symptom relief.
- Achieve specific metabolic or clinical effects.

Key dietetic skills of clinical reasoning and evidence based practice are employed to develop a dietary intervention plan. Dietary modification should provide benefit to the individual or group, but it should be noted that the interactions between foods and nutrients are complex and altering one dietary component may affect another, e.g. increasing the energy density of a diet in oral nutritional support may increase the intake of saturated fat with the associated cardiovascular consequences. A total diet approach allows for an overall view of the likely consequences.

Factors that influence food choice

In deciding the most effective dietary intervention, any factors that will potentially influence adherence to the proposed modification should be identified.

Access to food

This will include factors such as purchasing patterns, budgetary constraints and cooking skills. To achieve

dietary change it will be necessary to identify whether the foods that have been recommended are available where the individual shops, if support is needed with shopping or if the individual has the required skills to prepare the foods in the modified diet, e.g. for a texture modified diet, it is important to assess if the necessary equipment is available to modify foods to the correct consistency. At a community level, shopping and leisure facilities available in the local area may influence the effectiveness of interventions.

Taste and food preferences

Individual food preferences and the role food plays in an individual's life need to be considered when making dietary modifications.

Lifestyle influences

The lack of time and the burden of juggling work and home commitments can be a significant constraint in adopting healthy eating practices or dietary advice. It is important that the burden of proposed dietary modification in terms of time and effort is considered.

Cultural background

Developing effective dietary intervention strategies for individuals and groups from minority ethnic backgrounds requires an understanding of their relevant health behaviours (Thomas, 2002). Cultural food practices affect taste preferences and play a role in purchasing patterns. When developing dietary interventions for minority ethnic groups, it is necessary to take account of dietary patterns and acknowledge the variations in health beliefs, attitudes and practices within each cultural group (Bronner, 1994) (see Chapter 3.5).

Religious or ethical beliefs

In order to ensure that dietary modifications are compatible with an individual's or group's beliefs, it is necessary to establish them and the extent to which they are followed. There can be a wide variation in the interpretation of and adherence to the dietary restrictions associated with a particular faith.

Media

The media plays an important role in influencing food choice and shaping beliefs about nutrition and the role of the dietitian. It is important that dietitians keep abreast of media reporting on nutrition and diet in order to ensure that dietary education is effective and targeted, and that incorrect dietary beliefs can be addressed.

Practical aspects of dietary modification

All dietary modifications should be individualised and based on a detailed assessment. How dietary modification can be approached in order to achieve a range of dietary goals is shown in Box 1.2.1.

As well as the food based approaches outlined in Box 1.2.1, a range of other modifications may be used in order to achieve dietary goals and include:

Box 1.2.1 Practical examples of dietary modification strategies

Macronutrient modification

- Aim of dietary modification is to decrease the percentage of dietary fat:
 - Identify foods contributing to dietary fat intake
 - Limit frequency of consumption of high fat foods
 - Limit portion size of high fat foods
 - Recommend lower fat alternative foods
 - Recommend lower fat cooking methods
- Aim of dietary modification is to increase dietary intake of protein:
 - Increase frequency of consumption of high protein foods, including between meal snacks
 - Increase portion size of high protein foods
 - Fortify commonly consumed foods with additional protein
 - Consider need for supplements to achieve dietary aim

Micronutrient modification

- Aim of dietary modification is to increase dietary intake of iron:
 - Increase frequency of consumption of high iron foods
 - Increase portion size of high iron foods
 - Consider foods that increase or decrease the bio-availability of dietary iron
 - Consider need for supplements to achieve dietary aim
- Aim of dietary modification is to decrease dietary intake of potassium:
 - Eliminate or limit frequency of consumption of high potassium foods
 - Recommend cooking methods to reduce potassium content of foods

Single/multiple food exclusion

- Aim of dietary modification is to exclude cow's milk protein and egg:
 - Eliminate all foods sources of cow's milk protein and egg, including where these are present as an ingredient
 - Advise alternatives to foods eliminated in order to ensure nutritional adequacy
 - Consider need for supplements to ensure nutritional adequacy of diet

- *Meal patterns* – the timing or frequency of meals may be adjusted, e.g. the provision of small, frequent meals may promote dietary intake. It may also be necessary to modify when foods or fluids are taken together.
- *Meal environment and eating behaviour* – altering the environment in which food is consumed may be an effective modification strategy. Changing feeding behaviour may be an important part of achieving

dietary targets and may involve other healthcare professionals.

Conclusion

Dietary modification underpins many aspects of dietetic practice and it is vital that the dietitian understands the principles detailed in this chapter so that these principles can then be applied to practice.

1.3

Changing health behaviour

Dympna Pearson

Key points

- The art of dietetic practice is to integrate the science of food and medicine with the psychosocial aspects of people's lives in the context of changing health related behaviours.
- An integrated approach to changing health related behaviours embraces the underlying theory, principles, skills and processes that are necessary to initiate and maintain changes to lifestyle behaviours.
- A behavioural approach is directive and client centred. Consultations need to be structured and focused, where both the practitioner's and service user's (client's) agendas are considered through working in a collaborative way.
- There should be clarity of purpose and it must be ensured that any goals agreed will help the client achieve the desired outcome.
- Increasing self awareness is an important aspect of becoming an effective change agent, as is working collaboratively with clients.

'I do not understand my own actions. For I do not do what I want, but I do the very thing I hate.'

(Romans 7:15 Revised Standard Version)

Dietetics was originally based on the traditional medical model of expert led, advice giving with the expectation that once people are told what to do, they will follow this advice. However, research has shown that giving advice alone does not automatically change behaviour (Thomas, 1994; Contento *et al.*, 1995; Thorogood *et al.*, 2002). The challenge for dietitians and other healthcare professionals is to develop an understanding of what influences health behaviour and to acquire the necessary skills that will enable them to facilitate change.

Traditional medical care has moved towards a client centred model that takes into account the psychosocial aspects of care, as well as the clinical picture (Stewart, 1995). Setting the stage psychologically is of prime importance when helping others change their behaviour (Brownell & Cohen 1995a; 1995b). It is necessary to have some understanding of a person's previous experience and how they think and feel about their situation, as this will ultimately influence their health behaviour. Attitudes, beliefs, individual learning styles and the social, cultural, religious and economic situation will also affect their behaviour.

The environment in which somebody lives has a major influence on health. Public health interventions, such as those proposed in *Healthy Lives, Healthy People* (Department of Health, 2011), are designed to make healthy choices easier and are likely to have maximum impact if fully implemented. If people are motivated to change

their health behaviour, easy availability of healthy and economic choices will support the process. Dietitians have a key role to play in implementing food health policies, which are of major importance if better health outcomes are to be secured in the future. This chapter focuses on achieving change at an individual level and how interventions can be maximised through enhancing traditional practice to achieve an integrated approach to changing health behaviours.

An integrated approach to changing health behaviour

A range of approaches can be used to facilitate health behaviour change. Different approaches may work for different people at different times. An integrated approach to changing health behaviour in dietetic practice:

- Enables the client to take the next concrete, practical step to change eating or other lifestyle behaviours.
- Combines a directive and non-directive client centred approach by using a guiding style (Rollnick *et al.*, 2010).
- Includes a range of tools and approaches adapted from the world of psychology to provide information, strengthen motivation and facilitate behaviour change, taking the client's context into consideration.
- Integrates whichever approach seems most relevant for that individual at any given time, e.g. exploring motivational difficulties or working on modifying behaviour.

- Treats the whole person, taking into account the world in which they live, what matters to them and the factors that are likely to influence their health behaviour. It looks at how diet and activity fit into the client's life.
- Recognises that the skills and mindset of the practitioner will influence how effective they are as a behaviour change agent. It therefore acknowledges that the need for practitioners to engage in ongoing self development and self awareness as part of continuing professional development is just as important as it is for them to facilitate this process in their clients.

Differences between traditional advice giving and an integrated approach to changing health behaviour

The traditional approach often consists of advice giving combined with persuading the client to adopt a preferred course of action. This approach can render the client a passive recipient of expert knowledge, and can reduce client autonomy and create discord in the helping relationship (Heritage & Sefi, 1992). When the client's perspective is not fully taken into account, it is possible that mental and/or emotional harm may be inflicted, which can have long lasting consequences. In an integrated approach to changing health behaviour, *first do no harm* is as applicable as in any other clinical procedure. This means that practitioners need to be mindful of the client's overall situation rather than just following their own agenda (see Chapter 1.1).

A consultation based on an integrated approach to changing health behaviour has the following characteristics:

- The client and practitioner work together as equal partners.
- The client is treated with courtesy and respect at all times.
- Information and ideas are shared.
- The language and approach is collaborative.
- The client is actively involved and there is a two way conversation.
- The practitioner actively listens and interprets what the client says, checking for understanding.
- There is common agreement and a clear plan about the way forward.

Foundations underpinning behaviour change approaches

The foundations of an integrated approach to changing health related behaviours are its theoretical underpinning, guiding principles, good communication skills and ongoing practitioner development.

Theoretical underpinning

Models

A model attempts to understand and describe what factors affect behaviour and from this, specific approaches and

Box 1.3.1 Models used to influence health behaviour

The Helping Model (Egan, 1998)

A simple three stage model for use within a consultation which helps guide the dietitian through the interview in a structured way:

- Stage 1 (the assessment) establishes the current scenario and helps both client and practitioner work towards a common agenda as a basis for moving to Stage 2
- Stage 2 involves exploring the options, setting goals and developing a change plan
- Stage 3 is the action stage, which mainly happens outside the consultation, with the sessions used for monitoring, review and follow-up

The Transtheoretical Model (Stages of Change Model) (Prochaska & DiClemente, 1986).

The model can increase understanding of the process people go through to make changes; people who successfully change go through:

- A thought process (weighing up the pros and cons of change) and
- A preparation stage before embarking on
- An action stage of change.

Most people who reach a stage of maintaining change have gone through the process of thinking, preparing, action and relapse several times before eventually changing permanently. This highlights the ongoing nature of change and that many different interventions may be required depending on the stage a person has reached.

The limitation of this model are that, because of the shifting nature of change, it is not possible to identify someone as being in a particular stage. In addition, people may be at different stages for different eating behaviours.

applications are developed to effect or influence this behaviour. There are a number of health behaviour models that contribute to the understanding of human behaviour in relation to health. The models that have had most influence on dietetic clinical practice are the Helping Model (Egan, 1998) and the Transtheoretical Model of Change (Prochaska & DiClemente, 1986) (Box 1.3.1). The complexity of human behaviour can never be fully understood; therefore, no model or approach can be complete or definitive. Models can however help understanding of how things function. An integrated approach to changing health related behaviours embraces elements from many different models and approaches.

Psychological approaches

The most commonly used psychological approaches in dietetic practice are motivational interviewing (MI), behaviour therapy (BT) and cognitive behaviour therapy (CBT).

Motivational interviewing

Motivational difficulties are often the greatest challenge for people struggling with change. The task of the dietitian is to tap into the intrinsic motivation that exists within each individual and to help build and strengthen that motivation in order to facilitate change. Clients often express a desire to change but somehow find they cannot. Motivational interviewing (MI) aims to help individuals explore and resolve the discrepancy between where they are and where they want to be in relation to their health behaviour. A collaborative conversation style of consulting is used to strengthen someone's motivation and commitment to change (Miller & Rollnick, 2012). It is part of an integrated approach, rather than a standalone therapy, and consists of a range of therapeutic strategies, which are underpinned by a person centred approach. The use of high level interpersonal skills in this context enables the client to build commitment and reach a decision to change if that is appropriate for them (Miller & Rollnick, 2012; Rollnick *et al.*, 1992).

Behaviour therapy

Behaviour therapy or behaviour modification helps clients to identify unhelpful behavioural patterns and develop ways of modifying these. A wide range of practical behaviour modification strategies are commonly used in dietetics that help clients manage eating and activity behaviours (Pearson & Grace, 2012), as shown in Box 1.3.2.

Cognitive behaviour therapy

Cognitive behaviour therapy includes behaviour modification strategies as well as cognitive restructuring. Cognitive restructuring aims to help clients identify and then change unhelpful thoughts, ideas and beliefs that might maintain undesirable behaviours. The application of these approaches to dietetic practice has been described and explored by Rapoport (1998). It is essential that appropriate clinical supervision is in place for practitioners using this approach.

Box 1.3.2 Examples of behavioural strategies used in dietetic practice

- Do nothing else whilst eating; sit down at a table
- Do not eat when watching TV or reading
- Chew each mouthful thoroughly
- Put your knife and fork down between mouthfuls
- Use a smaller plate or bowl
- Put food away – out of sight
- Plan menus for the week ahead
- Always shop from a list
- Never shop on an empty stomach
- Do not sit for longer than 30 minutes
- Plan activity for the week ahead

Guiding principles

Health professionals ideally base their practice on underlying principles, ethics and beliefs (see Chapter 1.1). Good communication skills play a major role in the outcome of a consultation and underlying these skills are principles that motivate or guide the practitioner and influence the way they apply any skills they may have acquired. These guiding principles provide a foundation for any model, theory or skills that are used. In an integrated approach they include the following:

Person centred approach

A person centred approach forms the basis of the helping relationship. Rogers (1951) described the essential core conditions that need to be present in order to work in a person centred way: empathy, genuineness and acceptance.

Empathy

Empathy involves caring in a truly genuine and accepting way, and developing a sensitive and accurate understanding of the way in which the client perceives their experience. An empathic person shares another person's experience as if it were their own, whilst being aware throughout that it is not. Clients feel they have been heard and understood.

Genuineness (congruence)

Genuineness is important for the formation of a helping relationship, which is built on trust. It means being who we truly are, being honest and matching what we say with how we say it, both verbally and non-verbally.

Acceptance (unconditional positive regard)

Acceptance means having respect for another as a human being, regardless of who they are or what they have done. This means accepting the client unconditionally without condoning and being judgemental. Health professionals need to guard against forming judgements about clients who do not adhere to recommended treatment and to seek to understand the client's perspective rather than label them as non-compliant.

The core conditions are often difficult to adhere to but their importance highlights the need for continual reflective practice. When consultations do not go well, a natural response is to blame the client as being difficult, but it may be more productive to reflect and consider if any of the core conditions were absent.

Respecting client autonomy

This is a key element of facilitating health behaviour change; it is accepting the right of the individual to make choices about their own actions. Practitioners need to resist the urge to tell people what to do, in the belief that they know what is best. Experience and expertise need to be shared in a collaborative way in order to achieve the best outcomes, with clients being fully involved in any decisions.

Client responsibility

This principle acknowledges that people are responsible for their own actions. Practitioners need to try to understand the difficulties that people experience with change, whilst at the same time respecting client autonomy.

Social influence

Dietitians have a remit to influence health behaviour and this influence can be very powerful, even when time is limited. Practitioners can sometimes feel that the situation is hopeless when the client has multiple problems, e.g. poor relationships, low income and poor health. It is important to remember that everybody has the ability to change (Miller & Rollnick, 2012); although not everyone will change, they may be able to take some steps towards improving their health.

Collaboration

The principle of collaboration helps to accommodate both the client's and the healthcare professional's agenda. It recognises that two parties with expertise have met; one with expertise about themselves (the client) and one with expertise in the topic area, along with specific helping skills (the healthcare professional). A collaborative helping relationship is built on trust and mutual respect; it considers both parties as equals in exploring the possibilities for change (Pearson, 2010).

Self efficacy

In order to change people need to believe that change is possible. The task of the practitioner is to help people develop self belief in their ability to make changes. This can be achieved by helping to build the client's confidence and competence (Bandura, 1977).

Empowerment

Empowerment for health is a process through which people gain greater control over decisions and actions affecting their health. This principle has especially influenced the development of care offered in diabetes management (Funnell & Anderson, 2003). It recognises that clients are in control of and responsible for the daily self management of their health and that, to succeed, a self management plan has to fit clients' goals, priorities and lifestyle, as well as health problems.

The client centred method

The client centred clinical method (which includes many of the above elements) was developed by Stewart (1995) to address the limitations of the biomedical model. It includes the conventional biomedical approach but extends it to include consideration of the client as a person. The model consists of six interconnecting components:

- Explore both the disease and the illness experience.
- Understand the whole person.
- Find common ground.
- Incorporate prevention and health promotion.
- Enhance the client–practitioner relationship.
- Be realistic.

A client centred approach has been shown to be associated with improved health status and increased efficacy of care (Stewart *et al.*, 2000).

Communication skills

Effective client care relies heavily on good communication skills that can be applied in any setting, e.g. during consultations and when discussing client care with medical staff, relatives, administrators, etc. These skills may be variably described as counselling, consultation, interviewing, active listening, reflective listening and communication or interpersonal skills. Many dietitians are naturally good listeners while others develop their listening skills through years of practice. These skills must be continually developed and refined. Using these skills throughout the consultation can have an enormous impact on facilitating health behaviour change.

There is evidence to support the use of communication skills. Najavits & Weiss (1994) reported that the single most important factor that influences change is the practitioner's possession of strong communication skills. The health practitioner's way of working or therapeutic style can strongly influence the intervention outcome (Miller & Rollnick, 2012). Stewart (1995) showed a positive and significant relationship between communication and client health outcomes, concluding that '*good communication is good evidence-based medicine*'.

Attending behaviour

Actively listening to another person, both verbally and non-verbally, conveys acceptance. Attending also involves being aware of personal verbal and non-verbal behaviour, which reflects personal thoughts, feelings and attitudes.

Non-verbal communication

In addition to words, non-verbal communication gives very powerful messages and may account for as much as 85% of communication (Ivey *et al.*, 1997). The practitioner should also observe clients' non-verbal cues. Important aspects of non-verbal communication include:

- Body language that is appropriate to the context of the conversation. An open, relaxed posture and leaning slightly forward is generally recommended, rather than an unnatural or stiff posture. It is also important to avoid distracting behaviours such as constant nodding, fiddling with pens or looking at a watch. Hand movements are a normal part of non-verbal communication, but they should not be invasive. Sitting at an appropriate distance so as not to invade the other person's space, but equally, not too far away, should be taken into consideration.
- Eye contact that is varied and non-staring.
- Facial expressions that convey empathy and provide encouragement, e.g. an encouraging smile or nod. Facial expressions need to match the mood of the conversation, e.g. not smiling when the person is describing something sad.
- Pace of an interview. Rushed consultations can leave the client feeling confused or unsure about what has

been discussed. It is important to allow time for clients (and practitioners) to think clearly and express their thoughts; a brief silence or a pause can help achieve this.

- Tone of voice and general demeanour make a difference to the meaning of what is said and its interpretation. It is important for dietitians to take note of these factors as clients may be communicating something different from the actual words that are being said. Dietitians also need to be aware that their tone of voice and body language can convey meaning in either a more or less helpful way, e.g. disapproval or encouragement.

Practitioners need to be familiar with and take into account cultural differences, along with the age and gender of the person. Disabilities such as hearing, sight or cognitive impairment will also impact on communication.

Minimal encouragers

These are used to indicate to clients that they are being *actively* listened to and to encourage them to talk. They can include non-verbal language such as nodding, an encouraging smile, or minimal utterances, e.g. 'mm, mm', 'ah hah', 'and', 'so . . .'. Finding the right balance of how and when to use (and not to overuse) minimal encouragers is a skill that needs practise. Some words used in everyday conversations such as 'right' and 'ok' can convey the wrong meaning or become irritating if constantly repeated throughout the conversation.

Verbal following or restating

This consists of a word, a phrase or a sentence (sometimes phrased as a question) that repeats what has just been said (although not verbatim). For example:

Client: 'I'm really struggling to fit this diet in with the rest of the family.'

Dietitian: 'Family?' or 'You are struggling to fit the diet in with the family.'

Client: 'Yes, they all like . . .'

It encourages the person to expand on what they have said; it needs to be used skilfully without overuse, but combined with other skills to convey accurate empathy.

Paraphrasing

Paraphrasing is the skill of rephrasing that conveys the factual essence of what has been said and is used to reflect back the essence of the conversation in 'pieces' of content for example:

Client: 'This diet is just too hard to follow when I'm eating out.'

Dietitian: 'You are struggling to manage with eating when you are not at home . . .'

To be effective, a paraphrase requires a level of accuracy that helps provide clarity for both the client and practitioner. A paraphrase should be used tentatively so that the client can agree or correct any inaccuracies. A succinct

accurate paraphrase is very powerful in helping clients feel understood.

Reflecting feelings

A reflection of feeling conveys to the client that the practitioner is trying to understand what they are experiencing emotionally. People can show their feelings in different ways: verbally, non-verbally or a combination of both. Asking people how they feel is not always helpful as people can struggle to express their emotions, so avoid '*How do you feel?*' It is more useful to reflect tentatively and at the right intensity what the person appears to be experiencing. For example:

Client: 'And then he told me that I have got diabetes!'

Dietitian: 'It sounds as if the news was upsetting for you . . .'

Many dietitians are wary of addressing feelings but to neglect how people are feeling in relation to their health is missing a vital element of what is likely to influence their behaviour. However, dietitians need to recognise their limitations in this area and to know when and how to refer on when appropriate.

Questions

Questions are useful for eliciting important information. Closed questions are an efficient way for gathering specific information, e.g. '*Do you take milk in your tea?*' whereas an open question encourages the client to explain things from their perspective, e.g. '*Can you fill me in on what led up to your doctor suggesting you come to see me?*' Most consultations require a combination of open and closed questions. However, questions need to be used selectively to avoid what can feel like an interrogation. In general, ask open questions (unless specific information is required), avoid asking two questions in a row and for every question, offer at least two responses (Rollnick *et al.*, 2008).

Summarising

Summarising helps to pull things together at different points in the consultation and is especially useful at the beginning and end of the session. Short summaries help to clarify the situation as the consultation proceeds. For example:

Dietitian: 'Can I check what we have covered so far? You went to see the doctor because you were feeling unwell and the result of all the tests was that he told you that you have diabetes, which was unexpected and the news has left you feeling upset and worried. Is that right? (Pause).

Is there anything else?'

Longer summaries may be needed to clarify long and complicated stories as they provide a pause, time to think and help give direction on what to focus on next. Summaries are also useful to help dietitians remember what needs to be recorded in the notes.

Potential pitfalls for practitioners

Dietitians and health professionals often feel they have an obligation to make their clients change – we cannot *make* people change. Despite the best of intentions, this can get in the way of facilitating change. In an integrated approach, the dietitian aims to enable the client to choose and implement changes to their health related behaviour. Anything that results in the client feeling disempowered or criticised may inhibit this process and can be a potential pitfall. Examples of common pitfalls are:

- *Trying to persuade or force clients to change*, e.g. ‘Your blood pressure is raised; you really must make some lifestyle changes . . .’ Using pressure to try and convince or persuade someone to change assumes that the practitioner knows best about what the person should do. If a person feels under pressure, they are less likely to be able to make a free choice.
- *Trying to solve the problem*, e.g. ‘What I think you need to do is cut out chocolate and go walking instead’. This is often portrayed as well meaning advice or a solution offered from the practitioner’s point of view. In practice, however, clients are their own experts and are best at finding a solution that will work for them. They may need some guidance from the practitioner but this does not mean that the practitioner should lead or dictate rather than facilitate.
- *Underplaying the real health risks*, e.g. ‘The situation could be worse . . .’ This may take the form of trying to appease clients. It arises from an apparent desire to protect clients and is often due to fear of upsetting them or a fear of not knowing how to cope with a client’s distress if they become upset. How information about health risks is presented is of vital importance.
- *Presenting information in a threatening manner*, e.g. ‘If you don’t lower your cholesterol, you risk getting . . .’ Fear can motivate some people, but others may become defensive as a result.
- *Hiding behind or dictating policy*, e.g. ‘If you don’t lose more than a couple of pounds by your next appointment you will be discharged’. This strategy may be an attempt to control caseload by discharging anyone who is not succeeding according to a predetermined specification, but in practice is likely to reinforce a person’s sense of failure and may exert unrealistic pressure. Policies need to incorporate negotiation and flexibility.
- *Interrogating*, e.g. ‘Why didn’t you follow your eating plan?’ This is difficult to answer and may make clients defensive. Asking lots of questions, often in a desire to get to the heart of the problem so that it can be ‘fixed’, or to try to get the client to ‘tell the truth’ is counter-productive. It does not encourage clients to talk openly as the agenda is practitioner led and can close down the conversation.
- *Blaming or judging*, e.g. ‘You must be eating more than you have said or you would have lost weight’. This assumes that the client is lying and that the practitioner knows better than the client.

Ongoing practitioner development

In psychology and counselling, practitioners routinely receive supervision on developing their own responses and understanding, as well as improving how they work with their clients. This is not generally the case with other health professionals. It is unrealistic to expect anyone to be totally empathic, unconditionally accepting and genuinely collaborative, and also free from judgement, blame and criticism and the desire to want to rescue, protect or fix it for their clients. Although dietitians can aspire to these qualities, they are not necessarily present. Some elements can be acquired through skills training and can be further enhanced through self development (Gable, 1997). Ongoing self evaluation, developing self awareness and life management skills can all help this process. Regular supervision is essential and all health professionals should be involved in ongoing self development as an essential foundation to their practice and as part of continuing professional development (see Chapter 1.2).

The dietetic consultation in practice

Setting

A dietetic consultation has the explicit intention of discussing the person’s diet in relation to their health. It is clearly very different from an informal meeting and therefore needs to operate within certain boundaries, but should not be so formal that the client feels uncomfortable. The environment, or setting, in which people are seen needs careful consideration. Is the waiting room arranged in a way that is welcoming, with suitable seating and reading material? Is the consultation room arranged in the best way? Has clutter been removed and telephones or other interruptions been diverted? The dietitian (as the client’s advocate) has a professional responsibility to seek optimal consultation settings.

Proposed framework for the consultation

The dietetic consultation is made up of a series of different elements. Suggested frameworks for an initial and follow-up consultation are shown in Figure 1.3.1 and Figure 1.3.2. These should be flexible with different elements being applied interchangeably within each interview, depending on the varying needs of the client. Not all elements are necessarily included in all interviews, e.g. if someone is very ambivalent about making changes, the whole of the first session may involve exploring this. How interpersonal skills link to the elements involved in the consultation and how to manage difficulties that may arise are explored later. It is important to be aware of one’s limitations and to refer on appropriately. Difficulties generally outside a dietitian’s expertise include psychiatric or psychological problems, relationship problems, bereavement, stress, social and economic problems, and problems that are more properly the remit of other health professionals, e.g. speech and language therapists.

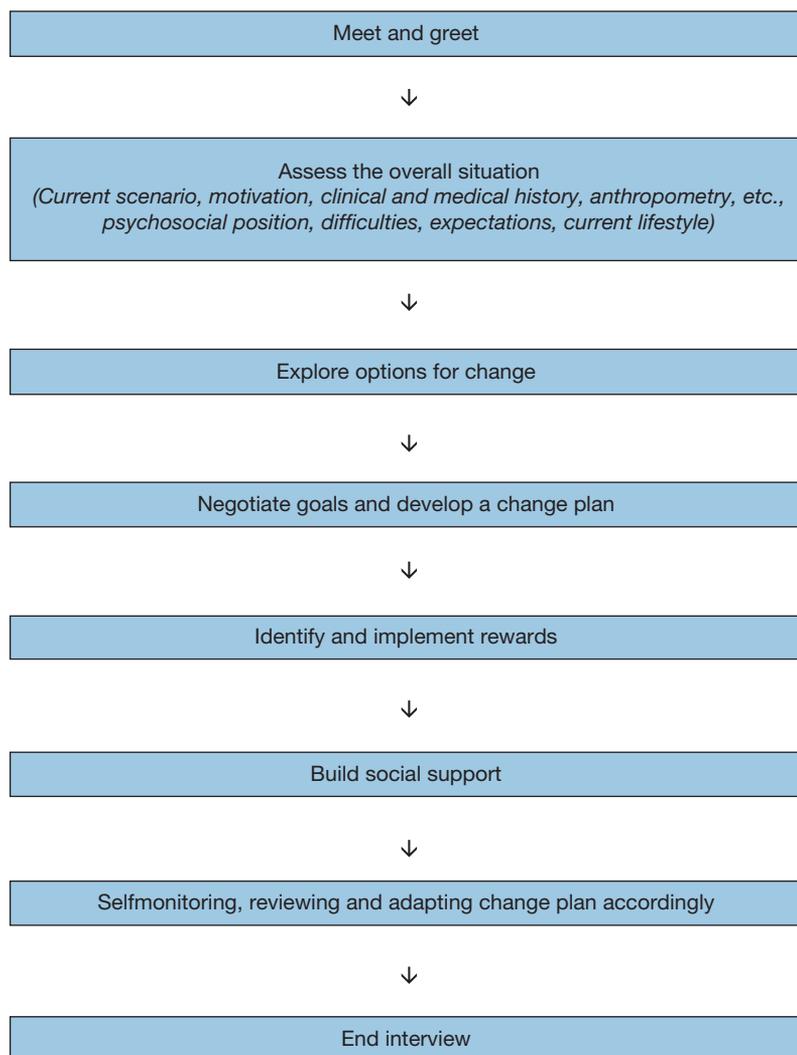

Figure 1.3.1 A suggested framework for an initial dietetic consultation

Elements of the consultation

The following elements within the dietetic consultation form a highly specific focus in an integrated approach to changing health related behaviours. It is essential to skilfully interweave interpersonal skills with specific elements seamlessly. Not all these elements will necessarily be used in each consultation. The skilled practitioner learns to work with different elements flexibly, using the most appropriate one at any given time.

Meeting and greeting the client

It is easy to rush this part of the consultation, but it is important to take time to greet clients in a warm and friendly manner. Introductions are important, including checking how the client wishes to be addressed and stating the amount of time available for the consultation. It is also important to include client relatives or carers, if that is the wish of the client, in the conversation and to treat them in the same respectful manner. The consultation itself should start with an open invitation to talk, allowing clients to state what is on their mind, as well as

giving an indication of their understanding of the reason for the referral. For example:

‘Your doctor has written and asked me to see you. Would you like to tell me what has been happening from your point of view that has led up to this?’

Or for a review appointment:

‘How have things been going since we last met?’

Assessing the overall picture

Assessment is standard practice and is likely to take up most of the first consultation, but it also needs to continue throughout further consultations as change takes place. It needs to be undertaken in a collaborative manner so that a true picture of the person’s situation emerges. Subsequent treatment goals can then be tailored to the individual with the ultimate target of achieving better health outcomes. The initial assessment needs to include the overall clinical and medical situation as well as the client’s experiences and circumstances. For example:

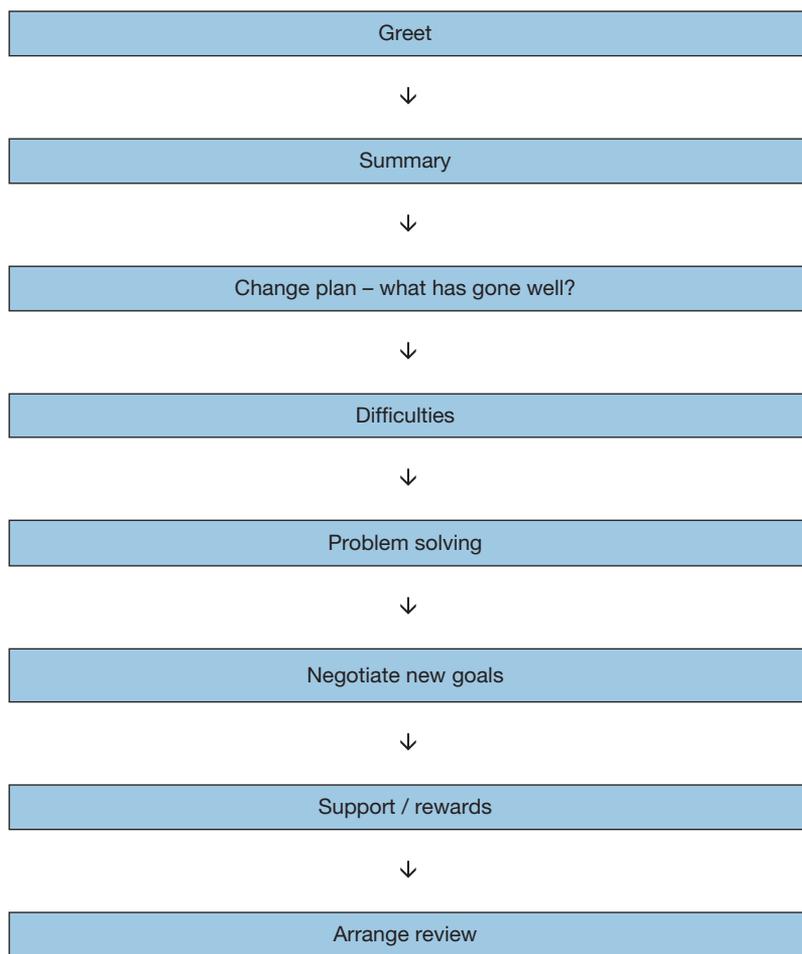

Figure 1.3.2 A suggested framework for a follow-up dietetic consultation

Dietitian: ‘Can you tell me a bit about your current situation (family, job, that kind of thing . . .) so that we can see how any dietary or lifestyle changes may fit in . . .?’

Client: ‘I work part-time . . .’

Dietitian: (*paraphrase/reflect this information*)

Try to avoid asking a lot of questions in a row without reflecting back the responses. If a series of closed questions is necessary, it is less intrusive if permission is asked first. For example:

Dietitian (assessing calcium intake): ‘Would it be alright with you if we go through a number of questions, so that we both get a clear picture and don’t miss anything important?’

Client: ‘That’s fine.’

Dietitian: ‘Can you tell me how much milk you consume? . . . do you eat cheese? . . ., how often . . ., how much . . ., what about yogurt?’

Providing information

Exchanging information is a process that needs to be interwoven into all aspect of the consultation. It can either focus on providing information to the client or gathering information about their overall situation. The aim is to assess the client’s knowledge about their own

condition, biochemistry results, approaches to treatment, etc., and on that basis to give relevant new information that may help in their decision making regarding making changes or managing their condition. Pitfalls in a dietetic consultation include:

- Making assumptions about the client’s current levels of knowledge or understanding.
- Interrogating the client.
- Imposing information on the client that they do not want or are unable to assimilate at that particular time. This may make them more resistant to change.

Exchanging information needs to be done in a client centred way, so that the person feels free to disclose relevant information. For example:

- Find out what they know, e.g. about their diabetes:
Dietitian: ‘Has your doctor explained what diabetes is?’

Client: ‘Yes . . .’ (*sounding unsure*)

- Ask permission to give them further information:
Dietitian: ‘Would it be helpful if we talked a bit more about that now?’ or ‘Would you like me to go over any of it again?’

Some people do not want or need information because they already know the facts or because the timing is not right. If someone is genuinely not interested or ready to

know more, asking permission alerts the dietitian to this and enables the consultation to progress at the client's pace. Information given when someone is not ready can seem like undue pressure and stop people from wanting to know more or from wanting to make a return visit. When clients agree to receive information, they listen more carefully.

- *Provide the information in an objective, neutral manner.* Information should be given in a simple, objective, non-emotional manner and always related to current scientific understanding, e.g. 'There is good evidence that losing weight can help lower blood pressure'.

Avoid long complicated explanations and the use of jargon or scientific language.

- *Find out what their interpretation is of the information you give them.* 'What do you think about that?' or 'Does that make sense?'

Motivation

Motivation is affected by many factors and can fluctuate to a greater or lesser degree. How important the client sees a change in terms of their overall life will affect the likelihood of them implementing it, and therefore needs to be explored. For example:

Dietitian: 'Would you say that making changes to your diet in order to lose weight is a priority for you at the moment?'

Client: 'Oh, yes, I mean if it will help with my blood pressure . . .' or 'I'm not sure it will make any difference . . .'

Dietitian: (reflecting the response and continuing to explore) 'You are keen to get your blood pressure down' or 'You can't see much point in making any changes to your diet . . .'

This is part of establishing a common agenda. It is the responsibility of dietitians to ensure that the client has the correct information at this point. This helps to raise awareness in a non-threatening manner about the unhelpful behaviour and its implications. Increasing concern about the behaviour may increase its importance to the person and therefore make change more likely.

If the health related change is important to the individual, the next step is to explore whether they feel confident in their ability to do so and to offer support. For example:

Dietitian: 'Do you feel able to make some change to your eating at the moment?'

Client: 'I know I should if it will help with my blood pressure, but I have tried lots of times . . .'

Dietitian: (reflecting the response and continuing to explore) 'You have tried lots of times and are feeling a bit disheartened by that experience?'

Client: 'Yes.'

Dietitian: 'Is there anything that we could do together that would help?'

It is possible to use scaling questions to establish levels of motivation, e.g. 'on a scale of 0–10, where 0 is not important/not confident at all and 10 is extremely important/confident, where would you place yourself?' (Rollnick *et al.*, 1999). This approach however needs to be used with a high level of good interpersonal skills and applied with sensitivity. It can be a helpful way broadly to establish how important change is to the client, but should not be regarded as a precise or rigid assessment tool. The response should be met with reflective statements rather than judgement.

Eliciting information on current health related behaviours

An overview of current eating and activity levels can be undertaken by asking the client to describe a typical day. For example:

Dietitian: 'Can I ask you to describe a fairly typical day, in terms of how food (or activity) fits into that day, starting from when you get up in the morning to last thing at night?'

Client: 'Well, the mornings are always a rush . . .'

Dietitian: (follow the person's description with reflective responses and summarise to capture what has been said.)

Taking a diet history is another way of gathering detailed information about current diet. It is traditionally the mainstay of dietetic practice but there are pitfalls:

- As it involves asking lots of questions, it can feel like an interrogation. Intensive questioning, as with any succession of closed questions, risks damaging the helping relationship. People who eat for emotional reasons will be less likely to disclose this with intensive questioning as they often feel vulnerable, and this can expose the vulnerability and increase defensiveness.
- All methods of assessing dietary intake, and especially dietary recall, have inaccuracies (see Chapter 2.3). People are likely to report what they think the professional wants to hear rather than what they actually do.

Initially, general information regarding how the diet fits in with life can be gathered as this is what will ultimately influence change. Further necessary information can then be elicited when options for change are discussed. Self monitoring (see later) is another tool that can be used to gather information about diet and keeping diaries can be informative. Once a supportive relationship is formed, clients are more likely to offer accurate information. By threading the process of exchanging information regarding dietary intake and activity levels into different aspects of the interview, clients are less likely to feel they are being judged.

Exploring options for change and helping decision making

Once someone decides to make changes, it is helpful to explore what options are available. Initially it is helpful to identify the change that is most favoured by the client. This can then be discussed in terms of whether it

is realistic to make this change. Focusing on this makes it more likely that the change will be implemented and maintained. In some cases however, it may be necessary to concentrate on the option that will have most impact on the immediate health concern, e.g. reducing saturated fat intake where there is a raised cholesterol level. Generally, the following approach can be helpful:

Dietitian: ‘There are a range of possibilities that would help your overall health – changing the types of fat you eat, eating more fruit and vegetables, eating less sugar, etc. Where do you think you would like to start?’

This exploration can be helped in a various ways, e.g. with visual aids. The recommendations can be discussed and further information about a person’s dietary practices gathered at the same time. For example:

Dietitian: ‘The recommendations are to eat five portions of fruit and vegetables per day – How does that compare with what you are doing at the moment?’

Negotiating goals and developing a change plan

Setting appropriate behavioural goals is the basis of achieving a successful outcome. These need to be negotiated with clients so that they have an active role in deciding what they can realistically achieve. Goals set by health practitioners may not take account of other factors that are affecting people’s lives. Unrealistic goals can set clients up for failure and undermine the confidence of both the patient and the practitioner. Clients should be encouraged to use a stepwise approach to achieve a particular goal. Ideally, goals should fulfil SMART (specific, measurable, achievable, relevant and time specific) criteria:

- Specific, e.g. eating less fat might be achieved by spreading fat more thinly on bread.
- Measurable, e.g. eating five portions of fruit and vegetables each day.
- Achievable and realistic, e.g. reducing chocolate intake by consuming one bar each day instead of two.
- Relevant to the goal of treatment, e.g. if the aim of treatment is to decrease fat intake, clients need to concentrate on eating foods that are low in fat.
- Time specific, e.g. setting a goal to be achieved within an agreed time frame.

For a goal to make a difference in the specified time, it needs to be as far reaching as possible. For example, if the main goal is to reduce fat intake, the main dietary source of fat intake needs to be identified and reduced to a level that will make a difference (e.g. if fried foods are eaten daily, an appropriate weekly goal may be to use fat free methods of cooking). This would have a larger effect than a goal of not eating a food that is only consumed once a fortnight.

Only two or three specific, realistic and achievable changes should be chosen. Successful negotiation of each of the smaller steps gives people a sense of achievement and helps keep them motivated in the longer term. Once the precise nature of the goal has been agreed, and ways of implementing it explored, it is helpful to summarise

Box 1.3.3 Example of a change plan that can be agreed between the dietitian and client

- **What** do I want to achieve overall?
- **Why** it is important to me?
- Specific goal (**what** exactly am I going to do?)
- Steps to achieve this (**how** am I going to do it?)
- **What** needs to be in place?
- **What** might get in the way?
- I will ask for **support** to help me work towards my goal from . . .
- **What** will help to reinforce new habits (reward or encouragement)?
- **How** will I keep a record of progress?
- **When** will I review progress?
- **When** will I start?

this by completing a change plan (Box 1.3.3). A change plan should be a starting point that is regularly reviewed and updated in the light of what is or is not working. Once goals have been established and a change plan has been agreed, it is important to ensure that the elements that are known to support behaviour change, such as rewards and support, receive due attention.

Identifying and implementing rewards

People can be encouraged to reward themselves on a regular basis for the efforts that they are making. This may make them more likely to repeat the change and is a method of reinforcing new eating habits. Suitable rewards may be enjoyable leisure time activities and hobbies, being with favourite people, buying small things they want, or doing what they find relaxing or fun (Holli & Calabrese, 1998). Rewards need to be something that is truly pleasurable (and non-food based) for the individual and this may need exploring. Practitioners need to avoid making suggestions for rewards that would appeal to them personally. People should also be encouraged to mentally congratulate themselves on every effort and achievement, however small, to help build self esteem and belief in their ability to change. Other methods of reinforcing new habits may not necessarily be pleasurable, e.g. asking the family to remind you to go for a walk each evening, but can still be effective.

Building support

The importance of social support from a range of sources cannot be underestimated. As well as support from the dietitian and other health professionals, family members, friends and colleagues can play key roles. Responsibility for enlisting support from elsewhere lies with the client, but they may need help in how to do it. Family members and carers can be included in consultations and leaflets can be produced for them explaining how to support the person making the changes and, where appropriate, the benefits that changing the diet can have on the health of the client. The client may also need to clarify the type of support that would be most helpful to them. For example:

'I really appreciate your support. What would help me even more would be if you don't nag me, but encourage me, and offer practical support, like helping me with planning and preparation of meals.'

Other sources of support include self help groups, books, telephone help lines, the Internet and social networking. The dietitian may give information on these resources.

Self monitoring and developing self awareness

Self monitoring, e.g. keeping a diary, helps achieve changes in behaviour. This increases self awareness of current behaviour, highlights problem areas and to reinforces success. A willingness to observe behaviour often indicates a willingness to recognise it and to change it if appropriate. Self monitoring can be used in many ways, e.g. to identify:

- Time and place of eating.
- What a person was doing prior to eating.
- Who they are eating with.
- How the person felt and what they were thinking.
- Symptoms.
- Behavioural outcome.

It is unrealistic and inappropriate to ask clients continuously to record all of the above. Diary keeping is a difficult skill that often needs practice in order to focus on the behaviour that is being targeted, e.g. timing of meals. For self monitoring to be effective, care needs to be taken to ensure that the client knows what is expected, and the purpose and benefit of keeping a diary. Diaries need to be used collaboratively; clients must agree to keep the diary and be able to use their preferred method, e.g. preprinted sheets or their own notebook; they should not be used as a means of checking up on clients. In order to reinforce that self monitoring is for the client's own benefit, it is helpful to ask what they have learnt from the exercise. Monitoring needs to be regularly reviewed by the client in order to use the information to adapt and update their change plan. Difficulty in keeping to the self monitoring process may suggest that unresolved motivational issues exist and need to be addressed (see Managing common difficulties later).

Ending the interview

This is just as important as a good beginning. Sufficient time needs to be allowed to ensure that the main points of the consultation are summarised and that there is clear agreement about goals set, monitoring, review and any follow-up arrangements. The client should be given the opportunity to ask questions to clarify any concerns.

Managing common difficulties

Clients who want advice

Clients usually recognise that the dietitian they are consulting has expertise. It is important to give information when clients are seeking it (this can be an indication of readiness to change), but at the same time it is important

to draw on the expertise that clients have about themselves. For example:

Dietitian: 'You would like me to tell you exactly what to eat in order to . . . ?'

Client: 'Yes, what I need is a diet sheet; that is what I have come for.'

Dietitian: 'It sounds like an eating plan would really help, as well as being clear about which foods are best to avoid and which ones to include. I can certainly give you that information and we can work out together what would be the best eating plan for you. That way, we can make sure that we include some of the foods you really like and make sure that the plan fits in around your life. How does that sound?'

Referred clients who do not want advice

Sometimes clients feel that they have been sent to see the dietitian, rather than choosing to come themselves. A consultation where this is the underlying feeling will only be met with resistance. It can help to find out the client's understanding of what led to the referral being made: it is more helpful to ask '*Can you tell me what led up to your doctor suggesting that you come to see me?*' rather than '*Do you know why this appointment was made?*' It is useful to find out what their thoughts are about the referral: '*I wonder what your thoughts were when the doctor suggested coming to see me?*', rather than '*How do you feel about coming here?*'

Clarify that your role is to explore the situation with them and consider any possible options, but do not to tell the client what to do. Ask permission to progress on that basis and explain what service you can offer.

Clients who cannot come up with their own solution

Clients should be given the opportunity to make suggestions, although not all clients have ideas or solutions for their situation. The temptation is to jump in with suggestions; however, there is a risk that the dietitian's ideas might be inappropriate, that clients will feel this as pressure and be inclined to agree without thought, and then find that they cannot do it in practice. In this situation, it can help to present possible solutions in the context of what has worked for others. This still allows the client either to accept or decline a particular suggestion. Always ask permission before making suggestions, e.g. '*Would you like me to tell you about some of the things that have worked for other people?*'

Ambivalence about change and motivational difficulties

Ambivalence about change is normal; clients often feel torn between wanting better health and not wanting to change established eating habits. Exploring ambivalence by looking at all the implications of change, the benefits and disadvantages of change, or no change, can

be liberating and help build motivation for change. It should be explored in a non-judgemental way; either verbally or on paper, but writing points down usually clarifies the situation and develops a common understanding between client and practitioner (Miller & Rollnick, 2012). It is important to respect client autonomy if the client decides not to change.

A decision not to make a change at the present time is a viable option. If the client has already tried and failed many times to change, a further half hearted attempt and failure might reinforce low levels of self esteem. Providing unasked for advice in this situation is likely to be met with resistance. Motivation for change can be triggered by helping a person become more aware of the discrepancy between where they are and where they would like to be. Clients need to recognise this (facilitated by a skilled practitioner who highlights the discrepancy between their intentions and their behaviours), rather than having it exposed as a product of their inadequacy. For example, instead of *'You need to keep away from the biscuits, you know the effect it has – you need to work on your will power,'* a reflective response can be more helpful: *'So although you want to lose weight, you are finding it hard to keep away from the biscuits.'*

If a person clearly is unmotivated, many of the strategies already mentioned can help. In addition, increasing their perception of the importance of proposed change can help by raising awareness about the unhelpful behaviour. For example:

Dietitian: 'Are you aware that low calcium intake has certain health risks?'

Client: 'No, tell me more.'

Dietitian: 'It increases your risk of developing osteoporosis. What are your thoughts about that?'

Lack of confidence

A client's level of confidence about their capacity to make and sustain a change is key (Rollnick *et al.*, 1999). Self esteem and self efficacy impact on a person's confidence to implement and sustain a change. Supporting self efficacy and self esteem involves encouraging an environment that increases the client's confidence that they will be successful. The dietitian can assist by:

- Exploring what worked in the past and trying to incorporate it into the present change plan.
- Encouraging clients to talk about their past and present successes.
- Drawing attention to success in other areas of their life.
- Helping to devise a change plan (see earlier) with small achievable steps.
- Looking for opportunities to support clients' confidence in their ability to change.
- Conveying optimism in a supportive and realistic manner.

Problems

Problems can arise at all stages of making change and need to be addressed. It is important to address any dif-

iculties related to change and to encourage clients to generate solutions to the perceived difficulties themselves. This helps to increase their sense of confidence and competence. It also emphasises that there is no one right option for change and requires experimentation to find what works best for each person. The following steps have been identified as key elements of the problem solving process. This process can be used at any stage in the intervention:

- Identify the problem.
- Explore all possible options and evaluate the advantages and disadvantages of each option.
- Choose the preferred option(s).
- Develop a plan.
- Implement and monitor the plan.
- Review the plan.

Distractions to the planned change

A number of feelings, thoughts, beliefs, events and situations can initiate a behaviour. The environment can be changed to make new behaviours more likely to happen and undesirable behaviours less likely to happen, e.g. putting away the shopping. Making changes to eating habits usually means changing long established habits related to eating, including shopping and cooking. Planning ahead can aid success by drawing attention to problems or difficulties that the client may be able to resolve in advance. This makes revising the plan easier if the client has clear expectations of themselves. Any changes need to be developed collaboratively with the client, rather than presented as solutions from the practitioner's viewpoint, e.g. *'Why don't you . . .'*, *'Do you think you could . . .'*, *'How about . . .'*

Examples of strategies for modifying *external* cues to eating used in weight management but that can be adapted for use with other conditions are:

- Plan meals and shopping in advance so that appropriate foods are available to eat regularly.
- Plan daily eating times in advance.
- Carry suitable snacks.
- Ask a friend, partner or workmate to make a change at the same time, or to be encouraging.
- Avoid tasting when cooking, as this may result in overeating.
- Limit the opportunities to see tempting foods other than at meal times, e.g. put things away in cupboards, do not shop when hungry.
- Take a route home that does not involve passing a tempting food shop, e.g. bakery or sweet shop.
- Always make sure there are suitable foods, e.g. fruit and vegetables, available to avoid being tempted to eat less suitable foods if hungry.
- Do not buy, or only occasionally buy, tempting or energy dense foods, such as chocolates, cakes and crisps.

Strategies for modifying *internal* cues include:

- *Ask in response to an urge to eat: 'Am I really hungry?'* Urges to eat or cravings need to be distinguished from

hunger. The former are psychological triggers to eating and distinct from physical hunger, which is the real need to eat. Real hunger needs to be responded to, but there are a number of strategies that can be learned to help overcome psychological urges. Some people find it helpful to use a hunger score (*'How hungry am I on a scale of 0–10 where 0 is not at all hungry and 10 is extremely hungry?'*) to check if they are truly hungry. Urges and cravings are sometimes described as being wavelike: they build and build until they peak, but then break and fade away within 15–30 minutes (Brownell, 2004). An urge or craving can be withstood by doing something incompatible with eating until it has faded.

- *Make a list of alternative activities* that make it impossible to give into urges, e.g. walking, reading a novel, running, painting or practising a relaxation exercise.
- *Mood changes can be due to other worries*, e.g. relationship problems, job worries or long term effects of illness. These may need to be addressed and it may be necessary to refer the client for more in-depth counselling or therapy.

Setbacks

Lapsing from a planned change or a made change is normal, but clients frequently see it as a failure (Marlatt & Gordon, 1985). Prevention and management of lapses need to be anticipated and worked with throughout the consultation process. Lapses often lead to feelings of guilt, which makes a person more susceptible to other slips and potentially complete abandonment of changes and a return to previous patterns. How a person thinks about a lapse or setback is likely to determine the outcome. It can be helpful to explain:

- Lapses are a natural and accepted part of change, and can provide a learning experience. Eating an unplanned food is a slip and not a personal failure.
- High risk situations (ones that present an increased and significant risk of returning to old behaviours) are either triggered by internal states, e.g. anxiety, boredom, anger, loneliness, or external events, e.g. social situations, passing a bakery, or a combination of both. An individual can learn to cope by identifying their particular high risk situations and then learning how best to manage them.
- Change is an ongoing process and a goal in itself. The process should be the focus rather than perceived failure or success at any given step. Every small change in behaviour in the desired direction is a step forward and a sign of important progress.
- Even if clients abandon their change plan for now, they can return to it at a later time.

Dietitians can help people to identify what leads to a lapse so the client can plan in advance to prevent them. Coping strategies can be established and accessed when necessary. The way a person copes after a setback can influence the likelihood of further lapses. The six steps shown in Table 1.3.1 can help a client cope with lapses.

Table 1.3.1 Coping strategies for coping with lapses in behaviour change

	Strategy
Stop	Go away from the situation to a safe place to think about what has happened.
Say	It is not a catastrophe – one error does not mean the end of the world.
Learn	What was going on before the lapse? Analyse the situation to see why it happened.
Plan	What can be done in the same situation to avert another lapse? Use the above information to plan in advance to reduce the risk of it happening again. Decide what can be done immediately to stop the slip spiralling out of control. Put these strategies into practice at once.
Be positive	Has anything really changed? Review personal goals and motivation for change.
Ask	Is there anything that can be done to balance out the slip? For example, do some extra exercise. (It is not recommended that clients skip a subsequent meal as a result of a lapse as this in itself can trigger overeating.)

Unhelpful thinking

People can be helped to identify unhelpful thoughts and to replace these with more helpful, coping thoughts. As this process can be complex, further training, accompanied by appropriate supervision is recommended. Referral to specialist practitioners may be necessary. Steps involved in modifying unhelpful thoughts include:

- identifying the unhelpful thoughts through keeping a diary, e.g. *'What were you thinking at that time?'*;
- generating alternative ways of thinking and test out if these alternatives are more helpful in everyday life.

Implications for practice

Integrating a behavioural approach to changing health related behaviours involves using a wide range of skills. Behaviour change intervention has been described as combining art and science (Hunt & Pearson, 2001). In other words, not only the message but also the way in which it is delivered is important. Dietitians need to ensure that they equip themselves with the necessary skills to integrate a behavioural approach into their practice. This includes having appropriate training and clinical supervision, and ensuring that this way of working becomes an integral part of continuing professional development.

SECTION 2

Nutritional status

2.1

Dietary reference values

Joan Gandy

Key points

- Dietary reference values (DRVs) are estimates of the nutritional requirements of a particular population and assume that requirements are normally distributed.
- They are based on the best evidence available when they are set and must be regularly reviewed.
- DRVs are applicable to groups and populations and should be used with caution when assessing the nutritional adequacy of individuals.
- DRVs are devised for healthy populations and may not be applicable in some clinical situations.
- Dietitians should understand the guiding principles of establishing DRVs and their limitations.

Dietary reference values (DRVs) are established within a population as a measure of nutritional adequacy. As such they are aimed at preventing deficiencies rather than preventing nutrition related diseases. However, DRVs are used as the basis for dietary based food guidelines, such as the eatwell plate, and dietary recommendations that are aimed at optimising health and preventing disease related to over- and under-nutrition (see Chapter 4.2).

The first DRVs were devised in the late 19th century and international values were established by the League of Nations (the forerunner of the United Nations) in 1936–1938 to prevent deficiencies in a population group (Beaton, 1991). Many countries have their own values and international values have been published by the Food and Agriculture Organization of the United Nations (FAO)/World Health Organization (WHO)/United Nations University (UNU). In Europe the European Food Safety Agency (EFSA) has begun publishing a series of scientific opinions on DRVs, with the most recent being average requirements for energy intake for infants, children, pregnant and breastfeeding women and adults. To date, the EFSA has also published scientific opinions on DRVs for water (see Chapter 6.6), carbohydrates and fats, fibre, and protein.

In a separate initiative, the European Commission funded the EURRECA (EUropean micronutrient RECommendations Aligned) project to harmonise micronutrient recommendations across Europe. This project included scientists from 17 countries and aimed to deliver an aligned set of standards that provided a robust scientific basis for establishing micronutrient requirements and for devising micronutrient recommendations. It focused on

the needs of specific vulnerable groups, e.g. infants, children and adolescents, adults, pregnant and lactating women, the elderly, people with low income and immigrants. In addition, EURRECA evaluated the impact of socioeconomic status, ethnic origin, interindividual variability and vulnerability due to genetics, environmental factors and epigenetic phenomena on dietary requirements. A full list of publications is available at www.eurreca.org.

In the UK, the Department of Health Committee on Medical Aspects of Food Policy (COMA) revised DRVs for nutrients in 1991 (Department of Health, 1991) with the exception of energy, which was revised in 2011 by COMA's successor, the Scientific Advisory Committee on Nutrition (SACN) SACN, 2011a.

Development of dietary reference values

Dietary reference values are developed by an expert group reviewing the evidence; DRVs are then derived by the expert group, e.g. WHO, for a specific population of a country or a group of countries. The values are based on the assumption that individual requirements for a nutrient within a population or group are normally distributed and that 95% of the population will have requirements within two standard deviations of the mean, as shown in Figures 2.1.1 and Figure 2.1.2. They assume that individuals are healthy and also consider gender, age, growth and physiological status, i.e. pregnancy and lactation. Guiding principles for the development of recommendations for micronutrients have been developed by EURRECA (van't Veer *et al.*, 2012).

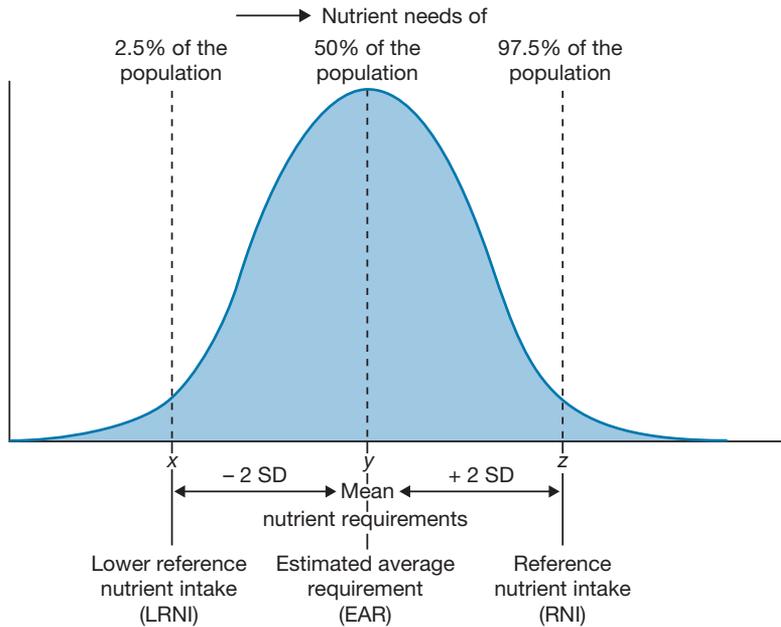

Figure 2.1.1 Derivation and definition of dietary reference values in the UK (source: Public Health England 1991. Reproduced with permission of Public Health England)

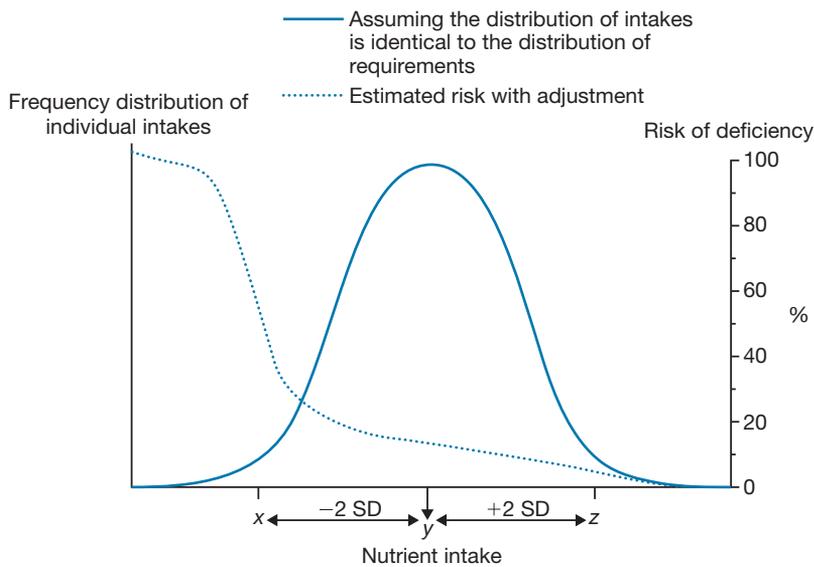

Figure 2.1.2 Dietary intakes and risk of deficiency (source: Public Health England 1991. Reproduced with permission of Public Health England)

The first UK dietary reference standards were established in 1950 as a single set of recommended daily amounts (RDA). In 1991, the standards were extensively reviewed and replaced by a range of reference standards for use in different applications (Department of Health, 1991). Several terms were used in this report, with DRVs as the collective term for the standards. The DRVs will vary according to the country or organisation responsible for the recommendation. Table 2.1.1 gives the definitions of the DRVs used in the UK and by other expert groups, such as WHO and the Institute of Medicine (USA).

Limitations

While DRVs are useful, they are open to misuse and the inherent problems associated with developing recommendations for an entire population should be consid-

ered. It is assumed that nutrient requirements are normally distributed for a population; however, the data may be skewed or sufficient data may not be available to establish normality. Robust data are required for the expert group to evaluate requirements; these data may be derived from tissue levels, balance studies, body pool size, etc., amount required to prevent symptoms of deficiency, or a measure of function of the nutrient. However, these data are not always available. When there is insufficient data the expert group will recommend a safe level of intake rather than a recommended intake value. It is important to remember that DRVs are recommended for healthy populations and many factors may affect dietary requirements, as shown in Table 2.1.2.

In particular, it is important to consider bioavailability; while the majority of macronutrient intake is absorbed, the absorption of micronutrients is more variable. This is

Table 2.1.1 Definitions of dietary reference values**Definitions used in the UK (Department of Health, 1991)**

Recommended daily amount (RDA)	Average amount of the nutrient that should be provided per head in a group of people if needs of practically all members of the group are to be met (Department of Health, 1979)
Recommended Intakes	Amounts sufficient, or more than sufficient, for the nutritional needs of practically all healthy persons in a population. Intake emphasises that the recommendations relate to food actually eaten (Department of Health, 1969)
Requirement	The amount of a nutrient that needs to be consumed in order to maintain normal nutritional status
Estimated average requirement (EAR)	The mean requirement of a nutrient for a population or group of people. On average, 50% will consume more than the EAR and 50% less (point y in Figure 2.1.2)
Lower reference nutrient intake (LRNI)	The level at which only approximately 2.5% of the population or group will have an adequate intake; it will not be enough for most people. An individual with this intake may be meeting their requirement but it is highly probable that they are not (point x in Figure 2.1.2)
Reference nutrient intake (RNI)	At this level, intake will be adequate for 97.5% of the group or population. It is possible that an individual's intake at this level will not meet their requirement, but it is highly improbable
Safe level	This is given when insufficient information is available to derive requirements. It is an average requirement plus 20% and is believed to be adequate for most people's needs. The panel judged that there is no risk of deficiency at this level and that there is no risk of undesirable effects above this level

Other values used for dietary reference values (DRVs)

Protective nutrient intake (PNI)	Amount >RNI for some micronutrients that may be protective against a specified health or nutritional risk of public health relevance. PNI are expressed as daily value or an amount to be consumed with a meal
Upper tolerable nutrient intake level [upper limit (UL)]	The maximum intake of some micronutrients that is unlikely to pose risk of adverse health effects in almost all (97.5%) apparently healthy individuals in a gender and age specific population
Recommended dietary allowance (RDA)	Average daily dietary intake that meets the requirements of nearly all (97–98%) healthy persons
Adequate intake (AI)	Established for a nutrient when available data are insufficient to estimate an intake that would maintain adequacy. The AI is based on observed intakes by a group of healthy persons
Estimated energy requirement (EER)	The average dietary energy intake that is predicted to maintain energy balance in a healthy adult of a defined age, gender, weight, height and level of physical activity consistent with good health
Dietary reference intake (DRI)	A term used in the USA and Canada to broaden the use of RDAs, particularly in food labelling and fortification
Nutrient reference value (NRV)	A collective term for recommended values; used by some expert groups instead of DRVs (see Chapter 4.5)
Daily value (DV)	These were developed by the US Food and Drug Administration (FDA) to help consumers compare the nutrient contents among products within the context of a total daily diet

Table 2.1.2 Factors affecting dietary requirements

Factor	Example
Metabolic requirements	Age, gender, body size Lifestyle (smoking, obesity, physical activity, etc.) Disease, e.g. fever, catabolism Trauma Growth Pregnancy and lactation
Bioavailability	Malabsorption or altered absorption, e.g. milk calcium is better absorbed than non-milk calcium Reduced utilisation Increased losses, e.g. diarrhoea, burns, renal disease Environment, e.g. heating of nutrients Drugs, e.g. diuretics Dietary concentration Dietary interactions Drug–nutrient interactions

recognised to an extent by DRVs, e.g. DRVs for iron are calculated to reflect the fact that only 15% of dietary iron is absorbed. However, they cannot take into account other factors that affect bioavailability, such as amount consumed, body stores, the presence or absence of other nutrients or dietary constituents, the form of the nutrient, e.g. haem or non-haem iron, and the food source from which it is derived (Hurrell & Egli, 2010). These factors may have considerable impact on the adequacy of dietary intake.

Reference values are devised to cover the requirements of the majority of a population and therefore will overestimate the needs of a significant part of that population. It is important to remember that DRVs reflect the needs of healthy people and may not be appropriate in many clinical circumstances. While they are a useful basis to calculate individual needs, they cannot be used alone and other factors, including those shown in Table 2.1.1, must be considered. This is discussed further in Chapter 6.1.

Uses of dietary reference values

They should be used with caution in the dietary assessment of individuals as it must be remembered that DRVs are based on populations and groups, and the nutritional needs of individuals within that group or population, as well as the factors discussed earlier, will vary. Within a population the nutritional requirements of individuals form a continuum and where a particular individual lies on that continuum will be unknown. It is therefore impossible to determine whether an individual's needs are being met on the basis of a DRV. It is only possible to assess the degree of probability that an individual's needs will or will not have been met. If the estimated average requirement (EAR) for a nutrient is being consumed, there is an approximately 50% chance that needs will be met. If intake is at or above the reference nutrient intake (RNI), it is highly likely that needs are being met (and probably exceeded). If intake is below the lower RNI (LRNI), it is highly unlikely that sufficient is being consumed, unless that person is part of the 2.5% of the population with unusually low requirements.

The diet of groups or populations may be assessed by comparison with DRVs; however, it is important that the group or population is comparable to that for which the recommendations are derived. Dietary reference values are also used for the development of diets for groups of people, e.g. prisoners, and the provision of supplies, e.g. school meals. Nutrient reference values are also used in food labelling, fortification and formulation.

UK dietary reference values for specific nutrients

DRVs have been set for many nutrients but not all have an EAR, RNI and LRNI. It is clearly inappropriate to set a RNI (covering the needs of 97.5% of the population) for energy because such an amount would far exceed the needs of most people and, if consumed, would lead to

weight gain and associated health problems. The DRV for energy is therefore only set as an EAR. Similarly, the DRVs for the main energy yielding nutrients, such as fat, carbohydrate, sugars and starch, are also expressed in terms of average needs.

Energy

Estimated average requirements for energy are based on regression analyses of measured basal metabolic rate (BMR) against gender, age and weight. The analyses have been used to generate prediction equations. Numerous equations are available and ideally they should be population specific. In 1991, the Department of Health used the equations of Schofield *et al.* (1985), but in 2010 SACN recommended the use of the Henry (2005) equations for this purpose. Energy prediction equations are discussed further in Chapter 6.1. Appendix A8 shows age and gender specific equations with additional data on men aged 60–70 years (Department of Health, 1991). Increments are also added for the last trimester of pregnancy and for lactation. As energy requirement is given as an average, 50% of a population will need more than the EAR and 50% less.

In healthy populations, the total daily energy expenditure (TEE) is traditionally calculated by the factorial method, where BMR is multiplied by a physical activity level (PAL), e.g. a sedentary 40-year-old man weighing 90 kg with a PAL of 1.4 and BMR, as derived from prediction equations, of 7.973 MJ (1880 kcal) would have a TEE of 11.16 MJ (2665 kcal). In their report on DRVs for energy, SACN (2011b) do not recommend this approach but recognise that there no viable alternative is currently available. In 1991, the Department of Health defined the following PALs:

- 1.4 – inactive men and women (this applies to most people in the UK)
- 1.6 – moderately active women
- 1.7 – moderately active men
- 1.8 – highly active women
- 1.9 – highly active men

The methodology for deriving the current UK dietary recommendations for energy is described in more detail by Millward (2012).

Protein

Dietary reference values for protein (EAR and RNI) are based on estimates of the amount needed to maintain nitrogen balance with an allowance for the fact that only about 70% of protein consumed is incorporated into body tissue. Incremental amounts are added to these figures for pregnancy and lactation. It is recommended that protein intakes do not exceed twice the RNI. The DRVs for protein assume that energy requirements are met, as protein will be used preferentially for energy when the body is in negative energy balance. The

DRVs also assume that the protein is of high biological value.

Fat and carbohydrate

These nutrients cannot be given EARs or RNI as there is no absolute requirement for them (other than for small quantities of essential fatty acids) and they do not cause specific signs or symptoms of deficiency or toxicity. However, it is recognised that the proportion of fat and carbohydrate in the diet has important health implications; therefore, values are given as the percentage of total food energy they should provide. It is assumed that 5% of energy intake is from alcohol and values are expressed as percentage of food only energy. These figures are recommended averages for populations and are not necessarily appropriate for all individuals (see Chapter 4.2).

In 2008 SACN (2008) endorsed the recommendations that total dietary fat should be <35% of food energy, with saturated fat not exceeding 11% of food energy. The Department of Health (1991) recommendations for categories of fatty acids were that monounsaturated fatty acids should provide about 12% of food energy, with 6.5% of food energy from n-3 and n-6 fatty acids (linolenic and alpha-linolenic acid should provide at least 1% and 0.2% of total energy, respectively) and not more than 2% from *trans* fatty acids.

Total carbohydrate should provide 50% of food energy, with non-milk extrinsic sugars providing <11% of food energy. Intrinsic and milk sugars, and starch should provide 39% of food energy.

Non-starch polysaccharides and dietary fibre

By definition, dietary fibre is not a nutrient and therefore no specific requirement exists, although its importance in the diet is unequivocal. However, as there is still much debate regarding the terminology, analysis and physiological significance of what is a heterogeneous group of compounds, recommendations regarding fibre intake are difficult to formulate.

In the Department of Health (1991) report, the DRV for a specifically defined form of dietary fibre, non-starch polysaccharide (NSP), as analysed by the Englyst and Cummings method, was expressed as a recommended average intake for the adult population (18g/day). For individuals, recommended minimum (12g/day) and maximum (24g/day) intakes of NSP were also given.

However, it should be noted that these recommended intake figures are not comparable with the dietary fibre declared on many food labels (see Chapter 4.5). These are now usually derived from the Association of Official Analytical Chemists (AOAC) method of analysis, which measures a range of components in addition to NSP and results in figures that are about 30% higher than those obtained by the Englyst and Cummings method. As yet, the UK DRVs have not been revised but it is estimated that the recommended average fibre intake for the popu-

lation based on AOAC analysis would be about 24g/day, rather than 18g (see Chapter 2.4).

Minerals and vitamins

For most vitamins and minerals, DRVs are given as the EAR, RNI and LRNI (see Appendix A2). Insufficient information was available for establishing the distribution of requirement for pantothenic acid, biotin, vitamin E, vitamin K, manganese, molybdenum, chromium and fluoride, and guidance only on safe intakes is given. In 2003, in response to concerns for supplemental intakes of some micronutrients, the Food Standards Agency's Expert Group on Vitamins and Minerals (EGVM) has reviewed the available evidence on the safety of 31 vitamins and minerals and has made recommendations on safe upper levels of their consumption (EGVM, 2003).

In 2003 SACN reviewed the evidence on the role of sodium in cardiovascular disease and made recommendations on salt, as opposed to sodium, intake. The recommended intake of salt in adults should be <6g/day (see Chapter 4.2).

Conclusion

Dietary reference values are based on the best evidence available at the time of publication and should therefore be constantly reviewed. There is a paucity of evidence for some nutrients and the requirements for optimal health are continuously being researched; therefore, it is important to use DRVs as reference rather than definite set values. It is essential that dietitians understand the guiding principles used in the derivation of DRVs and understand their limitations and applications. The DRVs in the UK and other countries are revised periodically and further details can be found on the relevant web sites.

2.2

Assessment of nutritional status

Joan Gandy

Key points

- Assessment of nutritional status is fundamental to dietetic practice.
- It is a detailed, specific and in-depth evaluation by a competent health professional of an individual's nutritional status.
- Nutrition assessment encompasses many domains and no single parameter should be used in isolation.
- Nutritional assessment is a continuous process.
- Tools for nutritional assessment can be simple, e.g. visual assessment, or more complex, e.g. anthropometric or biochemical measurements.
- A multidisciplinary approach to nutritional assessment is vital to ensure timely and effective intervention.

Nutritional assessment was first described by the Health Organization of the League of Nation in 1932 and referred to a set of procedures to describe populations at a national level (Gibson, 2005). It now encompasses a number of domains, e.g. physical and dietary assessments, and is used in a variety of settings, e.g. clinical, sport, research. Many countries collect data on the nutritional status of populations and use these data to identify health priorities, and develop public health policies and interventions (see Chapter 4.2). Nutritional assessment of an individual will establish present nutritional status and identify potential concerns that can be dealt with promptly and thereby avoid future problems. It is a continuous process especially in clinical practice. Nutritional status can be defined as *the degree to which the individual's physiologic need for nutrients is being met by the foods he/she is eating. It is the state of balance in the individual between the nutrient intake and the nutrient expenditure or need* (Krause & Mahan, 1979).

The assessment of nutritional status is a detailed procedure that should be conducted by trained and experienced professionals. As such it should be a fundamental part of dietetic practice. The British Dietetic Association (BDA, 2012) defines assessment as '*. . . a systematic process of collecting and interpreting information in order to make decisions about the nature and cause of nutrition related health issues that affect an individual, a group or a population.*' It is the first step in the nutrition and dietetic process (see Chapter 1.1).

It is important not to confuse nutritional assessment with nutritional screening. Nutritional screening is a

simple procedure that uses tools designed and validated for use by all healthcare professionals, specifically to identify individuals at risk of malnutrition (over- and under-nutrition) (see Chapter 6.2). Individuals identified as being at risk of malnutrition may then be referred to dietitians, according to local or national guidelines, who are trained and experienced in the full range of nutritional assessment techniques.

Nutritional assessment should be structured and standardised and therefore usually follows the ABCDE format:

- Anthropometry, body composition, functional.
- Biochemical, haematological tests.
- Clinical, physical.
- Dietary.
- Environmental, behavioural and social.

Table 2.2.1 gives examples of what may be assessed in each domain. The tools used and information collected in the assessment will vary depending on the practice setting, i.e. individual, group, community or population. This chapter discusses the assessment of adults; further details of the assessment of children can be found in Chapter 3.8.

An individual's clinical status has the potential to affect nutritional status in many ways; examples are shown in Table 2.2.2. Acute or chronic illness, injury and surgery can have considerable impact on nutritional status, both directly (due to the effects of the disease or injury itself) and indirectly (via possible effects on food intake). These effects may result in increased nutritional requirements, increased nutrient losses and/or impaired

Table 2.2.1 Nutritional assessment domains

Domain	Example procedure
Anthropometry, body composition, functional	Weight, height, body mass index, skinfold thickness, waist circumference Bioelectrical impedance analysis Grip strength dynamometry Physical activity questionnaires
Biochemical and haematological	Vitamin status tests Lipid status Iron status – haemoglobin, ferritin, etc.
Clinical	Physical appearance, blood pressure, medication, indirect calorimetry
Diet	24-hour recall, food frequency questionnaire
Environmental, behavioural and social	Shopping habits, housing, cooking facilities, education

Table 2.2.2 Examples of the effects of illness, injury and surgery on nutritional status

Increased nutrient requirements	Increased nutrient losses	Impaired nutrient ingestion, digestion and/or absorption
The metabolic response to trauma or surgery	Vomiting Diarrhoea	Lack of appetite Lack of digestive enzymes, e.g. pancreatitis
The metabolic costs of repairing tissue damage, e.g. wounds, pressure ulcers	Renal excretion Surgical drains	Loss of absorptive surfaces, e.g. resection of any part of the gastrointestinal (GI) tract, coeliac disease
Sepsis or infection	Bleeding	Effects of treatments on GI tract, e.g. radiotherapy
Involuntary activity, e.g. tremors, spasms	Wound or fistula exudates	Effects and symptoms of other conditions on food intake, e.g. dysphagia, breathlessness
Certain conditions, e.g. cystic fibrosis		Difficulty self feeding, chewing or maintaining food in the mouth

nutrient ingestion, digestion and/or absorption. Drug therapy may further affect nutrient intake, absorption, metabolism and excretion (see Chapter 5.3). Each chapter in Section 7 details assessment of nutritional status, the effect of the title condition on nutritional status and monitoring as appropriate.

Anthropometry, body composition and function

Anthropometry is one of the most frequently used assessment methods, with weight and height forming the most basic of anthropometric assessment. Historically, body composition and functional assessments were confined to the research setting. However, with increasing availability of the necessary equipment, e.g. dynamometry and bioelectrical impedance, dietitians are increasingly including these techniques in nutritional assessment.

Anthropometry

Anthropometry is the external measurement of the human body and reflects health and nutritional status; it can be used to predict performance (Shetty & James, 1994) and survival. Anthropometry is affected by nutritional and

other factors, including age, gender and ethnicity. Anthropometric measurements are frequently compared with standards or used in prediction equations, and it is important to use standards and equations derived from the same or comparable ethnic, gender or age group. The most commonly used anthropometric measures are height, weight, waist circumference and skinfold thickness. All measurements will depend on the expertise of the operator and the quality of the equipment used. It is essential that all equipment be serviced, e.g. weighing scales, or replaced as appropriate, e.g. tape measures as they may stretch with continued use.

Training is essential to ensure that the measurements are performed correctly and are reproducible. The World Health Organization has produced a manual describing techniques (WHO, 1995), although more recent publications are available (Frisancho, 2008). It is essential to establish what, if any, standards are used within the local context, e.g. NHS guidance. It is good practice to periodically check proficiency using methods that assess technical error of measurement (Ulijaszek & Kerr, 1999). In longitudinal studies, using the same operator for specific measurements will improve precision.

Standards and reference ranges are available for many anthropometric measures, e.g. WHO (1995), and classifications such as body mass index (BMI) and waist circumference categories are also available. Increasingly, standards, reference ranges and classifications are available for different ethnic groups; it is important to consider the derivation of the standards, etc. when applying these to an individual, group or population.

Body weight

Weighing scales must be maintained and calibrated (Department of Health, 2008) regularly and should be Class III or above. It is recommended that the maximum weighing interval on adult weighing scales for weight monitoring should be 200 g.

A single measurement of body weight is not particularly useful in assessing nutritional status, other than to determine an individual BMI category. Measurement of body weight at regular intervals is vital to record changes in weight over time and to calculate percentage increase or decrease. Unless weights are recorded daily to measure change in fluid balance, weight over the longer term gives no indication of changes in body composition, since weight does not differentiate between fat, fat free mass (FFM) and fluid. It is important to use the appropriate weight for the clinical status of an individual, e.g. dry weight in renal dialysis patients (see Chapter 7.5.1).

Factors that affect body weight

Fluid retention, oedema or ascites

The causes of fluid retention may include hypoalbuminaemia, certain medications, e.g. steroids, and response to injury, renal, cardiac and hepatic dysfunction. The presence of additional fluid has been estimated by Mendenhall (1992) to contribute between 1 and 14 kg of measured weight (see Table 7.4.22). For barely detectable oedema, a correction of 2–3 kg can be subtracted from the measured weight (Elia, 2003).

Accuracy of scales

As previously stated, scales should be calibrated at regular intervals. Weights can vary between different scales and at different times during the day. For more accurate and useful results, individuals should be weighed on the same set of scales, in similar clothing and at roughly the same time of day.

Amputations

Table 2.2.3 shows the adjustments to weight that should be made if limbs have been amputated (Osterkamp, 1995.).

Plaster casts, splints and replacement joints

These can add significant amounts of weight. Typically, a cast for an upper limb weighs <1 kg, and for a leg can weigh up to 5 kg. Adjustments should be made when using weight to calculate BMI and these noted in the dietetic records. Fibreglass casts will weigh less than plaster of Paris casts. The weight of a replacement joint is not usually significantly different from that of the bone

Table 2.2.3 Weight adjustments for amputations

Body part	Percentage of body weight
Upper limb	5.0
Forearm	1.6
Hand	0.7
Lower limb	16.0
Lower leg	4.4
Foot	1.5

it is replacing. If there are concerns, advice should be sought from a specialist in this area.

When weight cannot be measured

Sometimes it is not possible to obtain a weight for a patient due to their clinical condition or simply due to the lack of accessible, suitable working scales. In these circumstances weight, may be estimated, e.g.:

- Self-reported usual weight from the patient. Studies have shown this results in a certain amount of underestimation in the overweight and obese (Dekkers *et al.*, 2008) and in women (Gunnare *et al.*, 2013), and overestimation in the underweight (Rowland, 1990). The reported figure is unlikely to take into account any change in weight since admission or illness began.
- Estimates are sometimes made by the dietitian, relatives, carers or other health professionals. Reed & Price (1998) showed that first degree relatives can estimate weight to within 3–5% of measured weight.
- Other anthropometric measurements have a linear relationship with weight change, e.g. mid upper arm circumference (MUAC) (see later).

Specialist weighing equipment may be available, such as weighing beds in some clinical settings, e.g. spinal cord injury units (see Chapter 7.17.3).

Percentage weight change

This is calculated as:

% Weight change =

$$\left[\frac{\text{Usual or previous weight (kg)} - \text{Actual weight (kg)}}{\text{Usual or previous weight (kg)}} \right] \times 100$$

This equation is used more often for calculating percentage weight loss than weight gain, as this is an important indicator of the risk of malnutrition. Using percentage weight loss as a guide, nutritional support should be considered when someone has experienced unintentional weight loss of more than 10% over a 3–6-month period or the patient has a BMI of <20 kg/m² and unintentional weight loss of more than 5% over a 3–6-month period (NICE, 2006a).

In a clinical situation, weight loss may have a greater detrimental effect in a lean individual than an obese individual, even when the same percentage weight loss has

occurred. However, it is important to remember that significant, rapid weight loss in an obese individual also makes them vulnerable to malnutrition associated morbidity. Rapid weight loss over a few days reflects changes in fluid balance rather than body tissue.

Height

Height is usually measured using a stand alone stadiometer or one fixed at the appropriate height to a wall. Subjects must stand straight and stretched, with their heels against the wall or rod. The measurement should ideally be taken with the head in the Frankfort plane (top of external ear canal and top of the lower bone of the eye socket are in a horizontal plane parallel to the floor). The head plate is lowered until it lightly touches the top of the head.

Proxy height measures

When it is not possible to measure a patient's height, this can be estimated using alternative methods.

Self reported height

Studies have shown that people, especially the elderly, are not usually aware of the reduction in height with progressing age and can overestimate their height by approximately 2 cm (Spencer *et al.*, 2002; Rowland, 1990). However, the estimated height is unlikely to affect the BMI category. Self reported height has been shown to be reliable (Wada *et al.*, 2005). For individuals with spine curvature it is advisable to obtain and use reported maximum height as an adult. Measuring recumbent height is accurate but 2% higher than standing height (Gray *et al.*, 1985). This can be estimated if the length of the bed is known. Relatives can usually estimate height to within 1% of actual height (Reed & Price, 1998).

Alternatively, other anthropometric measurements can be taken and from these height can be estimated. These are:

- Ulna length.
- Knee height.
- Demispan.

Ulna length

The use of ulna length as a proxy for height is generally the easiest and quickest measure to use in bed bound patients. It is validated for use on the left side but, as no systematic differences have been found, either side can be used. The arm is bent diagonally across the chest with the palm facing inwards and the fingers pointing towards the shoulder. The measurement is taken between the central and most prominent parts of the styloid process and the centre (tip) of the bony prominence (olecranon) at the elbow (see Appendix A7). Estimates of height from ulna length can also be found in this appendix. However, caution should be used in non-Caucasian populations as predicting height from ulna length has been shown to overestimate height in Asian and Black adults (Madden *et al.*, 2012).

Knee height

Knee height is measured with the leg flexed so that the thigh and calf create a right angle. The fixed blade of a knee height caliper is placed under the heel and the sliding blade moved down to rest on the top of the knee, about 4 cm behind the knee cap. The knee height is then read from a scale to the nearest 0.1 cm. The procedure can be carried out with a tape measure with little loss of accuracy. Height is calculated using the following formulae (Chumlea *et al.*, 1985; 1992; 1994):

Men	18–60 years:	Predicted height (cm) = [knee height (cm) × 1.88] + 71.85
	60–90 years:	Predicted height (cm) = [knee height (cm) × 2.08] + 59.01
Women	18–60 years:	Predicted height (cm) = [knee height (cm) × 1.87] – [age (years) × 0.06] + 70.25
	60–90 years:	Predicted height (cm) = [knee height (cm) × 1.91] – [age (years) × 0.17] + 75.00

Demispan

Demispan can be undertaken on people sitting on a chair or lying in bed. It requires the individual to be able to outstretch their arm perpendicular to their body. It is measured by placing the end of a tape measure between the middle and ring fingers of the person with arm outstretched and running the tape along to the centre of the sternal notch (Kwok & Whitelaw, 1991). It is important to ensure the arm is horizontal and straight, and that the wrist is in natural flexion and rotation. Height is predicted using the following formulae:

Men	16–54 years:	Predicted height (cm) = [demispan (cm) × 1.3] + 68
	>55 years:	Predicted height (cm) = [demispan (cm) × 1.2] + 71
Women	16–54 years:	Predicted height (cm) = [demispan (cm) × 1.3] + 62
	>55 years:	Predicted height (cm) = [demispan (cm) × 1.2] + 67

There is some evidence suggesting that estimating height from demispan may be less reliable in the elderly.

Body mass index

BMI is a weight for height indicator that may be used to classify overweight and obesity, and is calculated as weight (kg)/height (m²). However, it does not give any indication of adipose distribution. In addition, it assumes that the relationship of weight to height is constant in adults and therefore may underestimate obesity in individuals with reduced levels of FFM, e.g. the elderly, and overestimate obesity in muscular individuals with high levels of FFM, e.g. athletes. It is a simple measure for use in nutritional assessment of individuals and populations, and forms part of many screening tools. The BMI cut-off ranges are based on the effect body weight has on morbidity and

Table 2.2.4 Classification of body mass index and risk of comorbidities in adults (WHO, 1998; 2004)

Classification	BMI (kg/m ²)	BMI (kg/m ²) Asian origin	Risk of comorbidities
Underweight	<18.5	<18.5	Low (but risk of other clinical problems increased)
Normal range	18.5–24.9	18.5–22.9	Average
Overweight	25.0–29.9	23–27.4	Increased risk
Obese class I	30.0–34.9	27.5–32.4	Moderate
Obese class II	35.0–39.9	32.5–37.4	Severe
Obese class III	>40.0	>37.5	Morbid obesity

mortality (Table 2.2.4). The higher the BMI, the greater the risk of developing certain conditions, including type 2 diabetes, heart disease, osteoarthritis and some cancers (see Chapter 7.13.1). Conversely, the lower the BMI, the greater the risk of osteoporosis and of complications associated with malnutrition. A ready reckoner of BMI can be found in Appendix A7. The BMI classification of WHO (1998; 2004) is shown in Table 2.2.4. BMI is now being superseded as a measure of obesity associated health risks by waist circumference. However, due to its simplicity, BMI is still widely used and is particularly useful in populations.

BMI is affected by many factors including:

- **Ethnicity** – the BMI ranges were primarily developed for use in public health using healthy Caucasian adults. The range for other ethnic groups reflects the differences in body composition between races and the subsequent risk to health (James *et al.*, 2001).
- **Setting** – BMI can be and is used in a clinical setting; however, it must be used as part of the overall assessment and not as a standalone result. Clinical judgement can override BMI category where necessary. It will also be affected by over- or under-estimates of weight or height as discussed earlier.
- **Age** – a BMI value may have different prognostic significance in different age groups, particularly the elderly (Beck & Ovesen, 1998). BMI ranges were derived from people aged between 18 and 65 years, so care should be taken when interpreting calculated values for people above this age range. Adult BMI reference ranges are not appropriate for children as they assume a constant height. BMI age specific centiles should be used in children (see Chapter 3.8).
- **Body composition** – BMI should be used with caution in people who have a distorted fluid balance (oedema, ascites or dehydration) or a high proportion of muscle mass, e.g. athletes, body builders and military personnel (Prentice & Jebb, 2001).

Other indices of obesity are used, e.g. Ponderal index; however, these are not in common practice and have not been researched anywhere near to the extent of BMI.

Table 2.2.5 Waist measurements in adults as a predictor of health (WHO, 2008)

	Men	Asian men	Women	Asian women
Waist circumference (cm)				
Increased risk	≥94		≥80	
Substantially increased risk	≥102	≥90	≥88	≥80
Waist to hip ratio				
Increased risk	≥0.9		≥0.85	

Demiquet and mindex

Alternative indices to the BMI based on weight and demispan (rather than height) have been derived for use in the elderly (Lehman *et al.*, 1991). In men over 64 years, the demiquet can be used:

$$\text{Demiquet} = \frac{\text{Weight (kg)}}{[\text{Demispan (m)}]^2}$$

In women over 64 years, the mindex is considered more suitable. This is defined as:

$$\text{Mindex} = \frac{\text{Weight (kg)}}{\text{Demispan (m)}}$$

Demiquet and mindex are independent of stature; therefore, they may be useful in studies of the elderly. However, they are not routinely used in clinical dietetic practice. Tables showing the percentile distribution of demiquet and mindex in the elderly are given in Appendix A7, although the limitations of these reference data (which are based on relatively small population samples) should be borne in mind (Bannerman *et al.*, 1997).

Waist circumference and waist to hip ratio

Waist circumference is now considered a more appropriate measure of obesity related morbidity and mortality (Seidell, 2010) as it assesses visceral adiposity. Visceral adipose tissue surrounds organs such as the liver and has a greater effect on health than peripheral adipose tissue. NICE (2006b) recommends the use of BMI and waist circumference in the assessment of obesity related health risks. It is a useful tool for monitoring weight loss programmes and can predict changes in risk, even if weight has remained stable. However, when BMI is >35 kg/m², measuring the waist circumference adds little predictive power. Table 2.2.5 shows the value of waist circumference and waist to hip ratio (WHR) as predictors of health (WHO, 2008).

The waist circumference is measured at the halfway point between the lowest rib and the iliac crest in the midaxillary line. The advantage of this method is that it uses a bony landmark and there is little scope for error provided that the patient can be partially undressed. It is important to ensure that the tape is snug but not tight

and is parallel to the ground, and that the patient is not breathing in (Ashwell *et al.*, 1996; Lean, 1998; SIGN, 1996).

Waist to hip ratio (WHR) is used less frequently in individual assessment, mainly due to difficulties in locating the appropriate place to measure hip circumference. However, it is a useful indicator of obesity related health risks.

As with BMI, the risk of morbidity occurs at lower levels of waist circumference and WHR in Asian populations and the WHO cut-offs are therefore lower these populations (see Table 2.2.5). There is a paucity of evidence for different cut-offs in other population groups (Lear *et al.*, 2010), although the International Diabetes Federation (2006) has made recommendations for several ethnic groups for the diagnosis of metabolic syndrome.

Mid-upper arm circumference

When neither weight nor height can be measured, the BMI can be estimated using the mid-upper arm circumference (MUAC). This is a useful tool when oedema is present as the upper arms tend not to be affected. It is also useful during pregnancy as MUAC changes little during gestation when weight obviously increases. This measurement can provide an estimation of BMI but only for the cut-off values for underweight, i.e. BMI <20 kg/m², and obesity, i.e. BMI >30 kg/m². The measurement is made with the patient sitting or standing. The arm must be bare and the top of the shoulder accessible. With the arm bent at right angles at the elbow and forearm across the body, the midpoint between the top of the shoulder and the tip of the elbow is identified and marked. The arm is then allowed to hang loosely by the side and the circumference is measured at the marked mid point.

If MUAC < 23.5 cm BMI < 20 kg/m², i.e. underweight
If MUAC > 32 cm BMI > 30 kg/m², i.e. obese

The reference values for MUAC derived from an American population (Bishop *et al.*, 1981) are given in Appendix A7. More recent data from the USA NHANES survey has been used to produce reference values (McDowell *et al.*, 2008), however their applicability to the UK population is being debated. Data for the UK population are not currently available. Patients with liver disease and alcoholism have greatly reduced arm circumference measurements compared with normal controls (Thuluvath & Triger, 1994).

Skinfold thickness

The relationship between subcutaneous fat and total body fat can be exploited by measuring skinfold thickness at specific sites to estimate adiposity. Durnin & Womersley (1974) produced equations from the relationship between total body fat, as measured by densitometry, and the sum of four skinfold thicknesses (biceps, triceps, subscapular and supra iliac), which can be used to estimate total body fat. To minimise measurement error, three separate readings should be taken and averaged. The same person

should make all the measurements for a particular individual.

Triceps skinfold

Measurement should be made on the non-dominant arm, which should be bent at a right angle. The length from the tip of the acromion process on the scapula to the olecranon process of the ulna is measured and the mid point marked. With the arm hanging loosely by the side, the skinfold at the mid point level on the back of the arm over the triceps muscle is picked up between the thumb and forefinger of the left hand. The calipers are placed on the skinfold just below the fingers, the fingers removed, and a reading taken 2–3 seconds later.

Biceps skinfold

Measurement is as for the triceps, but over the biceps muscle on the front of the arm.

Subscapular skinfold

This measurement is made about 2.5 cm in and below the angle of the scapula towards the midline, and at an angle of approximately 45 degrees to the spine along the natural line of skin cleavage. Alternatively, the skinfold is picked up just below the tip of the right scapula. The natural potential crease that is lifted to form this fold runs at an angle of about 45 degrees downwards from the spine.

Supra iliac skinfold

This is measured midway between the anterior superior iliac spine crest and the lowest point of the ribs, horizontal to the floor, or just above the iliac crest in the midaxillary line. Alternatively, the vertical skinfold can be picked up immediately above the anterior superior iliac spine in the midaxillary line.

In clinical practice, and especially in the bed bound patient, triceps skinfold thickness alone is most commonly used as an indicator of endogenous fat stores and, in conjunction with MUAC (see earlier), is a useful way of evaluating body composition in patients with ascites or peripheral oedema, or who cannot be weighed. Selected reference values of triceps skinfold thickness in a normal adult population (Bishop *et al.*, 1981) are given in Appendix A7.

Problems associated with measurement of skinfold thickness include:

- *Measurement error* – subcutaneous fat is compressible and it is difficult to determine at which pressure the reading should be taken. It takes time and practice to acquire a measurement technique that gives reproducible recordings. Measurements differ substantially when made on the same person by different observers (Ulijaszek & Kerr, 1999).
- *Measurement difficulties* – the correct anatomical site is difficult to establish, and in some cases the site may be inaccessible due to burns, bandages, etc. The jaws of the calipers may not be wide enough to encompass the fat fold in people who are obese.
- *Errors due to individual variation in fat distribution* – although the relationship between subcutaneous fat

and total body fat is relatively constant, there are variations between individuals, or within an individual, at different points in time. In addition it is assumed that the arm is a symmetrical cylinder, which is clearly not entirely true. The relationship of skinfold thickness to total body fat changes with age; as people get older, a greater proportion of body fat is deposited internally rather than subcutaneously. It should also be noted that loss of body weight results in non-proportional changes in muscle and fat stores at different sites (Katch & Hortobagyi, 1990).

- *Population differences in body fat distribution* – people of Afro-Caribbean origin tend to have more visceral and upper body fat deposition than Caucasians (Zillikens & Conway, 1990; Conway *et al.*, 1995). Asian adults have also been shown to have more upper body subcutaneous fat and a higher body fat to BMI ratio than Caucasian adults, a finding more pronounced in women (Wang *et al.*, 1994). Ethnic specific equations should be used, e.g. Ortiz *et al.* (1992) and Schutte *et al.* (1984) developed equations for Afro-Caribbean women and men.
- *Insensitivity* – small changes in body fat (<0.5 kg) cannot be measured by anthropometry (Heymsfield & Matthews, 1994). This therefore limits the value of the technique as a short term monitoring tool. However, serial measurements of skinfold thickness can be a useful way of monitoring nutritional status long term.

Mid arm muscle circumference (MAMC)

An estimate of muscle mass, an indicator of protein stores, can be derived from measurement of MUAC and triceps skinfold thickness (TSF) using the formula:

$$\text{MAMC (cm)} = \text{MUAC (cm)} - [\text{TSF (mm)} \times 0.314]$$

Standards for interpreting the MAMC are given in Appendix A7.

Body composition

Dietitians most frequently use skinfold thicknesses to evaluate body composition; however, increasingly other techniques such as bioelectrical impedance (BIA) are being used. In research settings, other techniques such as air displacement plethysmography (BodPod; used to estimate body density) or dual energy X ray absorptiometry are used. However, it is important that dietitians understand the underlying principles of these techniques as they are used to derive many standards, reference ranges and equations, e.g. under water weighing was used in the derivation of the Durnin & Womersley (1974) equations. A summary of methods used for the determination of body composition is shown in Table 2.2.6. Further details of the techniques can be found in Heymsfield *et al.* (2005).

Bioelectrical impedance analysis

Bioelectrical impedance analysis is an easy, non-invasive bedside measure used to estimate total body water and body composition. Analysers incorporate sophisticated software to interpret the measurements. It is based on the principle that fat does not contain water and that the water content of FFM is a constant. Body fat can be determined by subtracting the estimate of FFM from total body weight. An electrical current flows predominantly through tissues containing water and ions but not through fat, which is an insulator. Body resistance or impedance was originally used as an index of total body water (TBW). However, because of the complex electrical properties of tissues and the lack of uniformity of body shape and dimensions, an easy approach was adopted.

Table 2.2.6 Summary of methods for the determination of body composition (source: M.J. Gibney 2009. Reproduced with permission of Wiley-Blackwell Publishing)

Method	Accuracy	Cost	Radiation	Time	Convenience for subject
IVNAA	+++	–	–	++	++
Densitometry	++	+		++	±
Dilution	++	±	(–)	+	++
TBK	++	–		++	++
DEXA	+++	±	–	++	++
CT scanning	++	–	–	++	++
MRI scanning	++	–		++	+
Anthropometry	+	+++		++	+
Infrared interactance	+	++		++	++
BIA	+	+		+++	+++
TOBEC	+	–		++	++
Urinary metabolites	+	+		–	–

+++ , excellent; ++ , very good; + , good; ± reasonable; – bad.

IVNAA, *in vivo* neutron activation analysis; TBK, total body potassium; DEXA, dual energy X ray absorptiometry; CT, computer assisted tomography; MRI, magnetic resonance imaging; BIA, bioelectrical impedance analysis; TOBEC, total body electrical conductivity.

Whole body impedance was regressed against reference measures of TBW, and this then extended to FFM and fat, producing equations to estimate body composition. The equipment can be hand held (arm to arm current), requires electrodes to be placed on specific parts of the body (total body analysis), or foot to foot current can be measured using stand-on scales that incorporate the software.

Impedance is commonly adjusted for height and an equation is derived that is used to estimate body composition. The equations contain anthropometric data, such as weight and height, and different equations are used. It is difficult to establish the equations used by a particular manufacturer and therefore caution should be expressed.

Bioelectrical impedance analysis is useful for large population studies, due to portability and low cost. It can be useful when making serial measurements of an individual, but it is not recommended by some for single measurements in individual patients (Buchholz *et al.*, 2004) as it may be insensitive to underlying variability between individuals due to factors such as gender, age and disease state. However, other studies have shown it to be a useful tool in clinical practice (Desport *et al.*, 2003; Lammersfeld *et al.*, 2004).

Bioelectrical impedance analysis can be a useful tool, providing that the operator is aware of its limitations, which include:

- Inaccuracies in the measurement or inputting of body weight.
- It is important to standardise conditions, e.g. fasting or non-fasting state, and the consumption of drinks high in electrolytes can perturb the system.
- Many machines require data entry about exercise levels or have a different setting for standard or athletic. Variations in levels entered or setting chosen can greatly affect individual results.
- The assumed hydration of FFM is relatively constant in the healthy population, but significant variation can occur in subjects with abnormalities of water balance.
- Variation in body geometry – the contribution of different segments of the body to whole body impedance is assumed to be relatively standard. Significant individual variation in body shape and fat distribution may distort these conversion factors.

Bioelectrical impedance analysis can be useful for assessing nutritional status in seriously ill patients where anthropometric methods are less practical. Sequential BIA measurements may be used to monitor hydration status in the critically ill. However, the measurements are of limited use in patients with grossly abnormal fluid balance, e.g. severe dehydration or ascites, or at extremes of the BMI ranges (Kyle *et al.*, 2004a; 2004b). Bioelectrical impedance analysis has been used to monitor changes in body composition in patients during refeeding (Pencharz & Azcue, 1996).

Increasingly bioelectrical spectral analysis is being used to study fluid status and fluid shifts.

Table 2.2.7 Dynamometry (grip strength) [data derived from Griffith and Clark (1984) and Klidjian *et al.* (1980)]

	Normal values (kg)	85% of normal (values at or below this level are indicative of protein malnutrition) (kg)
Men		
18–69 years	40.0	34.0
70–79 years	32.5	27.5
80+ years	22.5	19.0
Women		
18–69 years	27.5	23.0
70–79 years	25.0	21.0
80+ years	20.0	17.0

Functional assessment

The functional test most frequently used by dietitians is grip strength dynamometry. An individual is asked to grip the handle of a dynamometer as tightly as possible and the exerted pressure is read off the scale; usually expressed in kilograms. Hand grip strength is a measure of muscle strength. Normal values are available and a reading of 85% or less is indicative of protein malnutrition. Hand grip strength is used in a variety of settings, including sport, and has been used as a measure of recovery following surgery. A recent review by Norman *et al.* (2011) concluded that impaired grip strength was an indicator of poor postoperative recovery, including increased complication rates and length of hospital stay. In the elderly, loss of grip strength was related to loss of independence. Grip strength is increasingly being used in nutritional research. Normal values and 85% values are shown in Table 2.2.7.

When assessing lifestyle, especially for energy balance issues, dietitians should also consider physical activity levels. Many tools are available to assess physical activity, including logs and pedometers. The tools most widely used by dietitians are physical activity questionnaires. Many validated questionnaires are available in the literature for specific groups.

Biochemical and haematological markers

Clinical chemistry can provide objective results for use during the nutritional assessment process and in the monitoring of nutritional status and nutritional support. Biochemical and haematological measurements have limited value in the assessment of nutritional status as many of these parameters are dynamic and change on a daily basis, and are compensated by homeostatic mechanisms, influenced by underlying disease and vary with age. However, clinical chemistry is essential to determine the status of specific nutrients, e.g. vitamin B₁₂ or iron deficiency in anaemia. Laboratory tests are not carried out on every individual but are patient specific as guided by

the clinical situation or research protocol. Appendix A9 gives reference ranges for some parameters; however, these ranges will vary depending on local laboratory standards and protocols. It is essential to use reference ranges that refer to the local setting.

The chapters in Section 7 discuss biochemistry and haematological tests for each clinical condition as appropriate.

Visceral protein status

The majority (30–50%) of body protein is found in skeletal muscle (also called somatic protein). Skeletal muscle wastes in ill people due to disease, malnutrition and inactivity. The remaining protein (visceral protein) is found in organs such as the liver, heart, pancreas and kidneys, and in serum proteins, e.g. albumin, blood cells. Other proteins found in the body are the non-structural proteins, e.g. in cartilage. These are not affected by trauma or stress and play no role in nutritional assessment.

Serum proteins, such as albumin, prealbumin, transferrin, thyroxine-binding prealbumin and retinol binding protein, are sometimes measured as an indicator of visceral protein status and hence clinical outcome. Synthesis of these proteins is compromised in malnutrition. However, it should also be borne in mind that non-nutritional factors such as trauma, sepsis, liver disease, and altered fluid state can have a much greater effect than nutritional influences.

Serum albumin

Serum albumin has a long half life of 14–20 days; therefore, it is not very sensitive to short term changes in protein status. Normal albumin levels in short term starvation and severe anorexia nervosa have been reported (Broom *et al.*, 1986). Albumin levels are affected by age, infection, zinc depletion (causing a decrease) and dehydration (causing an increase), and low levels correlate poorly with nutritional status (Anderson & Wochos, 1982; Friedman & Fadem, 2010). However, an albumin level of <35 g/L does indicate the body's impaired ability to cope with major illness, surgical intervention or sepsis, and can be a useful part of a nutritional assessment (Scott *et al.*, 1998).

Prealbumin

This has been used to monitor nutritional status and can be a sensitive index of early response to nutritional support due to its short half life of <2 days. It is affected by changes in hydration status and acute changes in liver and renal function, but the fluctuations are limited and smaller than is the case with albumin. Levels may be depressed in inflammatory states independently of nutritional status. It is wise to consider prealbumin results with C-reactive protein (CRP) values to distinguish between reduction due to illness or malnutrition (Robinson *et al.*, 2003).

Serum transferrin

Serum transferrin has a shorter half life than albumin (8–10 days), so responds more rapidly to changes in protein status. However, it is also affected by other factors such as metabolic stress, so it is not a sensitive marker of nutritional status. Transferrin is an iron transport protein and is markedly affected by changes in iron status, e.g. anaemia, use of iron supplementation, severe blood loss or blood transfusion. Transferrin tends not to be measured routinely in the acute setting.

Thyroxine binding prealbumin (2–3-day half life) and retinol binding protein (12-hour half life) are much more sensitive to protein depletion, but are of little value in assessing nutritional status as they are extremely sensitive to changes in stress or disease (Casati *et al.*, 1998).

Nitrogen balance

Measurement of nitrogen excretion over a period of time will reflect the nitrogen balance and changes in total body protein mass. It is a useful tool to assess and monitor catabolism. In practice, urinary urea nitrogen is measured using a 24-hour urine collection and the nitrogen output calculated, taking into account renal and other losses, e.g. from skin or faeces.

Vitamin, mineral and trace element status

Serum levels of trace elements are of limited value as indicators of nutritional inadequacy because body stores must be severely depleted before circulating levels are affected. Compensatory homeostatic mechanisms may mask nutrient deficiencies until an advanced stage of depletion. Periodic measurements of blood levels are, however, useful as a way of monitoring long term nutritional support, e.g. in home enteral feeding. Webster-Gandy *et al.* (2011) discuss the measurement of vitamin, mineral and trace element status further.

Calcium status can be monitored by measuring blood levels. However, total plasma calcium is a measure of both ionised and non-ionised calcium (the latter being calcium bound to albumin, citrate or phosphate). When plasma albumin is low, total calcium will also appear low. The biochemistry result for corrected calcium takes into account the reduction in circulating calcium secondary to low circulating protein levels, and is the better value to use. Plasma pH will influence calcium binding. In acidosis, less calcium is albumin bound and more exists in the ionised form. Calcium balance is influenced by hormonal and biochemical factors, including parathyroid hormone (PTH), calcitonin and calcitriol (the active metabolite of vitamin D) (see Chapter 7.9.1).

Hydration status and serum electrolytes

Iatrogenic, dietetic and clinical interventions can all influence these factors (see Chapters 6.6 and 7.17.1). Commonly used markers of hydration status include sodium, potassium and urea. However, results need to be interpreted alongside fluid balance charts and clinical examination for indications of over- or under-hydration. Urinary

sodium levels can be measured to check salt depletion. This is useful in conditions with large fluid loss, e.g. Crohn's disease.

Dehydration

This concentrates the extracellular fluid, reflected in the blood results as hypernatraemia, uraemia and raised serum haemoglobin. If sodium and urea rise concurrently, dehydration should be suspected even in the presence of fluid overload, e.g. oedema. Fluid balance can be monitored by daily measurement of body weight. Dehydration with raised urea may occur without raised sodium levels if patients are losing both sodium and fluid, yet are having a low sodium diet, e.g. diarrhoea while being enterally fed.

Refeeding syndrome

Prior to starting feeding an at-risk patient, blood levels of potassium, calcium and phosphate should be checked. If these are low, magnesium should also be measured and all acted upon according to local protocols. Once feeding has commenced, low blood levels of phosphate, potassium and magnesium should alert to refeeding syndrome (see Chapter 6.4).

Other parameters

Other parameters that may be used include:

- Renal function tests, e.g. creatinine, urea.
- Inflammation markers, e.g. CRP.
- Infection markers, e.g. white blood cells.

Clinical assessment

The clinical assessment should include medical history, test results and current medicines, including prescribed and over the counter medicines. It is important to consider drug–nutrient interactions (see Chapter 5.3). These factors can be ascertained from the medical or nursing notes or the patient, family and/or carers.

It is not possible to overestimate the importance of physical observations. Examples of physical signs of nutritional problems are shown in Table 2.2.8 (Shaw & Lawson, 2007). Other examples include:

- Physical appearance – does the person look thin, of acceptable weight or overweight? Emaciation, pale complexion and hair loss suggest long term undernutrition. Loose clothing, rings and ill fitting dentures indicate weight loss. Sunken eyes, dry mouth and fragile skin are indicative of dehydration. Is there evidence of fluid retention, e.g. swollen ankles? Badly damaged nails and surrounding tissue may be an indication of self induced vomiting in bulimia nervosa.
- Breathlessness may be a symptom of anaemia or due to a clinical condition, and can make it more difficult to eat.
- Poor wound healing may reflect impaired immune function as a consequence of undernutrition and/or vitamin deficiencies, and/or lack of mobility.
- Oedema may reflect underlying disease, or heart failure secondary to prolonged protein or thiamine deficiency. The presence of oedema may mask loss of lean tissue.

Table 2.2.8 Examples of physical signs of nutritional problems (source: Shaw and Lawson 2007, table 1.6, p. 9. Reproduced with permission of Wiley-Blackwell Publishing)

Assessment	Clinical sign	Possible nutrient(s)
Hair	Thin, sparse Colour change – flag sign Easily plucked	Protein and energy, zinc, copper
Skin	Dry, flaky Rough ‘sandpaper’ texture Petechiae, bruising	Essential fatty acids, B vitamins Vitamin A Vitamin C
Eyes	Pale conjunctiva Xerosis, keratomalacia	Iron Vitamin A
Lips	Angular stomatitis Cheilosis	B vitamins
Tongue	Colour changes	B vitamins
Teeth	Mottling of enamel	Fluorosis (excess fluoride)
Gums	Spongy, bleed easily	Vitamin C
Face	Thyroid enlargement	Iodine
Nails	Spoon shape, koilonychias	Iron, zinc, copper
Subcutaneous tissue	Oedema, over hydration Depleted subcutaneous fat	Protein, sodium Energy
Muscles	Wasting	Protein, energy, zinc
Bones	Craniotabes Parietal and frontal bossing Epiphyseal enlargement Beading of ribs	Vitamin D

- Adverse effects of illness or drug treatment, such as nausea, vomiting, diarrhoea.
- Physical problems affecting eating, e.g. poor dentition, dry mouth, sore or painful mouth, orofacial surgery.
- Repeated medical investigations, treatments and medications requiring fasting or dietary change.

Some vitamin deficiencies have clear visible signs, such as xerophthalmia (failure to produce tears), which is indicative of vitamin A deficiency, and the distinctive appearance of Casal collar in pellagra (niacin deficiency).

Dietary assessment

Dietary assessment is discussed in detail in Chapter 2.3. Establishing the extent to which nutritional needs are being met is core to the nutritional assessment. Factors that need to be considered include:

- Current food and fluid intake.
- Duration and severity of any changes in appetite and oral intake.
- Presence of factors affecting food and fluid intake.

The findings need to be interpreted in the context of the individual's nutritional requirements (see Chapter 2.1).

In clinical settings it is also important to consider recent changes in intake, including:

- Increase or decrease in appetite.
- Alterations in meal pattern or timings.
- Changes in food choice or food consistency.

The greater the extent and duration of these changes, the more marked the effect on nutritional status will be.

Environmental, behavioural and social assessment

These factors can have a significant impact on nutritional status. Factors that may affect food and fluid intake include:

- *Psychological status:*
 - Depression or apathy, bereavement.

Table 2.2.9 Monitoring nutritional status in clinical settings

Assessment parameter	Rationale	Method	Frequency
Weight	Assess change in body mass – intentional or unintentional Calculate percentage change Calculate BMI Determine whether nutritional goals are achieved	Scales Surrogate measures e.g. self reported usual weight from patient, family, carer	At initial assessment then as clinically indicated. Twice a week initially reducing to monthly Daily to assess change in fluid balance
Weight history	To assess recent weight loss or gain and over longer periods Ascertain normal weight for an individual	Medical notes Dietetic records Patient or carer recall	At initial assessment
Height	To calculate BMI	Stadiometer Self reported height Tape measure Surrogate measure, e.g. demi span	Once only unless shrinkage has occurred, e.g. osteoporosis
Other anthropometric measurements	Assessing fat or muscle status Monitor nutrition support	MUAC TSF Hand grip dynamometry Waist circumference	Monthly Monthly Weekly As necessary
Drug and medical history	Assess risk to nutritional intake, metabolism and requirements	Relevant notes Pharmacy chart	Every 2–3 days acutely, weekly long term
Clinical biochemistry	To assess hydration and protein status Monitor nutrition support	Medical notes Pathology systems	Daily initially then twice weekly Longer intervals, e.g. monthly according to individual circumstances
Nutritional intake	To establish usual intake To ensure oral and/or artificial intake are meeting requirements	Interview Food diary Food intake chart Fluid balance chart Discussion with patient, carer, family, ward staff	At assessment, then at considered intervals thereafter Dependent on patient's condition
Social history	Establish factors affecting nutritional intake	Dietetic record cards Consultation with patient, family, carer	Initial assessment and thereafter as required

BMI, body mass index; MUAC, mid upper arm circumference; TSF, triceps skinfold thickness.

- Confusion and or memory loss, e.g. in people with dementia.
- *Ability to buy, prepare and cook food* should also be considered. Especially when there is a sudden change in social condition, e.g. bereavement, particularly if it was the partner who organised the meals, or moving from a catered institution into the community. Mobility will affect the ability to shop, prepare and cook food. Weakness and impaired movement may result from loss of muscle mass.
- *Social factors*:
 - Living conditions and recent changes, e.g. an elderly person moving from their own home to sheltered accommodation or a care home.
 - Cultural and religious beliefs.
 - Low income and recent changes in income, e.g. redundancy, recent immigration.
 - Alcoholism.
 - Education, e.g. the inability to read or severe dyslexia will influence the ability to read nutrition labelling and understand health messages.

Nutritional requirements

In order to determine whether an individual's nutritional intake is meeting their needs it is important to consider their requirements. Nutritional requirements are available for population groups (dietary reference values) or can be estimated for an individual, taking into account age, gender, level of physical activity and clinical condition (see Chapters 2.1 and 6.1).

Monitoring nutritional status

In clinical settings nutritional status must be assessed on a regular basis to ensure that treatment, including nutritional support, is appropriate and effective. Monitoring can be carried out by the patient, dietitian or other health professional according to the stability and location of the patient. Suitable methods and suggested frequency of assessment are summarised in Table 2.2.9.

The nutritional status of groups and populations may be monitored for public health surveillance purposes (see Chapter 4.2) or epidemiological studies, e.g. the European Perspective Investigation into Cancer and nutrition project (EPIC). The parameters measured will be determined by set protocols.

2.3

Dietary assessment

Ailsa Welch

Key points

- A wide variety of methods are available for measuring dietary intake.
- Methods for estimating dietary intake in individuals can be retrospective measures, e.g. 24-hour recalls, diet histories or food frequency questionnaires, or current measures, e.g. weighed or estimated food records.
- The differences between methods and the impact of measurement error need to be considered when intending to use dietary methods.
- It is essential to understand the advantages and limitations of dietary assessment methods both for use in clinical practice and when reading and interpreting the scientific literature.

Dietary assessment methods are used for a variety of purposes from individual assessments in clinical situations, through to use in epidemiology. In epidemiology they are used to estimate intakes of populations and establish associations between nutrition and disease. They are also used as a basis for developing dietary guidelines and health policy, for monitoring change in intervention studies and for monitoring the effectiveness of public health interventions. Dietary assessments are traditionally used to estimate intakes of foods and nutrients, but more recent interest has arisen in estimating intake of bioactive phytochemicals, e.g. flavonoids, additives and contaminants. Ideally, assessment methods should have a low burden on respondents and investigators, and be rapid and cheap, but also result in accurate, precise data with minimal measurement error.

There are a number of dietary assessment methods for measuring food consumption at the national, household and individual level. This chapter focuses on assessment methods suitable for individual intakes. At the national level, food balance sheets can be used to assess dietary intakes. Household level methods include the food account method, inventory method, household record method and list recall methods, and further information on these methods can be found in Gibson (2005).

Table 2.3.1 describes the advantages and limitations of the main types of dietary assessment methods used for individuals. Although many methods are available for estimating dietary intake in individuals, they can mainly be divided into two types; retrospective measures of intake, such as 24-hour recalls (24 HR), diet history or food frequency questionnaires (FFQs), or current measures of

intake, such as weighed or estimated food records. Qualitative information is available from all methods, but quantitative estimates for nutrient consumption are possible only if data for weighed or estimated portion weights are available.

Weighed records, estimated food records, 24 HR and dietary histories are the most intensive methods. The quantity of food consumed may be weighed directly or estimated using household measures such as cups and spoons, photographs, standard units or average portions (Food Standards Agency, 2001; Nelson *et al.*, 1997). Data for portion sizes should be derived from weighed intakes, government surveys and research groups in populations similar to the one to be studied. Food models/replicas (three dimensional models representing foods) can also be used, particularly in clinical practice.

More recently, methods are being developed that utilise photographs of portion size recorded with mobile phone or digital camera technology (Penn *et al.*, 2010). For all methods the amount consumed can be measured or described either including or excluding wastage material usually discarded during food preparation, e.g., outer leaves and peel from vegetables or bones from cuts of meat. A number of newer methods for recording food intake are being developed involving online methods.

Number of days of recording

The number of days of report required for adequate measures of nutrients using 24 HRs, weighed or estimated records varies depending on the day to day variability of nutrient consumption (Nelson *et al.*, 1989;

Table 2.3.1 Characteristics of dietary assessment methods

Method	Advantages	Limitations
Retrospective methods		
24-hour recall (24 HR) (single or multiple days)	Not reliant on long term memory; interview length 20–45 minutes	Single 24 HRs can be used for group assessments but not for estimating intake of individuals
Diet history	Respondent literacy not required	Report of past intake is influenced by current diet; trained interviewers required
Food frequency questionnaire (FFQ) (if portion estimates included, termed semiquantitative FFQ)	Useful for large sample sizes; relatively straightforward to complete	Need to be developed for specific population group to ensure important food items are covered and requires updating to accommodate changes to supply of foods; responses governed by cognitive, numeric, and literacy abilities of respondents, also by length and complexity of the food list Not easy to develop for clinical practice since specific computer programs need to be developed.
Short frequency questionnaires	Targeted to specific food types, administration simpler and easier than long questionnaires	Need to be developed for specific population group to ensure questions are relevant
Current methods		
Weighed food record (weighed inventory technique)	No requirement for memory retrieval as it records current intake; food intake weighed so estimates of quantity consumed not required	Literate, cooperative respondents required as burden is high; possible that respondents change usual eating patterns to simplify the record; high data entry costs
Food record with estimated weights	No requirement for memory retrieval as it records current intake	Literate, cooperative respondents required as burden is high; possible that respondents change usual eating patterns to simplify the record
Duplicate analysis	Greater accuracy	Very labour intensive; requires laboratory to do food composition analysis
Records using electronic equipment, e.g. mobile phones, digital cameras	Visual records of foods Avoids need for paper records Data can be sent to investigators electronically	Currently involves labour intensive programs to convert to usable data, i.e. quantities and types of foods, although systems are in development to deal with this Limited use in older people who experience difficulties with using newer technology

Mennen *et al.*, 2002; Lanigan *et al.*, 2004). The number of days is partly dependent on the variation in nutrient concentration in foodstuffs. The concentration of macronutrients such as protein and carbohydrate in foods varies less than that of micronutrients such as vitamin C or iron. The number of days required to classify adult individuals into the correct third of the percentage distribution for usual intake for 80% of individuals has been calculated (Nelson *et al.*, 1989; Mennen *et al.*, 2002). Up to 7 days of recall are required for energy, protein, sugars and calcium. Nutrients with greater variability, including alcohol, vitamin C, riboflavin, and iron, require between 4 and 14 days of records. Fewer days of data collection are required to capture habitual diet in children (Lanigan *et al.*, 2004). More recent estimates of the number of days to estimate energy intake (using the doubly labelled water technique) suggest that 3 days of record are optimal of which 1 day should be a weekend day (Ma *et al.*, 2009).

Dietary assessment methods

24-hour recalls

Twenty-four-hour recalls determine intake during the preceding 24 hours and can be recorded on paper or using

interactive computerised software (Slimani *et al.*, 1999). Day to day variability in nutrient intake is large and a single day will not categorise individuals correctly within a distribution of intake. Particular issues are the capture of episodic (infrequently eaten) foods such as fish and liver; therefore, single 24 HRs are better used for group assessments than estimates for individuals. However, multiple 24 HRs can be used to overcome this problem. Newer methods of online recording of 24 HRs are under development. The 24 HR method is useful for assessment in clinical situations, but the difficulty with assessment and accurately reporting intake due to the variation in nutrient concentration of foodstuffs needs consideration. This will affect the number of days required to obtain adequate measures of nutrient intakes.

Diet history

The diet history consists either of an interview administered 24 HR or establishing usual eating pattern over a 1-week period, followed by a frequency questionnaire to provide additional information. The dietary history provides a representative pattern of usual intake and is interview administered only. Diet histories are traditionally

used in clinical practice and may take up to 1.5 hours to complete.

Food frequency questionnaires

Food frequency questionnaires (FFQs) consist of a list of specific foods or food types associated with frequency of consumption to record average consumption over the previous month or year. They are termed semiquantitative if portions are included. Food frequency questionnaires are thought to provide estimates of habitual intake and are widely used in nutritional epidemiology (Welch *et al.*, 2005; Cade *et al.* 2004). They need to be specific to a population group to ensure coverage of important foods and the population must be literate and numerate, as some mathematical ability is necessary to calculate relative frequencies (Smith, 1993). Factors influencing response to FFQs are the length and complexity of the food list and current diet (Smith, 1993). For clinical use it is necessary to develop specific software and databases to obtain nutrients and therefore record methods are likely to be preferable (Welch *et al.*, 2005).

Short frequency questionnaires

Short frequency questionnaires have been developed to estimate intakes of specific foods or nutrients and can be useful in clinical practice to determine where eating habits require change; examples are the Dietary Instrument for Nutrition Education (DINE) and the 5 A DAY Community Evaluation Tool (FACET) questionnaires (Roe *et al.*, 1994; Ashfield-Watt *et al.*, 2007; Welch *et al.*, 2006).

Weighed food record inventory and estimated food record

For weighed food records (WRs) all food and drink consumed over a period is weighed and recorded on forms or in booklets, with details of food type and method of preparation, to obtain consumption over a period of days. Portable scales need to be supplied. Leftover food should be weighed and deducted. The recommended time period for records is 4–7 days or more, although the number of days depends on the nutrient of interest, study population and objectives of the study. As some populations have different eating habits at weekends, weekend days should be included proportionately. For estimated food records all foods consumed over a period of days are recorded with details of food type, method of preparation and estimated portion sizes. If recorded over 7 days, this is often called a 7-day diary.

Both these methods have a high respondent burden and need cooperative, literate respondents. Respondents require training in the level of detail needed to describe foods. It is also possible that respondents may change usual eating patterns to simplify the process of the record and may also find this method tedious. It is also beneficial to include a review of weighed records during the period of recording either after the first day or at the end.

Duplicate sample technique

Duplicate samples of all foods consumed are made and the nutrient content analysed chemically. This method is used for metabolic studies and, though providing greater accuracy than other methods, its use is only feasible for certain purposes. Studies are conducted in hospital metabolic units or research centres; they are expensive, time consuming and require considerable technical support.

Use of methods in clinical practice versus research

Dietary methodology for clinical practice requires rapid assessments of nutritional intake in order to prescribe dietary change or to improve nutritional status. Traditionally, 24 HRs of usual intake or diet histories have been used for this purpose. Food frequency questionnaires and weighed or estimated food records are not generally used due to the more intensive burden on respondents and on the resources required for coding and processing the data. For research purposes a number of methods may be used from FFQs to multiple 24 HRs. When designing a study, it is advisable to obtain expert advice to decide on the optimum method.

Recall of remote diet – current intake biases recall of past diet

When designing studies or reading the literature, dietitians need to be aware that recall of diet in the remote past is heavily influenced by current dietary habit. Studies have found that the correlations between recalled past diet and current diet are higher than the correlations between actual past diet and recall of past diet (Willett, 1998). The onset of diseases such as cancer may affect appetite and dietary assessment, as recall of remote diet is strongly related to current diet. Therefore, studies where diet was measured prior to the onset of disease are less likely to suffer from bias than, for instance, case-control studies in which the diet of cases with disease is compared with controls.

Use of data and conversion of reported intake to nutrients and food types

Qualitative data

Dietary method data can be used qualitatively, e.g. during the process of reviewing nutritional intake for the purpose of dietary treatment, as in clinical practice. However, the majority of uses of dietary methods are targeted towards quantitative analyses.

Quantitative data

Food composition databases, data entry and nutrient calculation systems

The data collected by dietary methods are converted into food and nutrient consumption by calculating the amount

of food eaten and linking this to a database with values for the nutrient composition of foods. The governments of many countries provide the databases of nutrient composition of foods. The UK National Nutrient Database consists of *McCance and Widdowson's The Composition of Foods* (2002) and its supplements. It is essential to read the information distributed with the printed or electronic versions of databases to determine the uses and limitations of the data (see Chapter 2.4).

Nutrient databases vary in the coverage and comprehensiveness of the foods and nutrients, and in the conversion factors used for certain nutrients. Care should be taken when comparing values from different sets of food tables because the definition and expression of nutrients may not always be the same. Different conversion factors may have been used to prepare the values, e.g. to calculate protein from nitrogen or to convert the major nutrients to energy. The same nutrient may be quoted in different ways, e.g. carbohydrate may be expressed as monosaccharide equivalents, actual weights or by difference. In the UK food tables, carbohydrate is expressed as monosaccharide equivalents but for food labelling purposes carbohydrate should be provided as actual weight.

The nutrient values provided in food tables are generally averages of representative samples of foods or selected values from literature surveys. However, like any other biological material, the composition of food can vary considerably and so the values in food tables are only representative of the true biological range of values and should not be considered as having the accuracy of atomic weights. Values in nutrient composition databases are expressed as either per 100g of food or per common household measure. Most up to date information in the UK, European, US and international nutrient databases can be found at the Food Standards Agency (FSA) (www.food.gov.uk), European Food Information Resource Network (EuroFIR) (www.eurofir.org), USA Department of Agriculture <http://ndb.nal.usda.gov> and the Food and Agriculture Organization of the United Nations (www.fao.org/infoods).

Several steps are involved in calculating nutrient intake (also known as coding or processing). The first is to choose the item in the database that corresponds most closely with the food consumed. If the food consumed is not in the database, a suitable alternative can be chosen by considering food type, general characteristics and likely nutrient profile. Once the food has been chosen, the nutrient composition of the food quoted in the database is multiplied by the amount of food eaten. To calculate daily intake for an individual, the contribution of each food is calculated and all the foods for a day summated. If more than one day's data have been collected, it is usual to calculate the average for the number of days recorded. Although it is possible to compute intake by hand, using a calculator and a printed copy of a nutrient database, this is very labour intensive and in practice, has been superseded by computerisation for most purposes. A number of computerised data entry systems and nutrient calculation programs exist to calculate nutrient intakes (Welch *et al.*, 2001). Prior to purchasing a new

entry system, it is important to know on which version or food composition database it is based.

Dietitians should be aware that the UK food tables are not adequate for estimating salt intake because the nutrient intakes for recipe or composite dishes do not include salt and therefore calculations are systematic underestimates.

Estimated food quantities

To obtain quantitative information for nutrients or food groups, actual or estimated food weights are used. For methods using estimated food weights, values also need to be found for the foods described, such as standard units, average portions or household measures. Sources of data are national publications, surveys of weighed dietary assessments, and food manufacturers. Data may also be included in nutrient calculation programs.

Additional sources of nutrients

Proprietary medicines may contain sources of nutrients, and vitamin and mineral supplements can contain considerable amounts of nutrients. Therefore, they should be taken into account when assessing total nutrient intakes (Lentjes *et al.*, 2010). Current estimates of prevalence of supplement intakes are around 40% in the UK population aged over 40 years (Lentjes *et al.*, 2010).

Measurement error

Measurement error can be defined as the difference between the measured exposure (or measure of dietary assessment) and the true exposure; it is now known that there is measurement error associated with using dietary methods. Measurement error reduces the likelihood that true values have been measured with accuracy and in nutritional epidemiology, associations between dietary intake and disease outcomes will be affected (Schatzkin & Kipnis, 2004). As the proportion of measurement error increases, the scale of the relationship relating diet to disease status will tend towards no relationship. Overall the effect of measurement error would be to misclassify an individual within a range of intake.

The existence of measurement error also impacts on the interpretation of the scientific literature. For instance, it is known that FFQs tend to produce systematically greater estimates of fruit and vegetable intake and of vitamin C intake than record methods such as 7-day diaries (Dehghan *et al.*, 2007). As a result, fruit and vegetable intake for individuals and populations will be overestimated using an FFQ; more individuals measured with this method will appear to have sufficient intakes than if a record method had been used.

The technique of validation can be used to estimate measurement error. Although full detail of the impact, scale and detection of measurement error is beyond the scope of this chapter, an awareness of the differences between dietary methods and the potential pitfalls when using them is helpful to clinicians in interpreting the scientific literature.

Methods of detecting measurement error

There are four major methods of detecting measurement error:

1. *Comparison with other diet methods*, but this is not advisable since individuals report in the same way with all methods and the errors are correlated (Black & Cole, 2001; Kipnis *et al.*, 2003).
2. *Predictor reference methods*, such as the Goldberg equations, or percentile cut points to detect energy misreporting and potentially statistical model the effects of misreporting (Stubbs, 2002).
3. *Biomarkers* (biological markers) in blood or urine, quantitative recovery biomarkers (quantitative estimates of intake over a specific time period) and concentration biomarkers (measure relative concentrations over a distribution) are thought to be independent of errors when measuring intake (Potischman & Freudenheim, 2003). Examples of quantitative markers are urine nitrogen excretion over 24 hours (to estimate protein intake) and energy expenditure measured using the doubly labelled water technique (DLW). Examples of concentration markers are plasma concentrations of n-3 polyunsaturated fatty acids and fish consumption (Welch *et al.*, 2006).
4. *Comparison with disease risk biomarkers*, e.g. saturated fat and low density lipoprotein (LDL) cholesterol (Bingham *et al.*, 2008).

Examples of validation studies are those performed within EPIC Europe and the Observing Protein and Energy Nutrition Study (OPEN) in the US (Kipnis *et al.*, 2003; Slimani *et al.*, 2003).

Although biomarkers are useful in the detection of measurement error, it should be noted that a number of factors influence their interaction with nutrition, e.g. differences in gender or genetics and homeostatic or behavioural influences. Not all associations are linear, e.g. vitamin C concentrations in the blood plateau since additional concentrations are excreted, and smoking impacts on circulating concentrations of vitamin C.

Sources of measurement error in dietary assessment

Sources of measurement error when using dietary assessment are many. They may occur both during data collection and processing. Systematic bias, interviewer bias, recall bias and social desirability bias have been identified, but there are likely to be other sources of error. Bias can be defined as the modification of a method of measurement by a factor that influences the measurement in one or more directions. Measurement error associated with dietary methods may consist of one or more types of error.

Systematic bias is a systematic mismeasurement of data and can occur, for instance, if an interviewer consistently fails to use questions to probe for consumption of snacks and additional foods. If systematic bias is identified, it can be overcome by interviewer training and monitoring interviewers.

The behaviour of interviewers can influence the response of interviewees or clients and introduce interviewer bias. It is important to develop rapport between interviewers and respondents and for questions to be asked in an open ended, neutral manner without value judgements.

Social desirability bias can influence dietary assessment methods as respondents strive to report what they think is required, not what was actually consumed, e.g. reporting less alcohol consumption or greater consumption of foods with perceived health benefits, such as fish, fruit or vegetables. This is likely to be the cause of misreporting, under reporting or low energy reporting, which occurs in certain respondents and can affect clinical practice.

Conclusion

A wide variety of methods for measuring dietary intake exist and it is essential to understand their advantages and limitations, both for use in clinical practice and when reading and interpreting the scientific literature.

2.4

Food composition tables and databases

Edwige Landais and Michelle Holdsworth

Key points

- Food tables are a vital resource, but to avoid errors from their use, it is essential to understand their strengths and limitations.
- The composition of a particular food can vary as a result of differences in plant and animal genetics, strain and breed variety, farming practices, soil quality, climate, storage conditions and the way in which food has been processed, manufactured or cooked.
- Food tables do not take account of bioavailability (the extent to which a nutrient present in a food will be absorbed).
- In the UK, food composition data are recorded in a National Nutrient Databank maintained by the Food Standards Agency and published in book form as *McCance and Widdowson's The Composition of Foods* or electronically.

Food composition data provide information on the nutritional composition of foods and are available in print (referred to as food composition tables) and computerised formats (food composition databases). Food composition tables are generally used to calculate the food intake of individuals and groups from information gathered during dietary assessment (see Chapter 2.3). They are used in different settings, including clinical practice, research, health promotion and the food and agriculture industry, as shown in Table 2.4.1.

Data in food composition databases come from different sources:

- Original analytical values obtained from chemical analysis of food samples.
- Analytical values from scientific literature or food labels for branded foods.
- Imputed values derived from analytical values of a similar food.
- Calculated values derived from recipes using yield and nutrient retention factors.
- Borrowed values taken from other tables or databases.
- Presumed values which are presumed as being null or at a certain level.

National food tables

UK food tables

Tables of food composition have been published in the UK since the 1920s, stimulated by concerns over food shortages in the First World War (Church, 2006). They were continued by the pioneering work of McCance and

Widdowson, initially conducted under the auspices of the Medical Research Council and subsequently the Ministry of Agriculture, Fisheries and Food (MAFF). In 1987 MAFF, in conjunction with the Royal Society of Chemistry, began the production of a computerised UK National Nutrient Databank (UKNND) from which the fifth edition of *McCance and Widdowson's The Composition of Foods* (Holland *et al.*, 1991a) and a number of detailed supplements were produced. In 2000, responsibility for the maintenance of the UKNND was transferred to the Food Standards Agency (FSA), which published the most recent sixth summary paper edition in 2002.

The printed form of the summary edition of *McCance and Widdowson's The Composition of Foods* (FSA, 2002) is widely used; however, it should be appreciated that, whilst convenient, the single volume edition does not contain the complete set of data available, but only a subset of foods and nutrients. The most comprehensive information is contained within the separately published supplements, as shown in Table 2.4.2, and a complete collection of these should be regarded as the definitive UK food tables. Most of these are now in electronic form and have been integrated into the UKNND (www.food.gov.uk), and are regularly updated as part of a rolling programme of food analysis and analytical reports.

A range of nutrient analysis software programs using the UKNND is available for dietitians and nutritionists (see Chapter 2.3). Some less sophisticated nutrient analysis software programs, particularly those designed for the general public or schools which comprise summarised data derived from the main food tables, need to be used with caution. Data for groups of foods may either be averaged or confined to a few selected options, e.g. data for

meat may be confined to a few possible choices from the hundreds cited in the main food tables. Dietary estimates based on such generalised figures can be misleading.

Food tables used in other countries

In order to be useful and accurate, food tables need to reflect the foods consumed in the culture in which they are used. Dietary investigations carried out in other parts of the world should use the appropriate local data. Many other countries worldwide produce national food com-

position tables. Several European Union countries publish food composition tables, and the first European food composition table was published in Germany in the 1800s (Church, 2006). The USA also began producing food composition tables in the 1800s and has continued to produce widely accessible electronic food tables (www.ars.usda.gov). In the late 1970s, the Center for Food Safety and Applied Nutrition (CFSAN) of the United States Food and Drug Administration (FDA) developed a standardised system for describing food. This system, called LanguaL (Langua aLimentaria) (www.langual.org), facilitates links to many different food databases and enables data exchange of over 40 000 food products so far.

In 1984, the United Nations University's Food and Nutrition Programme set up the International Network of Food Data Systems (INFOODS), coordinated by the Food and Agriculture Organization of the United Nations (FAO), to improve the quality of food data and also worldwide access. The website of INFOODS (www.fao.org/infoods) provides information about all existing food composition tables, some of which are directly accessible through the website. More recently, a European initiative, called the European Food Information Resource project (EuroFIR), was established. The main objective of this was to deliver a comprehensive and validated European databank for nutrients and bioactive compounds for 27 European Countries (www.eurofir.net). In the USA, the Department of Agriculture maintains the nutrient database (www.ars.usda.gov).

Food tables are an extremely valuable resource, but it is important to understand their limitations and some of the associated problems.

Derivation of food table data

Before using food table data, it is essential to read the introduction explaining how the values in the tables were derived. This is particularly important if food composition data from more than one source, e.g. food labelling information, or food tables from other countries are used alongside standard food table data, because the definition

and expression of the nutrients may not be the same. The following factors should be considered when using food composition tables or databases.

Analytical methodology

Different analytical techniques can be used to obtain estimates of the same nutrient. Historically, food analysis consisted of determining the percentage of water, fat, nitrogen and ash (minerals) in a food. Protein content was derived by multiplying the percentage of nitrogen by 6.25 as protein is on average 16% nitrogen. While the latter is still widely used in food composition tables and databases, it is now recognised that the amount of nitrogen depends on the protein source (FAO, 2003). Carbohydrate content was estimated by difference; the percentage of other nutrients was calculated and carbohydrate was assumed to be the remaining percentage needed to give 100%. This derived figure for carbohydrate included the contribution from dietary fibre or other dietary components.

More recently, chemical analyses methods have become more sophisticated, so different types of sugars (glucose, fructose, galactose, sucrose, maltose, lactose and oligosaccharides) and complex carbohydrates (dextrins, starch and glycogen), amino acids and fatty acids, as well as individual minerals and vitamins can now be determined. Information on manufactured foods not included in the food tables can increasingly be obtained from food labels or food manufacturers, but much commercial food analysis is still carried out using simpler analytical techniques. The use of different methodologies will result in different estimates of nutrient content.

- *Carbohydrate* may be determined as monosaccharide equivalents, actual weights or by difference as described earlier. Monosaccharide equivalents, the usual form of expression in UK food tables, result in slightly higher estimates of carbohydrate content (due to the fact that disaccharides and polysaccharides gain water when hydrolysed) than when expressed as actual weight, as on most food labels. Direct determination of carbohydrates is used in the UKNND.
- *Dietary fibre* can be analysed using different methods that give differing estimates of fibre content. The McCance and Widdowson tables and the UKNND give

figures for non-starch polysaccharides (NSP) based on the Englyst method (Englyst and Cummings, 1988). However, the food industry measures fibre by the AOAC enzymatic gravimetric method, which is now recommended for food labelling purposes. The AOAC method usually gives much higher estimates of fibre content, particularly for cereal foods because it includes lignin (or substances measuring as lignin) and resistant starch. The sixth edition of *McCance and Widdowson* (FSA, 2002) includes a comparative table of the fibre content of a limited number of foods measured by both the Englyst and AOAC methods.

- Many *vitamins* are composites of substances with variable degrees of activity and either some or all of these may be cited depending on the type of analysis performed. For example, vitamin A may be expressed as retinol and beta-carotene separately, or as retinol equivalents. Different units may also be used, e.g. micrograms or International Units (IU).

Energy conversion factors used to calculate data

The energy content of food may be measured by bomb calorimetry, but not all food energy is metabolisable; therefore, conversion factors which account for this are used to calculate the energy yield. Atwater and colleagues derived these factors from meticulous human studies over a 100 years ago (Atwater & Benedict, 1902). It is important to remember that slightly different Atwater factor systems may be used and the energy content of foods may vary between McCance and Widdowson tables or the UKNND and those required for food labelling declarations (Table 2.4.3).

The two components of vitamin A are given separately as retinol (RET) and carotene (CAREQU). Retinol is expressed as the weight of all *trans* retinol equivalent, i.e. the sum of all *trans* retinol plus contributions from the other forms after correction to account for their relative activities.

Sampling procedure

Food composition data are derived from a sample of foods and, therefore, their accuracy depends on how

Table 2.4.3 Energy conversion factors (source: Webster-Gandy 2011, table 1.2, p. 11. Reproduced with permission of Oxford University Press)

Nutrient	kcal/g	kJ/g	Comments
Protein	4	17	For food labelling purposes, protein content is derived by multiplying the nitrogen content in all foods by 6.25 UK food tables use specific conversion factors for different types of foods
Fat	9	37	The original Atwater factor was 8.9kcal, but the lower kJ figure is preferable
Carbohydrate	3.75	16	If carbohydrate is expressed directly or by difference, 4kcal/g is used, which is the figure used on food labels Values for available carbohydrate are expressed as monosaccharides
Sugar alcohols	2.4	10	Food labeling uses mean value
Ethyl alcohol	7	29	
Glycerol	4.31	18	Complete metabolism assumed

representative the sample is; the UK food tables are designed to be as representative as possible. Significant numbers of food samples are purchased from different retail outlets and pooled before analysis. Market share information is used to assess which brands of a particular type of food are included, and recipes are chosen to be as similar as possible to those used in the normal domestic setting. Other sources of food composition data may not be based on such high standards. Details of the samples used in analysis are given for each food item in the tables and database.

Currency of data

Food composition tables need to be regularly updated for the following reasons:

- *New manufactured foods* are constantly developed and the composition of existing ones may change as a result of product reformulation, altered manufacturing processes, fortification and use of nutrients such as beta-carotene or vitamin C as colourings or antioxidants.
- *Changes in farming practices* can alter the composition of both plant and animal products over a period of time. For example, the fat content and fatty acid profile of meat has changed considerably in the last 20 years as a result of selective breeding programmes to produce leaner animals, changes in feeding techniques and modern butchery techniques which remove a greater proportion of carcass fat. Development of new varieties of agricultural crops or changes in the level of usage of fertilisers can also affect nutritional composition.
- *Domestic preparation and cooking practices* may change, e.g. vegetables may be steamed rather than boiled and bread may be made from a mix in a domestic bread making machine.
- *Previously unfamiliar foods* are now available in shops.
- *More accurate methods of analysis* are developed.

Use of old analytical data will considerably increase the likelihood of errors, which will introduce significant errors in even the most detailed dietary assessment. However, in some circumstances, e.g. the analysis of dietary information obtained many years ago, it may be necessary to use composition data that were contemporary at the time in order to obtain realistic figures of nutrient intake. It is particularly important that those engaged in dietary survey work are aware of the implications of using data from older editions and supplements of *The Composition of Foods* (Black & Paul, 1999). There are also a number of differences in code numbers between different editions of food tables, which can have implications in computerised analysis; a summary of these can be found in the introduction to the sixth summary edition (FSA, 2002). Data for food tables are updated on a rolling basis; it is also important to know which data have been incorporated into any nutrient analysis programmes purchased.

Limitations of food composition data

Food tables and databases will always have limitations for several reasons, including variability between foods consumed and food table values and bioavailability.

Variability between foods consumed and food table values

Despite careful sampling the resultant values will be representative of a particular food, but there will still be some variation from foods actually consumed. A number of factors, such as plant or animal species, seasonal changes in feeding practices or growing conditions, or the effects of storage on water content, affect the composition of natural foods such as meat, milk and eggs or plant crops. Further variability is likely to occur as a result of differences in food manufacture, catering or domestic cooking practices. For example, a lasagne may be a manufactured ready meal, an item prepared by a restaurant or made at home. All will differ in composition and probably none will exactly match the values given in food tables. In western diets, comparisons of the nutrient content of diets calculated from food tables and analysed by direct analysis have been shown to range between 2% and 20% (Bingham, 1987).

This variability is most likely to occur with micronutrients, i.e. vitamin and minerals content due to:

- The soil in which a plant was grown, e.g. this can markedly affect selenium content.
- Agricultural practices, e.g. antagonism between soil fertilisation using nitrogen and vitamin C content.
- Stage of maturity, e.g. in plant foods vitamin C content decreases during ripening, whereas carotenoid content increases.
- Duration and conditions of storage before being eaten, e.g. water soluble vitamin content will diminish with time.
- The way the food is cooked, e.g. the potassium content of boiled vegetables will depend on the amount of water used and length of the cooking time.
- Use of food fortification in some but not all brands of a particular food, e.g. folate or iron added to breakfast cereals.
- Use of food additives that are also nutrients, e.g. beta-carotene (colour) or vitamin C (antioxidant; may be unexpectedly present in foods such as meat products).

It should be noted that vitamin C and folic acid naturally vary widely in foods and that both heat and light affect them. It should also be noted that in food table analyses, vegetables would usually have been cooked in distilled water and without added salt. This means that the measured content of sodium, chloride and calcium (present in tap water) will be much lower than is likely in the typical domestic setting.

For most dietetic purposes, the importance of any differences between theoretical and actual nutrient composition may be relatively insignificant in the average mixed

diet. However, for metabolic studies based on the consumption of very few foods, or where extreme precision is required, duplicates of the actual foods concerned must be prepared for direct laboratory analysis.

Bioavailability

Bioavailability is defined as the proportion of a nutrient that can be absorbed and hence available to the human body. The bioavailability of a particular nutrient can vary according to a number of factors:

- Source of origin, e.g. calcium in milk is absorbed more readily than calcium in bread.
- Chemical form, e.g. haem iron absorption is greater than that of non-haem iron.
- Ease with which the nutrient can be released from the food structure, e.g. some carbohydrate in fibrous foods cannot be digested and is lost in faeces.
- Presence of factors that inhibit absorption, e.g. phytates in cereal foods can reduce calcium absorption.
- Presence of factors that enhance absorption, e.g. vitamin C enhances the absorption of non-haem iron.
- Physiological factors – absorption may be increased in states of nutritional depletion or at times of increased need, e.g. during pregnancy.

Bioavailability is most likely to impact on minerals and trace elements such as calcium, magnesium, iron, zinc, copper, manganese and selenium, and vitamins such as folate and B₆. Since these interactions are so variable, UK food tables take no account of bioavailability and the nutrient content given in the food table is the amount present in the food. The only exception is the allowance made for the reduced activities of the different forms of some vitamins, e.g. 13-*cis* retinol and retinaldehyde (vitamin A), carotenes other than beta-carotene, and tocopherols and tocotrienols other than alpha-tocopherol (vitamin E). It is important to check if the food composition data nutrient values have been modified to take account of their bioavailability.

Error associated with the use of food composition data

Coding errors

In addition to inherent error in the food table data, additional errors may be introduced into nutrient analysis programmes in a number of ways:

- Missing nutrient values in food composition tables may be treated as zero values during calculation, resulting in an underestimation of nutrient intake.
- There may not be a suitable code for the food consumed or an inappropriate code may be chosen.
- There may be incorrect entry of food code numbers into the computing system.
- Errors can occur in the measurement, recording and estimation of food weights.
- Misclassification can result from a food having different names in different parts of the country. For example,

in some parts of the UK, roast potatoes may be entered on a dietary record as baked potatoes. This is particularly important when working with other nationalities, e.g. in the USA, chips refer to potato crisps rather than fried potatoes.

Interpretation errors

Food tables are useful to help identify good and poor food sources of nutrients, but are not always used for this purpose in an appropriate way. The values given in the tables will identify foods that are particularly concentrated sources of a specific nutrient, but this does not necessarily mean that a food is an important source of that nutrient in the typical diet. The contribution that a particular food makes to nutrient intake depends on the:

- Concentration of nutrient in the food (content per 100 g) and its bioavailability.
- Amount of the food consumed, i.e. portion size.
- Frequency with which that food is consumed.

For example, parsley is a highly concentrated source of vitamin C, but is unlikely to be a significant dietary source because it is usually only eaten infrequently and in small quantities. In contrast, potatoes are a much less concentrated source of vitamin C, but because they are a regular feature of many UK diets, they may make a major dietary contribution to vitamin C intake in the UK. When giving dietary advice it is important to remember that however valuable a food may be as a source of a particularly nutrient, it will make only a small contribution to dietary intake if it is rarely eaten.

SECTION 3

Nutrition in specific groups

3.1

Women's health

3.1.1 Polycystic ovary syndrome

Yvonne Jeannes

Key points

- Polycystic ovary syndrome (PCOS) presents as a range of symptoms that vary in severity.
- Weight management should be the primary therapy in overweight women with PCOS.
- Dietary modification should aim to improve insulin resistance.
- A patient centred approach is needed to improve symptoms as well as reduce the risk of developing diabetes and cardiovascular disease.
- Binge eating behaviour is common in PCOS.

Polycystic ovary syndrome (PCOS) is a heterogeneous condition and women may present with one or several of the following symptoms: menstrual irregularity and fertility problems, excess male pattern hair (hirsutism), male pattern alopecia, acne, central adiposity, insulin resistance and depression (Azziz *et al.*, 2006; Dokras *et al.*, 2011). Symptoms vary in severity and can change over the lifecycle; PCOS often becomes clinically apparent during adolescence (Ojaniemi *et al.*, 2010). The diagnostic criteria for PCOS involve the presence of two of the following features and exclusion of other endocrine disorders (ESHRE and ASRM, 2004):

- Oligo-ovulation leading to oligomenorrhoea (fewer than nine menses per year), or anovulation leading to amenorrhoea.
- Hyperandrogenism – clinically (hirsutism, male pattern alopecia, acne) or biochemically.
- Polycystic ovaries.

It is important to note that women can be diagnosed with PCOS from the presence of oligo-ovulation and clinical signs of hyperandrogenism without polycystic ovaries. A woman with polycystic ovaries without the other symptoms should not be diagnosed with PCOS.

The aetiology of PCOS is complex, with a genetic heritability that is enhanced by environmental factors, espe-

cially obesity (Pasquali *et al.*, 2011). Hyperandrogenism is present in 60–80% of women, either clinically (hirsutism, male pattern alopecia, acne) or biochemically (elevated total or free testosterone) (Azziz *et al.*, 2006). Although insulin resistance is not among the diagnostic criteria for PCOS, most women with PCOS, both the lean and overweight, have a form of insulin resistance intrinsic to PCOS (Baptiste *et al.*, 2010). Hyperinsulinaemia promotes ovarian hyperandrogenism and reduces hepatic production of sex hormone binding globulin (SHBG), thus increasing free testosterone levels. Together hyperinsulinaemia and hyperandrogenaemia disrupt follicle growth, which leads to menstrual irregularity, anovulatory subfertility and accumulation of immature follicles (Goodarzi *et al.*, 2011).

Disease consequences

It is the most common endocrine disorder in women of reproductive age, affecting up to 10% (March *et al.*, 2010). South Asian women have the highest prevalence (Rodin *et al.*, 1998) followed by Black women (Azziz *et al.*, 2004). Between 30% and 70% of women with PCOS are obese (Barr *et al.*, 2011) and frequently exhibit central obesity (Amato *et al.*, 2011; Cascella *et al.*, 2008) that is linked to greater insulin resistance (Barber *et al.*, 2006).

Obese women with PCOS are generally more symptomatic and are at greater health risk compared with lean women with PCOS (Majumdar & Singh, 2009). Up to 50% of women with PCOS develop impaired glucose tolerance or type 2 diabetes by the age of 40 years (Ehrmann *et al.*, 1999) and there is a greater incidence of gestational diabetes (Bals-Pratsch *et al.*, 2011) (see Chapter 7.12). South Asian patients tend to exhibit greater insulin resistance and are at an increased risk of type 2 diabetes (Wijeyaratne *et al.*, 2002). Up to 47% of women with PCOS exhibit features of the metabolic syndrome (Ehrmann *et al.*, 2006). Women with PCOS have a greater prevalence of cardiovascular disease (CVD) risk factors, including hypertriglyceridaemia, low high density lipoprotein (HDL) cholesterol, hypertension and endothelial dysfunction (Wild *et al.*, 2010). They are also more likely to develop cancer of the endometrium (Chittenden *et al.*, 2009; Fearnley *et al.*, 2010).

The symptoms associated with PCOS have been shown to lead to a reduction in health related quality of life (Jones *et al.*, 2008). Depression and anxiety are common in PCOS (Dokras *et al.*, 2011). Studies have indicated a higher prevalence of eating disorders in women with PCOS (Morgan *et al.*, 2008; Kerchner *et al.*, 2009). Anecdotal reports suggest women with PCOS may have increased binge eating, food cravings and symptoms of postprandial hypoglycaemia (Herriot *et al.*, 2008). However, there remains a paucity of well designed studies investigating the eating behaviours or food cravings in women with PCOS.

It is important to consider the psychological impact of PCOS when advising sufferers and to involve them in every part of the care process.

Clinical management

Management of PCOS focuses on treating the presenting symptoms. Lifestyle management is advocated as the primary therapy in overweight and obese women with PCOS. A modest weight loss of just 5–10%, without medical intervention, has been shown to improve many of the symptoms associated with PCOS (Moran *et al.*, 2009; 2011), including lower fasting insulin levels, reduced free testosterone and increased SHBG, improved reproductive function, less hirsutism and an improvement in risk factors for diabetes and CVD.

Medical treatments are available for hirsutism, acne and infertility. Metformin is commonly prescribed for women with PCOS as it reduces serum insulin levels in insulin resistant individuals (Diamanti-Kandarakis *et al.*, 2010). Several studies have revealed some reproductive benefits of metformin and a beneficial effect on serum testosterone concentration has also been observed (Tang *et al.*, 2010).

Nutritional consequences

There are no known nutritional consequences specific to PCOS.

Nutritional assessment

Anthropometric measurements include determining body mass index (BMI) and waist circumference to inform risk of comorbidities and dietary management. A dietary assessment to determine habitual dietary habits should also aim to detect any binge eating behaviour (see Chapter 7.10.1). Due to the increased prevalence of impaired glucose tolerance and type 2 diabetes in PCOS, an oral glucose tolerance test may be performed, and due to the increased prevalence of cardiovascular risk factors, measurements of blood pressure, plasma total, low density lipoprotein (LDL) and HDL cholesterol as well as triglycerides are recommended (Wild *et al.*, 2010).

Nutritional management

Weight loss through dietary restriction and increased physical activity are key management strategies for overweight and obese women with PCOS (Moran *et al.*, 2009). The optimal method of achieving sustainable weight loss is under constant debate; the aforementioned studies demonstrating clinical benefit of weight loss in women with PCOS incorporated a variety of methods to reduce energy intake and achieve the weight loss. A range of weight loss strategies are available and a patient centred approach that addresses the needs and preferences of patients is important when managing PCOS. Behaviour change strategies have long been recognised as instrumental in managing chronic conditions, particularly weight management (see Chapter 7.13.2).

Dietary modification to improve insulin resistance may produce benefits greater than those achieved by weight loss alone and would also be suitable for lean women with PCOS (Marsh & Brand-Miller, 2005). Modifying carbohydrate and fatty acid content of the diet have both been proposed as methods to improve insulin sensitivity. The concept of a low glycaemic index (GI) diet aims to reduce the glycaemic load and hence insulin response to ingested foods and drinks. As previously mentioned, hyperinsulinaemia has a detrimental effect on symptoms and thus reducing the body's exposure to insulin may be beneficial. The delivery of a low GI diet should incorporate healthy eating principles to additionally reduce risk factors for CVD (see Chapter 7.14.1).

At present only a couple of studies have investigated the impact of a low GI diet independent of weight loss in women with PCOS. Marsh *et al.* (2010) reported greater improvement in insulin sensitivity and regular menses after weight loss with a low GI approach compared to weight loss through conventional healthy eating. Both diets were designed to provide reduced energy, low fat, low saturated fatty acids and moderate to high fibre; the low GI diet additionally modified the quality of carbohydrate. Twenty-nine women with PCOS followed the low GI diet and 20 completed the healthy eating regimen, and women were followed for 12 months or until they achieved 7% weight loss. Barr *et al.* (2010) demonstrated an improvement in insulin sensitivity through an isocaloric diet with a reduction in dietary GI in 21 women with

PCOS over a 12-week intervention period. These studies provide some evidence to support dietary advice to lean women with PCOS, many of whom are also insulin resistant. These studies are in agreement with studies that have indicated enhanced insulin sensitivity in individuals with type 2 diabetes (Rizkalla *et al.*, 2004). Herriot *et al.*, (2008; 2009) reported that an isocaloric low glycaemic load diet in lean women with PCOS resulted in a reduction in waist circumference. In addition, a reduction in carbohydrate craving and general hunger was observed.

Fatty acid intake has been shown to influence glucose metabolism by altering insulin signalling and cell membrane function, with a diet high in saturated fatty acids associated with a decrease in insulin sensitivity when compared to a high monounsaturated fatty acid diet (Galgani *et al.*, 2008). Furthermore, a review by Risérus (2008) concluded that saturated and *trans* fatty acids should be replaced with poly- (PUFAs) and mono-unsaturated fatty acids to improve insulin sensitivity and prevent type 2 diabetes. Phelan *et al.* (2011) indicated a role for PUFAs in modulating hormones, whereby supplementation with n-3 PUFA improved the androgenic profile. Further studies are required to substantiate the evidence in this area.

Increasing physical activity has been shown to improve glucose metabolism and insulin sensitivity, and to reduce abdominal adiposity independent of weight loss (Ross *et al.*, 2004). Benefits are seen without weight loss, and thus should be encouraged in all women with PCOS, irrespective of weight. Eighty-four per cent of women with PCOS self reported improvements in PCOS symptoms when they increased their level of physical activity (Jeannes *et al.*, 2009). Barriers to participating in physical activity, above and beyond those experienced by overweight women without PCOS, include: excess body and facial hair, acne, unpredictable menses, body shape concerns, low self esteem and feelings of being unfeminine.

A high proportion of women with PCOS report taking nutrient or herbal supplements, which many felt had a beneficial effect on their symptoms (Jeannes *et al.*, 2009). *Agnus castus* has been proposed to help relieve some PCOS symptoms, including restoring menses; however, at present there are no studies to support this in women with PCOS. Saw palmetto has been proposed to reduce circulating testosterone and hirsutism, but again there is inadequate evidence to support this.

A holistic approach to dietary management with consideration of immediate goals (improvement of symptoms and fertility, and weight loss) as well as reducing the long term health risks, e.g. of diabetes and CVD, should be incorporated. Women who are trying to conceive should also be following a nutritionally adequate diet with folic acid supplements.

Drug–nutrient interactions

Oral contraceptives may negatively impact upon insulin sensitivity and dyslipidaemia. Metformin can cause gastrointestinal side effects such as nausea and diarrhoea.

3.1.2 Premenstrual syndrome

Gaynor Bussell

Key points

- Most women experience premenstrual symptoms; for 8–20% it is severe.
- Premenstrual symptoms is cyclical and does not occur in anovulatory cycles, but it is unrelated to hormonal levels.
- A healthy diet and lifestyle can help relieve mild symptoms.
- Adequate dietary sources of calcium and vitamin D are important. For other supplements, the evidence is equivocal.

Premenstrual syndrome (PMS) is cyclical and occurs during the luteal phase of the cycle (1–2 weeks before menstruation); symptoms are relieved by the onset of or during menstruation. Most women experience mild symptoms, but for 8–20% its severity can prompt them to seek medical treatment (Chocano-Bedoya *et al.*, 2011); the most severe form affects 3–5% of women.

Symptoms of PMS vary between and within individuals, and include mood swings, irritability, increased appetite, carbohydrate and alcohol cravings, breast tenderness, headaches and bloating. Women with chronic disease, e.g. diabetes, irritable bowel syndrome (IBS) or allergies, may have a low threshold for developing PMS (Bussell, 1998). Good control of chronic medical conditions may reduce the severity of symptoms.

Aetiology

The cause of PMS is unknown, but it is believed to be due to an increased sensitivity to circulating progesterone and its metabolites (Brown *et al.*, 2009). Progesterone production by the corpus luteum of the ovary may provoke symptoms; cyclicity disappears in anovulatory cycles when a corpus luteum is not formed. It has also been suggested that a lack of prostaglandin E1 (PGE1) production from n-6 fatty acids (O'Brien, 1987) may be a contributing factor.

Management

It is difficult to diagnose PMS; the most definitive method is a symptom diary as symptoms will start in the luteal phase and cease at the start of or during menstruation (Ugarriza *et al.*, 1998).

There is no universally recognised single treatment for PMS and women will often use diet, supplements and alternative approaches to relieve symptoms. For mild to moderate symptoms, lifestyle changes and a healthy diet can substantially reduce, if not alleviate, the symptoms (Stewart, 1993). For those who are treated with drugs, a healthy lifestyle may make the treatment more successful (Bussell, 1998).

Nutritional management

A healthy diet, regular physical activity and stress reduction techniques can help to reduce symptoms (Andrews, 1994; Ugarriza *et al.*, 1998). Sustained dietary change is necessary for symptom relief.

Low glycaemic diet

Anecdotally, PMS sufferers complain of hypoglycaemia and sugar and carbohydrate cravings. An increased sensitivity to the fall in blood glucose after a fast acting carbohydrate and sugar load has been observed premenstrually (Benton, 2002), but low glucose blood levels are rarely observed. A low GI diet is anecdotally reported to be effective, particularly in the luteal phase.

Micronutrients

Sufferers frequently use supplements, although there is little evidence to support their use (Royal College of Obstetrics & Gynaecology, 2007). Only calcium has good quality evidence to support its use (Whelan *et al.*, 2009).

Calcium and vitamin D

A diet rich in calcium and vitamin D is associated with a lower incidence of PMS. Lower fat versions of dairy foods reduce the incidence of PMS (Bertone-Johnson *et al.*; 2005). Calcium (1000 mg/day) and vitamin D (10 µg) may be useful in treating premenstrual pain and emotional symptoms associated with PMS (Thys-Jacobs *et al.*, 1989; Alvir & Thys-Jacobs, 1991; Thys-Jacobs, 1994). Dietary vitamin D has been shown to reduce the risk of PMS in young women (Bertone-Johnson *et al.*, 2010). Women with PMS who consumed at least 100 IU/day of vitamin D had a significantly reduced prevalence of PMS compared with women who consumed less than this amount.

Magnesium

Low intake and blood levels of magnesium have been found in PMS sufferers (Posaci *et al.*, 1994; Quaranta *et al.*, 2007). An improvement in PMS symptoms with magnesium supplementation has been observed (Quaranta *et al.*, 2007). However, more recent reviews have concluded that there is little evidence for the effectiveness of magnesium in PMS (Labruzzo *et al.*, 2009; Whelan *et al.*, 2009).

B vitamins

Historically, vitamin B₆ supplements were used to treat PMS, but a pharmacological dose of 50–100 mg was required and such doses may induce neuropathy (Labruzzo *et al.*, 2009). As a consequence, in the UK B₆ supplements are only sold in 10 mg ineffective doses. Recently, an observational study showed that higher intakes of thiamine and riboflavin may reduce the incidence of PMS by 35% (Chocano-Beoya *et al.*, 2011).

Vitamin E, evening primrose oil and essential fatty acids

Recent studies have shown the efficacy of vitamin E combined with evening primrose oil for premenstrual breast pain (Pruthi *et al.*, 2010). A supplement containing a mixture of essential fatty acids (gamma linolenic acid, linolenic acid, oleic acid) and vitamins (including vitamin E) significantly reduced the symptoms of PMS, with the 2-g highest level supplement having the greatest effect (Filho *et al.*, 2011). Evening primrose oil was prescribable for PMS due to the presence of gamma linolenic acid. However, many trials were poorly designed and/or showed no reduction in breast pain or other PMS symptoms (Kleijnen, 1994); therefore, it was withdrawn as a prescribable product.

Fibre

Increasing dietary fibre can help to alleviate the constipation that may occur premenstrually (Bussell, 1998). Appropriate treatment for IBS is helpful in the premenstrual period (Kane *et al.*, 1998).

Alcohol

Alcoholics are prone to PMS (Allen, 1996) and alcohol aggravates symptoms (Gold *et al.*, 2007). Some PMS sufferers have alcohol cravings premenstrually (Bryant *et al.*, 2006); alcohol metabolism may also be impaired (Perry *et al.*, 2004).

Soya

A phyto-oestrogen rich diet has been shown to prolong the follicular phase of the menstrual cycle (Patisaul & Jefferson, 2010). However, the evidence is equivocal (Kim *et al.*, 2006).

Weight gain

Obesity is associated with PMS (Masho *et al.*, 2005). Many women report an increase in appetite during the luteal phase (Bryant *et al.*, 2006; Tucci *et al.*, 2009). Women with PMS have been shown to eat significantly more fat, carbohydrates and simple sugars premenstrually (Cross *et al.*, 2001). Conversely, energy expenditure has been shown to increase premenstrually in some women (Henry *et al.*, 2003).

Herbal treatments

Although herbal medicines are used, their effectiveness has not been fully evaluated in randomised controlled trials (Jing *et al.*, 2009). Single trials of Jingqianping, *Vitex agnus castus*, *Ginko biloba* and *Crocus sativus* have shown efficacy; however, more trials are needed (Dante & Facchinetti, 2010).

3.1.3 Menopause

Gaynor Bussell

Key points

- The menopause can be accompanied by weight gain, an increased risk of osteoporosis, cardiovascular disease and diabetes.
- Controlling weight and increasing physical activity can help to reduce menopausal symptoms.
- Menopausal women frequently increase their phytoestrogens intake, but evidence for its effectiveness is equivocal.

The menopause occurs when ovulation ceases and the production of oestrogen decreases. This results in the cessation of menstruation and other changes associated with the menopause. It is a gradual change (perimenopause) that usually happens between 40 and 58 years of age (Roberts, 2007); the average age is 51 years. Approximately 75–80% of women suffer menopausal symptoms; 45% find the symptoms distressing while 20–30% find them severe (Royal College of Physicians Edinburgh, 2003). The menopause is self limiting (usually 2–5 years), although for some women it can extend over a longer period.

The most common menopausal symptoms include hot flushes, night sweats, vaginal dryness, sleep disturbance, mood swings, forgetfulness and lack of concentration (Roberts, 2007). Menopausal and postmenopausal women are at increased risk of several conditions, including osteoporosis, hypertension, heart disease and stroke.

Nutritional problems and their management

Weight gain

Lean body mass and metabolic rate decrease in both older men and women. The menopause is associated with an average weight gain of 2–2.5 kg over 3 years (Polotsky & Polotsky, 2010). Weight is more likely to be deposited abdominally, so increasing the risk of insulin resistance, dyslipidaemia and metabolic syndrome (Mastorakos *et al.*, 2010). Weight gain can exacerbate hot flushes and night sweats (Whiteman, 2003), especially if the weight is carried centrally (Raeme, 2008). To prevent weight gain energy intake may need to be reduced and physical activity increased. Physical activity is also associated with fewer

menopausal symptoms and may help to reduce central adiposity (Leite *et al.*, 2010; Seo *et al.*, 2010).

Metabolic syndrome and heart disease

Oestrogen is cardioprotective; by the age of 65 years, the risk of heart disease in women is the same as that in men. Falling oestrogen levels lead to central adiposity, a risk factor for heart disease and insulin resistance (Llaneza *et al.*, 2010). The incidence of metabolic syndrome increases substantially during the perimenopause and leads to an increase in cholesterol and triglycerides, hypertension and risk of diabetes (Polotsky & Polotsky, 2010). Reducing the level of saturated fat in the diet is associated with an improved lipid profile and a reduced incidence of heart disease postmenopausally (Davidson *et al.*, 2002). The role of soya foods in improving the lipid profile is controversial (Beavers *et al.*, 2010; Llaneza *et al.*, 2010). Reducing glycaemic load (GL) has been shown to increase HDL cholesterol levels in postmenopausal women (Shikany *et al.*, 2009).

Bone health

Postmenopausal women are at risk of osteoporosis. The rate of bone calcium loss is escalated during the menopause, as osteoclast activity exceeds osteoblast activity due to falling oestrogen levels, and this continues for up to 10 years [North American Menopause Association (NAMA), 2010]. Menopausal women who are at risk of osteoporosis should be assessed and may need to receive specific dietary counselling (NAMA, 2010). The National Osteoporosis Society (2011) recommends a daily intake of 700 mg of calcium in postmenopausal women, which

should be increased to 1000–1200 mg in women with osteoporosis. Postmenopausal women considering taking calcium supplements should seek medical advice due the risk of heart disease (Bolland *et al.*, 2011).

Vitamin A is associated with an increased risk of osteoporosis; therefore, vitamin A or retinol supplements should be used with caution (Dennehy & Tsourounis, 2010). The results of studies on the benefits of isoflavones on bone mineral density are conflicting (Liu *et al.*, 2009; NAMA, 2010). Unfortunately, weight loss of as little as 5% of body weight is associated with increased bone turnover in postmenopausal women, even when combined with low impact, weight bearing exercise (Rector *et al.*, 2009). Weight loss programmes should be combined with high impact exercise (Engelke *et al.*, 2006) (see Chapter 7.9.1).

Breast cancer

Although oestrogen production decreases during the menopause, SHBG also decreases, leading to a rise in free circulating oestrogen, which increases the risk of developing hormone sensitive breast cancers and some other cancers (see Chapter 7.15.4). This may be modulated by the increased consumption of brassicas (Fowke *et al.*, 2000) and fibre (Park *et al.*, 2009; Suziki *et al.*, 2008). The evidence for the role of isoflavone is conflicting (Kang *et al.*, 2010; Steinberg *et al.*, 2011).

Hot flushes

Hot flushes are one of the most common symptoms of the menopause and can be treated with hormone replacement therapy (HRT). Reducing the intake of alcohol, spicy food and caffeine, and losing weight if overweight or obese (Roberts, 2007) have been shown to be beneficial. There is no evidence to support the use of herbal supplements, including black cohosh, dong quai, evening primrose oil and ginseng. A recent review has shown that 400 IU of vitamin E for 4 weeks reduced hot flush frequency and severity (Dennehy & Tsourounis, 2010).

Phyto-oestrogens for the relief of menopausal symptoms

Eastern populations that consume a diet high in isoflavones appear to have lower rates of menopausal associated problems (Avis *et al.*, 2001). However, a systematic review concluded that there was no evidence for the effectiveness of phyto-oestrogen treatments in the alleviation of menopausal symptoms (Lethaby *et al.*, 2007).

Many women use complementary and alternative therapies for menopausal symptoms and may seek advice from dietitians (Lunny & Fraser, 2010).

3.2

Preconception and pregnancy

Gail Rees

Key points

- A healthy diet and limited alcohol consumption should be advised during the preconceptional period.
- Supplements of folic acid (usually 400 µg/day) should be taken preconceptually and until the 12th week of pregnancy.
- Being under- or over-weight can affect the outcome of pregnancy.
- A healthy balanced diet is important for maternal and foetal health.
- A 10 µg supplement of vitamin D should be advised for all women throughout pregnancy and lactation.

Preconception

Body weight and fertility

Low body weight can affect reproductive function by causing hormone imbalances and anovulation; the relative risk of infertility increases in women who are underweight (Homan *et al.*, 2007). Compared with a reference body mass index (BMI) of 20–21.9 kg/m², the relative risk of infertility at 18 years of age at a BMI 16–17.9 kg/m² was 1.1 and 1.2 at a BMI of less than 16 kg/m² (Rich-Edwards *et al.*, 1994). Conversely, obesity also adversely affects ovulation and obese women have lower natural and assisted fertility rates. Relative rates of infertility gradually increase in women with a BMI greater than 25 kg/m² (Homan *et al.*, 2007). In women aged 18 years, the relative risk of infertility was 2.4 at a BMI 18–19.9 kg/m² and 2.7 at a BMI of greater than 32 kg/m² (Rich-Edwards *et al.*, 1994).

Polycystic ovary syndrome (PCOS) is the most common cause of anovulation and this is more common in obese women (see Chapter 3.1.1). High levels of body fat, particularly around the abdominal region, are linked to insulin resistance and this increases ovarian androgen secretion and abnormal development of follicles. Raised insulin levels also lower production of sex hormone binding globulin (SHBG) from the liver, resulting in high free androgen activity. High levels of androgens give rise to amenorrhoea, infertility, hirsutism, acne and alopecia (Ramsay *et al.*, 2006).

Weight loss is the first line therapy for obese women with PCOS wishing to become pregnant (The Thessalo-

niki Consensus, 2007). Studies clearly show a benefit from modest weight loss (5%). A systematic review of the literature on lifestyle changes and PCOS found that lifestyle intervention improves body composition, hyperandrogenism and insulin resistance. However, there was no evidence of effect for lifestyle intervention on improving glucose tolerance or lipid profiles, and there was no literature assessing clinical reproductive outcomes, quality of life and treatment satisfaction (Moran *et al.*, 2011).

A restrictive diet prior to conception or during pregnancy is not recommended as this may increase the likelihood of poor micronutrient intakes, which could have an adverse effect on foetal development, maternal nutrient stores and breast milk composition. Therefore, advice should focus on a varied, nutrient rich diet following healthy eating guidelines, with an active lifestyle to encourage a gradual weight loss before conception is attempted.

Male fertility and body weight

Undernutrition and obesity can affect steroid hormone production in men. Obesity in males is associated with reduced insulin sensitivity and decreased testosterone secretion (Pasquali *et al.*, 2007). A systematic review by MacDonald *et al.*, (2010) found no evidence for a relationship between BMI and average sperm concentration or total sperm count. Obesity is, however, associated with erectile dysfunction, which may be treated with weight loss (Pasquali *et al.*, 2007).

Alcohol

Female fertility

The relationship between alcohol and female fertility is equivocal. Some studies have shown that alcohol consumption reduces female fertility and some prospective cohort studies suggest that there is a dose–response relationship between alcohol and infertility. However, other studies find no effect on fertility or only find an effect at high levels of alcohol intake (Homan *et al.*, 2007). However, alcohol is known to be harmful to the foetus, especially during early pregnancy when the foetus is most susceptible to teratogens (compounds that are harmful to the foetus and cause malformations), and so alcohol is best limited or avoided preconceptually.

Male fertility

A meta analysis of social and behavioural factors and semen quality in men reviewed 57 cross sectional studies with 29914 participants from 26 countries and regions, and concluded that alcohol consumption was a risk factor for lower semen volume (Li *et al.*, 2011).

Folic acid and neural tube defects

The link between folic acid supplementation and a reduction in risk of neural tube defects (NTD) is well established (Czeizel & Dudas, 1992; MRC, 1991). Current advice from the Department of Health is to take a dietary supplement of folic acid (400 µg/day) from the time contraception is stopped until the 12th week of pregnancy. To prevent recurrence of NTDs in the offspring of women or men with a NTD, or for those who have previously had a child with a NTD or have a family history of NTDs, women who may become pregnant should take a daily supplement of 5 mg of folic acid (available on prescription) until the 12th week of pregnancy. Women with diabetes, obesity or coeliac disease or who are taking medication for epilepsy are also advised to take 5 mg of folic acid/day.

Despite campaigns to increase awareness, supplement use preconception (or prior to neural tube closure) continues to be low, especially in the socially disadvantaged and in ethnic minorities (Brough *et al.*, 2009). Therefore, opportunities to encourage preconception folic acid supplementation should be sought and women should also be advised to consume both naturally rich sources of folate and fortified foods. A good dietary intake is needed throughout pregnancy and lactation as requirements are increased. Women who have not taken folic acid supplements preconception should be advised to start immediately and continue until the 12th week of pregnancy. Many countries throughout the world (but not the UK) have introduced mandatory fortification of flour with folic acid. It is estimated that this produces a reduction in NTD incidence of 46% (Blencowe *et al.*, 2010). Table 3.2.1 shows the folic acid content of some foods.

Table 3.2.1 Folic acid content of some foods

Food source (portion size)	Folate per portion (µg)
Broccoli – boiled (85 g)	54
Spinach – boiled (90 g)	73
Baked beans in tomato sauce (135 g)	30
Orange juice (150 g)	27
Wholemeal bread – one slice (36 g)	14
Chicken – roast (100 g)	10
Fortified cereals:	
Cornflakes (Tesco) (30 g)	120
Cheerios (Nestle) (30 g)	51
Weetabix Bitesize (40 g)	68

Pregnancy

Basal metabolic rate and energy requirements

Energy requirements vary greatly between individuals according to body size and level of activity. During pregnancy additional energy is needed to support the increase in body tissues of the mother and foetus. Therefore, energy requirements increase due to increases in metabolically active tissues, and the increased energy cost of moving a heavier body (Butte *et al.*, 2004). Hytten & Leitch (1971) calculated theoretical estimates of the components of average pregnancy weight gain. A mean weight gain of 13 kg was calculated (uterus 0.9 kg; breasts 0.4 g; blood 1.2 kg; extracellular fluid 1.2 kg; fat 3.5 kg; plus the products of conception 5.8 kg). It should be remembered that this is a theoretical value and a wide range of weight gains are associated with a healthy pregnancy.

There are differences in changes in basal metabolic rate (BMR) during pregnancy between women in developed and developing countries. Generally, women in developed countries have been shown to have increased BMR, whilst in developing countries BMR decreases (Prentice *et al.*, 1996). Research also suggests that while the mean BMR for women in the UK changes little during early pregnancy, some women show increases in BMR at this stage and some show reductions in BMR, making it difficult to recommend an ideal energy intake (Prentice *et al.*, 1989). The UK estimated average requirement (EAR) for energy intake during pregnancy is therefore unchanged until the third trimester when there is an increment of 190 kcal (800 kJ)/day, but with the recognition that those who are underweight at the start of pregnancy and those who do not reduce their activity levels may require more (Scientific Advisory Committee for Nutrition, 2011).

Obesity and weight gain

Maternal obesity is increasing in the UK. In a 19-year period between 1989 and 2007, obesity doubled from 7.6% to 15.6% and the percentage of women in early pregnancy with a normal range BMI has decreased from 66% to 54% (Heslehurst *et al.*, 2010). Obesity during pregnancy has been associated with many adverse outcomes

Table 3.2.2 USA guidelines for weight gain during pregnancy (Institute of Medicine/National Research Council, 2009)

BMI category	Total weight gain (kg)
Underweight (BMI <18.5 kg/m ²)	13–18
Normal weight (BMI 18.5–24.9 kg/m ²)	11–16
Overweight (BMI 25–29.9 kg/m ²)	7–11
Obese (BMI 30 kg/m ² or above)	5–9

BMI, body mass index.

for the mother, including gestational diabetes, thromboembolism, pre-eclampsia, caesarean sections, haemorrhage and wound infections. It is also associated with miscarriage, congenital abnormality, stillbirth, preterm birth and neonatal death (Sebire *et al.*, 2001a; Yu *et al.*, 2006; McDonald *et al.*, 2010; Vasudevan *et al.*, 2011). A recent enquiry into maternal and child health recognised obesity as a risk factor for maternal death [Centre for Maternal and Child Enquiries (CMACE), 2011].

There are currently no UK recommendations for weight gain during pregnancy as a wide range of weight gain is associated with a healthy pregnancy outcome. However, American guidelines provide guidance for weight gain based on prepregnancy body weight, as shown in Table 3.2.2 (Institute of Medicine/National Research Council, 2009). There is currently a renewed interest in weight gain due to the increasing number of obese women of childbearing age worldwide. Gestational weight gain has also been found to predict postpartum weight retention (Kac *et al.*, 2004). Thus, it is important that excess weight gain is avoided to prevent postpartum obesity and prevent women conceiving again when obese. The Royal College of Obstetricians and Gynaecologists (RCOG/CMACE) (2010) have called for research to determine the optimal weight gain during pregnancy for women in different BMI categories.

Current guidance from the National Institute for Health and Care Excellence (NICE) (2008) in the UK does not recommend routine monitoring of weight gain unless clinical management is likely to be influenced. However, it does recommend that height and weight are measured and recorded for all pregnant women at the first booking clinic (before 12 weeks' pregnant) (NICE, 2010). Body mass index (BMI) should also be calculated. The guidance also states that all obese, pregnant women should be given advice about diet and activity levels, and have the opportunity for referral to a dietitian (or other trained health professional) for further advice.

Several intervention programmes have been developed to prevent excessive weight gain during pregnancy. However, a systematic review of randomised controlled trials found that the trials were of insufficient quality to develop evidence based recommendations for clinical

Table 3.2.3 Summary of nutritional requirements during pregnancy (females 19–50 years) (Department of Health, 1991)

Nutrient	Reference nutrient intake	Increment for pregnancy
Protein (g/day)	45	6
Thiamine (mg/day)	0.8	0.1
Riboflavin (mg/day)	1.1	0.3
Niacin (mg/day)	13	No increment
Vitamin B ₆ (mg/day)	1.2	No increment
Vitamin B ₁₂ (µg/day)	1.5	No increment
Folate (µg/day)	200	100
Vitamin C (mg/day)	40	10
Vitamin A (µg/day)	600	100
Vitamin D (µg/day)	–	10
Minerals	Various	No increment

practice in antenatal care (Ronnberg & Nilsson, 2010). More recently, a randomised controlled trial of a behavioural intervention aiming for adherence to US weight gain guidelines compared with standard care, showed that the intervention increased the percentages of normal weight, overweight and obese women who returned to their prepregnancy weights or less by 6 months postpartum (Phelan *et al.*, 2011).

Dietary management should ensure that the diet follows general healthy eating principles to provide sufficient micronutrients and protein, with supplementation of folic acid up to the 12th week of pregnancy and vitamin D throughout pregnancy. The diet should avoid those foods thought to be hazardous to the foetus (Table 3.2.3) and weight gain should be controlled by avoidance of high energy drinks and snacks, and limiting portion sizes where necessary. In the absence of evidence based UK guidelines for weight gain, US guidelines may be used if appropriate.

Underweight

It has been estimated in England that 5% of pregnant women are underweight (BMI <18.5 kg/m²) in the first trimester (Heslehurst *et al.*, 2010). Underweight women are at less risk of gestational diabetes and pre-eclampsia, but are significantly more at risk of anaemia, preterm birth and a birth weight less than the fifth centile (Sebire *et al.*, 2001b). A dietary assessment should be undertaken to ensure nutrient requirements are covered and advice given to ensure weight gain is appropriate. Discussion with midwifery colleagues to ensure adequate foetal growth may also be helpful.

Nutritional requirements during pregnancy

Protein

The current UK dietary reference values (DRVs) recommend an increment of 6g/day of protein during preg-

nancy. For women aged 19–50 years this would mean an increase in the reference nutrient intake (RNI) from 45 g/day to 51 g/day. Most women in the UK exceed this amount and so do not need to alter their protein intake.

Fat

There are no recommendations to change the percentage of energy derived from fat during pregnancy. It is assumed that there will be some increment in fat intake as energy needs increase in the third trimester. There has however been debate about the requirements for long chain n-3 fatty acids. Long chain n-3 fatty acids, particularly docosahexaenoic acid (DHA), are required for brain growth and development of the retina, and so requirements are increased in pregnancy and lactation, but the exact amounts are difficult to quantify. An increase in intake however, needs to be balanced with advice to moderate oily fish consumption. While limited, there is some evidence that seafood intake (>340 g/day) in pregnancy has beneficial effects on child development (Hibbeln *et al.*, 2007). Higher n-3 intake has also been associated with longer gestation, higher birth weight and lower rates of postpartum depression (Genius, 2008). However, in countries where fish is more common in the diet, mercury (high levels are associated with nerve damage in the fetus) in blood, placenta and cord blood has exceeded recommended levels and the levels were highest in those who ate fish more than three times a week (Hsu *et al.*, 2007). Therefore, women who could become pregnant or who are pregnant should be encouraged to eat oily fish within the guidelines offered by the Department of Health (Table 3.2.4). Fish oil supplements should be avoided during pregnancy due to their high vitamin A content. A pregnancy specific DHA supplement may be taken if it does not contain retinol.

Vitamins

There are modest increments in the dietary requirement for vitamins, as shown in Table 3.2.4 (Department of Health, 1991). Other than vitamin D and folate, vitamins

should be provided by a diet following usual healthy eating guidelines – see also Micronutrient supplementation and Healthy Start.

Minerals and trace elements

In the UK there are no recommended increments in mineral or trace element intakes; recommendations for non-pregnant women therefore apply. This is due to physiological changes whereby there is an increased intestinal absorption of minerals. This assumes that there are sufficient minerals in the diet and the woman has a good nutritional status pre-pregnancy, so stores can be mobilised. Iron is the mineral most likely to be deficient, and although there are some savings of iron during pregnancy from the cessation of menstruation, it is sensible to ensure that adequate dietary sources are consumed throughout pregnancy (see Appendix A2). Haem iron is better absorbed than non-haem iron and so regular consumption of lean red meat is useful. If meat is not eaten, absorption of iron from vegetable and cereal sources can be improved if consumed with a source of vitamin C and if inhibitors of iron absorption (especially tea) are avoided with meals. Retinol is teratogenic and pregnant women will require advice on how to avoid excessive amounts (Table 3.2.4).

Micronutrient supplementation

Supplementation of some micronutrients is recommended in pregnancy. Folic acid supplementation is discussed earlier – Folic acid and neural tube defects.

Vitamin D

The Department of Health recommends that all pregnant and breastfeeding women take a supplement of 10 µg/day of vitamin D. (See Appendix A2 for sources of Vitamin D.) Vitamin D insufficiency has been found in pregnant women of different ethnic groups. Brough *et al.* (2010) showed that 70% of women in the first trimester in a diverse ethnic group in London had 25-hydroxy vitamin

Table 3.2.4 Food to avoid in pregnancy

Risk	Sources – avoid
Listeriosis	Mould ripened soft cheeses, e.g. brie, camembert Soft blue vein cheeses, such as Danish blue Unpasteurised cow's, goat's or sheep's milk or soft cheese made from them All types of pâté including vegetable pâté
Salmonella and other food-borne infections	Raw, undercooked eggs and products containing, for example, homemade or restaurant-made mayonnaise, mousse, cold soufflés, etc. Raw or under cooked meat, poultry Raw shellfish
Toxoplasmosis	Unwashed fruit, vegetables and salad
Vitamin A toxicity	Liver, liver products such as liver pâté, liver sausage Supplements containing retinol, including fish liver oils
Mercury toxicity	Shark, marlin and swordfish Limit tuna to a max of two tuna steaks a week (140g cooked) or four cans of tuna a week (140g drained) Max of two portions of oily fish per week

D below 50 nmol/L, indicating insufficiency. There were significant differences between ethnic groups with 91% of Asian, 85% of African, 71% of Caribbean and 47% of Caucasian women having insufficient vitamin D. Vitamin D is synthesised under the skin from the actions of ultra-violet light, but in the UK (depending on the latitude) sunlight is at the correct wavelength to produce vitamin D only in summer months. At particular risk are women who cover themselves for religious or cultural reasons or who have limited time outside. Sunscreens also reduce the action of sunlight on the skin. Groups of women that are particularly vulnerable to vitamin D insufficiency include:

- South Asian, African, Caribbean and Middle Eastern Origin.
- Limited sunlight exposure.
- Diet containing no meat, oily fish, eggs, margarine or breakfast cereal.
- A prepregnancy BMI over 30 kg/m² – obese – have a lower bioavailability of vitamin D as it is sequestered in the body fat.

Iron

Iron demands increase in pregnancy and the mother is put at risk of anaemia by the demands of the foetus. Historically, all pregnant women were offered supplementation, but increasing understanding of changes in metabolism in pregnancy, such as haemodilution in the mother, has led to changes in routine practice. NICE guidance (2008) recommends that iron supplementation should not be routinely offered to pregnant women and is only advised where there is a clinical need. Haemoglobin levels are measured at the booking appointment and usually in the second and third trimester according to local policy. Women with haemoglobin levels less than 11 g/100 mL at booking or less than 10.5 g/100 mL at 28 weeks' gestation should be investigated and iron supplementation offered if indicated. Iron supplementation may result in constipation; appropriate dietary advice should be given.

Multivitamins

Currently, it is not standard advice to recommend universal multivitamin supplementation in the UK, as it is in other countries, e.g. the USA. The most recent Cochrane review found that there is insufficient evidence to recommend multiple micronutrient supplementation to improve birth outcomes, apart from folic acid and iron supplementation (Haider & Bhutta, 2006). The studies included in this review were based in low and middle income countries and, therefore, their applicability in wealthier countries is open to debate. For example, a placebo controlled trial carried out in London, in a multiethnic population, did not show an effect of supplementation on mean birth weight or numbers of low birth weight babies. However, fewer small for gestational age babies were born in the group receiving multi micronutrient supplementation compared with the placebo group. This analysis was based on a small number of women who

were compliant with taking the supplements and the results need confirmation in larger studies (Brough *et al.*, 2010).

A multi micronutrient supplement specifically manufactured for pregnancy should be considered in all those who are suspected of having an inadequate intake of micronutrients. Appropriate dietary advice should be given, but nutrients are needed quickly in a short time-frame for pregnancy and dietary changes may take time to adopt. Pregnant teenagers are particularly at risk of inadequate diets and may have additional requirements to support the growth of the mother as well as the foetus. A pregnancy specific micronutrient supplement should be advised to ensure that it does not contain retinol, and has the required dose of folic acid and suitable amounts of other nutrients for pregnancy. If insufficient calcium is consumed, a calcium supplement may be needed, as calcium is often not present in multi micronutrient supplements. Retinol containing supplements should be avoided due to the teratogenic effects of large doses of retinol (vitamin A).

Healthy start

In the UK the NHS scheme Healthy Start provides vouchers for mothers on low incomes to purchase milk, fresh and frozen fruit and vegetables or infant formula. Women can apply for vouchers at their booking appointment with their midwife and receive them until their child is 4 years old. Teenagers under the age of 18 years are eligible for the scheme even if they or their parents are not on government benefits. Pregnant women and those with children aged from 1 to 4 years receive one voucher each week (currently worth £3.10); two vouchers are given each week for children under 1 year. To qualify for Healthy Start vouchers, mothers must have an annual family income of below £16 190 (20011/12) or receive one of the following government benefits:

- Income Support.
- Income based Jobseeker's Allowance.
- Income related Employment and Support Allowance.
- Child Tax Credit.

Vitamin tablets containing folic acid (400 µg), vitamin C (70 mg) and vitamin D (10 µg) are available free during pregnancy and until the child is 1 year old under this scheme. Further details can be found at www.healthystart.nhs.uk.

Food safety

During pregnancy the mother is relatively immunocompromised and thus may be more susceptible to infections, including foodborne infections. More care should be taken with food hygiene to avoid infections such as salmonella by ensuring thorough cooking of eggs, meat, poultry and ready meals, and proper storage of chilled foods. Good kitchen hygiene practices should also prevent the cross contamination of cooked food from raw meat and poultry.

Toxoplasmosis

The bacteria *Toxoplasma gondii* can cause severe foetal abnormalities. It can be transmitted by unwashed fruit and vegetables and is avoided by careful washing of produce, cleaning kitchen surfaces and hand washing. Protective gloves should be worn for gardening and handling cat litter trays. It can also be found in raw meat and unpasteurised milk.

Listeria

Listeria monocytogenes is able to grow at low temperatures and may be present in cook–chill foods, mould ripened cheeses and pâté. Certain foods should be avoided as a precaution (Table 3.2.4). *Listeria* infection in pregnancy, although rare, can cause miscarriage, stillbirth and severe illness in the newborn.

Mercury and polychlorinated biphenyl

The Department of Health advises pregnant and lactating women (and those trying to conceive) to avoid or limit certain oily fish due to mercury and polychlorinated biphenyl (PCB) contamination. These contaminants are present in marine life and subsequently become concentrated up the food chain. Large oily fish, shark, marlin and swordfish should be avoided since a relatively small amount contains sufficient mercury to be potentially neurotoxic to the foetus. Tuna also contains significant amounts of mercury and advice is to limit the amount consumed (Table 3.2.3).

Caffeine

In the UK, the Department of Health recommends that pregnant women should restrict caffeine intakes to below 200 mg/day. High caffeine intakes have been linked to foetal growth restriction. The Committee on Toxicity (COT, 2008a) reviewed the evidence from a number of research studies, including a study by Konje *et al.* (2008), which found a positive association between caffeine intake and increased risk of foetal growth restriction, which was maintained throughout pregnancy. More than 60% of the caffeine consumed during pregnancy in this study was from tea, and only 14% from coffee and 12% from cola. The mean intake of caffeine in this study of 2635 women was 159 mg/day. Exceeding the limit occasionally is not likely to cause problems because the risks are likely to be very small. There is still the possibility that the association is not causal due to the influence of confounding factors, but a cautious approach is advised. The COT committee also states that there may be a positive association between caffeine intake and miscarriage, but the evidence is unclear.

The amount of caffeine in drinks and foods will vary depending on the manufacturer and personal preferences. The following examples of drinks and food contain roughly 200 mg:

- Two mugs of instant coffee (100 mg each).
- One and a half mug of filter coffee (140 mg each).
- Two to three mugs of tea (75 mg each).

- Five cans of cola (up to 40mg each).
- Two and a half cans of energy drink (up to 80mg each).
- Four (50 g) bars of plain chocolate (up to 50 mg each)
 - milk chocolate contains approximately 50% of the caffeine in plain chocolate.

Alcohol

Current advice from the Department of Health is not to drink alcohol during pregnancy, but if a woman chooses to drink, then the maximum intake should be one to two units of alcohol once or twice a week. The National Institute for Health and Care Excellence (NICE, 2008) advises avoidance of alcohol in the first 3 months in particular, because of the increased risk of miscarriage, but alcohol at any stage of pregnancy can cause foetal alcohol syndrome (FAS) (restricted growth, facial abnormalities, learning and behavioural disorders). There are various degrees of FAS, and for some women, drinking >1–2 units once or twice a week may cause learning and behavioural disorders that may only become more obvious later on in childhood. Results of a systematic review and meta analysis show that the risks of low birth weight and small for gestational age gradually increase in mothers who consume an average of one or more alcoholic drinks a day. Risks of preterm birth increase by 23% in those who consume three or more drinks per day (Patra *et al.*, 2011).

Peanuts

There is no clear evidence that eating peanuts during pregnancy affects the chances of the infant developing a peanut allergy. Results from research in humans are limited and it is not clear whether consumption of peanuts during pregnancy increases or decreases the risk of peanut allergy in offspring, or whether there is any effect at all. It is also possible that the effect could differ according to the level of intake. Therefore, current advice is that there is no need to avoid peanuts unless the mother herself is allergic to them (COT, 2008b) (see Chapter 7.11.2).

Nutrition related problems

Nausea and vomiting in pregnancy

Nausea and vomiting are common symptoms of pregnancy that usually begin at 4–8 weeks' gestation and last for the first trimester. Although often termed morning sickness, these symptoms can occur at any time of the day and can last all day. Approximately 50–90% of women experience nausea and vomiting, but only a minority experience this after 20 weeks' gestation. Symptoms range from periodic nausea to severe vomiting (Jarvis & Nelson-Piercy, 2011). Most women manage to keep hydrated and eat an adequate diet by avoiding foods and smells that precipitate the symptoms. Small, frequent, high carbohydrate snacks (such as sandwiches and breakfast cereals) and fluids such as milk or fruit juice can help to keep the patient nourished and hydrated. Reassurance can be given that during the first trimester energy

requirements are not increased and large hot meals can be avoided if these precipitate vomiting.

A Cochrane review considered several interventions for nausea and vomiting in early pregnancy and found a lack of robust evidence for any interventions. There was limited evidence of the effectiveness of acupressure, but acupuncture showed no significant benefit. The evidence for the effectiveness of ginger, vitamin B₆ and several antiemetics was limited and inconsistent (Matthews *et al.*, 2010). Although not evidence based, the following tips may be beneficial:

- Small frequent snacks – avoid getting very hungry.
- Drink liquids between meals rather than with meals.
- Dry foods may be better tolerated, e.g. dry biscuits, bread, toast, cereal, especially early morning.
- Avoid cooking smells and keep rooms well ventilated.
- Avoid high fat and highly spiced foods.
- Fizzy drinks and ginger flavoured drinks have anecdotally been reported as helpful.

Hyperemesis gravidarum is a severe form of vomiting which affects less than 1% of pregnant women. It is a serious condition often requiring hospital admission. It is characterised by intractable vomiting and weight loss of >5% of prepregnancy weight, dehydration, electrolyte imbalances and ketosis. Patients require intravenous rehydration, antiemetics and vitamin supplementation. Thiamine deficiency can occur if vomiting is prolonged, which can result in Wernicke's encephalopathy, and so thiamine administration may be required. Dextrose containing fluids can increase requirements for thiamine and should be avoided (Bottomley & Bourne, 2009). Although trials of efficacy for antiemetics are lacking, many are safe to use (antihistamines, phenothiazines and metaclopramide). The aetiology of hyperemesis is not fully understood and management aims to relieve symptoms and avoid complications (Bottomley & Bourne, 2009). Foetal complications can include foetal growth restriction (Jarvis & Nelson-Piercy, 2011).

Constipation

Constipation is a common problem during pregnancy and is probably caused by changes to gut transit time mediated by hormonal changes associated with pregnancy. Standard dietary treatment for constipation can be advised; high fibre containing cereals, fruit and vegetables and ensuring plenty of fluid (see Chapter 7.4.11). Faecal bulking agents can be used and changing the type of iron supplementation may be beneficial.

Heartburn

Heartburn and gastrointestinal reflux are also common problems experienced in pregnancy. Symptoms result from increased abdominal pressure and changes in gut transit time. Symptoms are usually more severe in the final trimester but can start from early pregnancy. Milk based foods can alleviate the symptoms and small frequent meals and snacks are sometimes better tolerated than large meals. Some foods may exacerbate the symp-

toms, such as spicy, fatty or acidic foods and drinks. Antacids are commonly prescribed.

Cravings and pica

Pregnant women frequently report cravings for certain foods and food aversions. Common food aversions include tea, coffee and alcohol. There are no reported patterns to the type of foods craved and no reports that cravings for foods adversely affect the nutritional intake of women. Pica is the craving and consumption of substances other than food and has been reported worldwide. Substances consumed include earth (geophagy), stones or pebbles (lithophagia), ice (pagophagia) and raw starches (amylophagy). It has been associated with both negative effects on health, e.g. heavy metal poisoning, micronutrient imbalances and transmission of parasites, and positive health effects, e.g. providing micronutrients and relieving gastrointestinal discomfort (Young *et al.*, 2010). Pica is more common in developing countries than in developed countries. A study of well nourished Danish women reported an incidence of 0.02% (Mikkelsen *et al.*, 2006).

3.3

Older adults

Vicki Pout

Key points

- The older population is diverse with a wide range of nutritional issues and needs.
- Food has biological, social, psychological and economic roles, and these aspects will affect food patterns of older people.
- Intakes of energy, protein, vitamin C, vitamin D, folate, iron, zinc and fibre are of most concern in older people.
- Good nutrition contributes to health and ability to recover from illness, may lessen health costs by promoting independence for as long as possible and improve overall quality of life.
- The biggest challenge is to maintain adequate nutrition when multiple factors conspire to reduce appetite and food consumption.
- A patient centred approach to care planning should be followed to establish individual dietary problems and formulate effective interventions.
- Team working can improve nutritional status in older adults.

There is no standard definition for when a person becomes elderly or old. Most developed countries take the age when pension benefits can be claimed as the starting point for old age. However, although it is common to use chronological age as a marker for old age, this is not synonymous with biological age. In the UK, the age of 65 years is usually taken as old, with age ranges after this of 65–74, 75–85 and 85+ years. The World Health Organization classifies 45–59 years as middle aged, 60–74 years as elderly, 75–89 years as old and 90+ years as very old.

The UK population was estimated to be 62.3 million in 2010, of which 10.5 million (17%) were 65 years and older and 1.4 million (2.3%) were 85 years and older [Office for National Statistics (ONS), 2010]. The UK population is growing older and is projected to age: those aged 65 years and over increased from 15% in 1985 to 17% in 2010 (an increase of 1.7 million people). In addition, the population aged <16 years decreased from 21% to 19% over the same time period. By 2035 23% of the population is projected to be aged 65 years and over compared with 18% aged <16 years (Older People's Day, ONS (2011)).

Within this ageing population there is also an ageing of the older population itself. The 'oldest old' in the UK have increased in number and proportion from 690 000 people aged over 85 years (1% of total population) in 1985 to

1.4 million in 2010 (2% of total population). It is estimated that in 2033 there will be 3.2 million people in the UK aged 85 years and older (5% of total population) (ONS, 2011). Similarly, the number of centenarians in the UK has grown from 2500 in 1980 to an estimated 12 640 in 2010. This includes an estimated 10 supercentenarians (people aged 110 years or more). It is projected that the number of centenarians in the UK in 2035 will be approximately 100 000 (ONS, 2011).

The World Health Organization (2011) has stated that the ageing of the world's population, in developing and developed countries, is an indicator of improving global health. Currently, the world's population aged 60 years and over is 650 million; by 2050 this population is forecast to reach 2 billion.

The ratio of women to men aged over 65 years is changing. It has fallen from 154 women for every 100 men in 1985 to a current ratio of 127 women for every 100 men. By 2035 it is projected that the sex ratio will have changed to 118 women for every 100 men. This change is also seen among centenarians, with nine women to every one man in 2000 to six women to every one man in 2009 and five women to every one man in 2010. The change in ratio is due largely to recent improvements in male mortality (ONS, 2011).

Currently life expectancy in the UK has reached its highest level on record for both men and women: 78.1

years for newborn boys and 82.1 years for newborn girls (ONS, 2011). Women continue to live longer than men but the gap between the sexes has narrowed from 6 years to 4.1 years. In the UK, life expectancy varies by country. England has the highest life expectancy at birth (78.4 years for males and 82.4 years for females), while Scotland has the lowest (75.8 years and 80.3 years, respectively) (ONS, 2011).

This ageing population poses a challenge for the future. Society needs to prepare to meet the needs of older people, including health promotion, management of age related chronic diseases, long term and palliative care and age friendly services. As the population ages there is also a change in ethnographic make-up. Within minority ethnic groups there is a trend towards a younger age structure; however, this too may change as the population as a whole grows older.

Older people occupy up to two-thirds of NHS beds and as many as 60% of these will have mental health needs, mainly delirium and depression (Royal College of Psychiatrists, 2005).

Over the last 20 years the spectrum of accommodation available for older people has grown enormously and now encompasses extra care housing, very sheltered housing, assisted living as well as residential and nursing homes. Approximately 5% of over 65s live in residential or nursing care and of this population around 20% are aged over 80 years (Office of Fair Trading, 2005). In 2009 the British Association for Parenteral and Enteral Nutrition (BAPEN) reported that 700 000 older people were resident in sheltered housing in England.

The ageing process and nutrition

Ageing is a natural process that has effects on many body systems (see Table 3.3.1). The anorexia of ageing is seen where appetite and intake are reduced due to changes related to the ageing process (Morley, 1997).

Food habits and nutritional status of older people

The National Diet and Nutritional Survey of People Aged 65 Years or Over (Finch *et al.*, 1998; Steele *et al.*, 1998) explored the eating habits and nutritional status of people aged 65 years and older. Eating habits and nutritional status of older people are summarised in Table 3.3.2. Intakes of energy, protein, vitamin C, vitamin D, folate, iron, zinc and fibre are of most concern in older people. There are many factors that influence dietary intake and thus nutritional status. Food has biological, social, psychological and economic roles within life and these aspects will all affect food patterns of older people. If appetite is affected, this will lead to a change in intake. Table 3.3.3 gives examples of factors associated with dietary intake in older people.

Dietary recommendations for older people

Older people are a diverse group and as such have a wide range of nutritional needs. When making recommenda-

tions it is important to consider biological as well as chronological age. Good nutrition contributes to health and ability to recover from illness, may lessen burden of health costs by promoting independence for as long as possible and improves overall quality of life (King's Fund Centre, 1992).

Older people should be eating for health, which is not the same as healthy eating. People age at different rates and each individual needs to eat a diet that meets their own health and nutritional needs. For many people this will be traditional healthy eating but others will need increased levels of energy and nutrient dense foods and fluids. Older people should be encouraged to consume a variety of nutrient dense foods and maintain an active lifestyle where possible (Department of Health, 1992).

Appetite often declines with advancing age but other than energy requirements, most other requirements remain at the recommended levels for younger adults (Scientific Advisory Committee for Nutrition (SACN), 2011). Where appetite is decreased, the focus should be on nutrient dense, appealing and palatable meals and snacks. The emotional and social aspects of food and the role that food and drink plays in life's events must not be underestimated. The impact of acute or chronic illness and disability should be considered as this can quickly compromise food intake, nutritional status and body weight. Although older people are at higher risk of nutrient deficiencies, the population is diverse and this may not always be the case with individuals. Low intake may not always lead to deficiency due to individual variations in requirements or adaptation. Conversely, some nutrient intakes may appear adequate when compared with reference nutrient intakes (RNIs), but may be inadequate for individuals with higher requirements (see Appendix A3).

Energy

Older people should be advised to consume enough energy to maintain a healthy body weight. There is only a small age related decline in energy requirements, as shown in Table 3.3.4.

Calcium and vitamin D

Calcium, sunlight exposure and dietary vitamin D are important for bone health. Osteoporosis and associated fractures are a major cause of morbidity and mortality in older people. For those aged 50 years and over, osteoporosis is a contributory factor in at least 85% of fractures at all sites, most of which occur in the wrist, spine or hip (Department of Health, 2001). An intake of 700 mg/day of calcium is recommended for the elderly. Most of this will be consumed from milk and milk based foods, white fortified flour products and vegetables (Department of Health, 1998). An intake of 10 µg/day of vitamin D is recommended (Department of Health, 1998). Older people are particularly vulnerable to deficiency as they tend to have less sunlight exposure than younger people and there is a reduced efficiency of skin synthesis with age. In addition, oily fish consumption may be poor,

Table 3.3.1 Effects of ageing on body systems (Copeman & Hyland, 1999; Department of Work and Pensions, 2012)

System	Changes produced by ageing
Skin	Wrinkling, thinning, reduced strength and elasticity Increased fragility and susceptibility to damage with elongated wound healing time Touch and pain thresholds increase Loss of hair, slowing of hair and nail growth Loss of pigment cells leading to the appearance of paler skin with age spots Reduced function of sweat and sebaceous glands Reduced synthesis of vitamin D (MacLaughlin & Holick, 1985)
Heart	Loss of heart muscle with increased fibrous tissue Decreased cardiac output
Renal function	20–30% decrease in weight and volume affecting nephrons, decreased filtration rate and increased glucose threshold Impaired renal function and fluid balance Less concentrated urine Benign enlargement of the prostate gland in 25–50% of men over 65 years leads to incomplete emptying of the bladder and a weak stream of urine, or signs of irritation with frequency of urination
Bone	Increased resorption Skeletal changes Osteoporosis
Immune system	Impaired T cell function leading to greater susceptibility to viral infections
Small and large intestine	Decreased motor function and muscle tone, constipation is more common Impaired digestive capacity Diverticula
Muscle	Sarcopaenia (decreased muscle strength and power, and lean body mass and increased fat body mass) resulting in decreased functional capacity
Hearing	Elevated sound threshold Loss of perception of high frequencies Degenerative changes in the inner ear may lead to balance impairment
Taste and smell	Decreased number of taste buds and loss of taste sensitivity Reduced number of nasal sensory cells
Vision	Diminished colour fidelity and peripheral vision Decreased visual acuity Decreased ability to focus on near objects Diminished ability to see in low or dim light and to distinguish objects of low contrast
Nervous system	Changes in central and peripheral nervous system Decreased size and mass of the brain Loss of neurones with fewer connections in the brain and spinal cord Slower thought processes Slower reaction time Decreased vibration and position sense Reduced sensitivity to temperature changes
Homeostatic regulation	Reduced ability to maintain homeostasis
Whole body composition	Sarcopaenia and frailty Physical fitness and strength reduced Loss of muscle and bone strength lead to increased risk of falls and resulting fracture Changes to muscles, bones and joints lead to height loss

especially in those in institutions. A supplement of 10 µg/day is recommended, especially in the winter for older people in residential care settings and those who are housebound or rarely go outside (Department of Health, 1998) (see Chapter 7.9.1).

Vitamin C

An intake of 40 mg/day is recommended for adults (Department of Health, 1998), but in older people consumption of fruit and vegetables may be insufficient to

achieve this. This is of particular concern in those individuals who have a poor appetite, are frail or are dependent on institutional catering. Recommendations for vitamin C fortified drinks or supplements may need to be made. Where supplementation is advised, it should not greatly exceed the RNI.

Folate

Intake of folate is of concern in people who are frail or depend on institutional catering. A daily intake of 200 µg/day is recommended (FSA, 2006).

Table 3.3.2 Eating habits and nutritional status of people aged 65 years or over

Free living	Institutions	All
Lower socioeconomic status correlated with significantly lower average intakes of energy, protein, carbohydrate, fibre, some vitamins (especially vitamin C) and minerals	Oral health poor compared with free living individuals Poor oral hygiene and root decay especially prevalent	Better oral health, including the number of natural teeth, linked with better diet and nutritional status
People heavier than people of same age 30 years previously but recorded food energy intake lower	Vitamin D status poor in some people especially those in institutions in winter	Presence of root decay showed strong relationship with frequency of intake of high sugar foods independent of age, gender, social class and region of origin
90% of people had seven of 10 staple items from a list in their home	Residents were more likely to consume sugar, preserves, buns, cakes, pastries and cereal based milk puddings	As a group, people met COMA recommendations for total fat as opposed to national adult average, but had above recommended intakes of saturated fat and non-milk extrinsic sugars and below recommended intakes of fibre
86% visited shops but 55% said food shopping was sometimes done by someone else		For most people, biochemical status of most vitamins and minerals was adequate as measured by blood levels
53% had milk delivered where this was available		Folate status poor in a significant proportion of older people, especially in those aged 85+ years
One in three reported taking non-prescribed dietary supplements; the most common was cod liver oil		A traditional diet was common, especially as age increased and in those in institutions Most commonly consumed foods were tea, boiled/mashed/baked potatoes, white bread and biscuits Traditional meal pattern was for three meals a day plus smaller snacks in between. For some, nutritional contribution from snacks and drinks was considerable

Vitamin B₁₂

Dietary deficiency is uncommon and pernicious anaemia is usually caused by absorptive problems. However, low intake may be found in those with restricted intakes, e.g. vegetarians or vegans. Particular attention should also be paid to people who have intestinal conditions such as Crohn's disease and achlorhydria or have had a gastrectomy (Finch *et al.*, 1998).

Iron

The RNI for iron is 8.7 mg/day for those aged over 50 years (Department of Health, 1991). A lower iron intake may be sufficient to maintain iron status in older people, especially postmenopausal women, compared with younger individuals. Iron intake can be of particular concern in those individuals who do not have a varied diet or who need texture modification, especially men aged 65 years and over living in institutions and free living men and women aged 85 years and over.

Gastrointestinal blood loss is the most common cause of iron deficiency in older people. This can be caused by a range of factors, including diseases of the genitourinary system, colorectal cancer, anti-inflammatory drugs, e.g. aspirin, or frequent blood tests. In 2010 SACN produced a report on iron and health and recommended that emphasis should be placed on a healthy balanced diet including a variety of iron containing foods. Less empha-

sis should be placed on the inclusion or avoidance of enhancers or inhibitors of iron absorption.

Zinc

Wound healing may be delayed with overt zinc deficiency. Decreased taste acuity in older people has been associated with zinc deficiency (Prasad, 1995; Prasad *et al.*, 1993). Again, zinc intake can be of particular concern in those individuals who do not have a varied diet or who need texture modification.

Fluid and hydration

Older people are at greater risk of dehydration and a fluid loss of 20% can be fatal. Up to 10% of older people admitted to community hospitals suffer from clinical dehydration and up to 25% of immobile older people have chronic mild dehydration (Rolls & Phillips, 1990). Restoring normal hydration increases sense of wellbeing and comfort. Common causes of dehydration in older adults are shown in Table 3.3.5. The effects of dehydration on older people can compound the problem and lead to further reduction in fluid intake (Ritz & Berrut, 2005). The effects of dehydration in older adults include:

- Loss of appetite.
- Increased risk of development of pressure sores.
- Constipation.

Table 3.3.3 Examples of factors associated with dietary intake in older people

Theme	Factors
Availability of food	<ul style="list-style-type: none"> Loss of control over food when shopped for or in care Out of town supermarkets may restrict food choice if no car or unable to use public transport or carry heavy shopping Lack of help with shopping or food and beverage preparation Carers may not appreciate/ realise importance of nutrition
Finances	<ul style="list-style-type: none"> Low finances and limited budget. Food may be available but not able to afford nutritionally adequate diet Supermarkets usually offer best value and special offers on larger pack sizes of food, which may cost too much or not be able to be stored or used Concerns about paying bills, e.g. fuel bills in winter
Cooking	<ul style="list-style-type: none"> Time available to prepare and eat food Cooking for self and/or others Eating alone or with others Cooking and living facilities
Sensory perception	<ul style="list-style-type: none"> Loss of or altered sense of taste, sight, hearing, smell and thirst
Health issues	<ul style="list-style-type: none"> Decreased mobility or physical or mental illness affects ability to shop, prepare and consume food and may affect appetite Pain – chronic or acute Constipation Confusion or dementia Drug side effects or interactions may affect appetite, cause taste changes or constipation or affect absorption of nutrients. May be compounded by polypharmacy Impaired communication skills, e.g. dementia, loss of hearing or dysphasia Dysphagia especially if a modified texture diet is required Constipation Altered nutritional requirements due to medical conditions
Food provision	<ul style="list-style-type: none"> Unfamiliar or culturally inappropriate foods or menu terminology Repeated investigations and periods of fasting Poor nutritional content of food Lack of provision for second helpings Inappropriate mealtimes with long gaps when no food or drinks are offered
Lack of interest in food	<ul style="list-style-type: none"> Poor appetite Anorexia Nausea Depression, dementia, confusion or cognitive impairment, drowsiness, anxiety, side effects of drugs Secondary to malnutrition Illness and anxiety
Inappropriate food	<ul style="list-style-type: none"> Cultural/religious restrictions Dietary misconceptions, food myths and incorrect media messages Unfamiliar foods or menu items, Lack of patient/resident choice and poor menu planning
Previous experience	<ul style="list-style-type: none"> Cooking skills – skills needed to prepare a varied diet, reliance on prepared foods Budgeting skills Education and nutritional knowledge Personal likes and dislikes, cultural and religious needs Habit Fear of complaining about food or asking for food or beverages or assistance in case care is compromised Lack of appreciation of importance of food in treatment of illness and rehabilitation
Mealtime experience	<ul style="list-style-type: none"> Narrow range of foods eaten and reluctance to try new foods Unprotected mealtimes where staff breaks coincide with resident mealtimes, medical or drug rounds at meal times Poorly served food Inappropriate portion sizes Lack of garnishes and condiments Food served at incorrect temperature or kept warm for long periods Lack of choice as to whether to join others for meals Monotonous menus

- Electrolyte imbalance.
- Falls.
- Altered cardiac function.
- Unpleasant taste in mouth.
- Headaches.
- Drowsiness and confusion.
- Urinary tract infections.
- Irritability.
- Loss of skin elasticity.

Older people should be encouraged to maintain an adequate fluid intake. Although there is no set recommended amount in the UK, for most individuals this will be between 1500 and 2000 mL daily, which equates to six to eight drinks (FSA, 2009). The European Food Safety Agency (2010) recommends adequate daily intakes of water of 2000 mL for adult women and 2500 mL for adult men; the value is the same for adults of all ages. Awareness that all fluids count towards this target should be promoted. Where poor appetite or nutritional intake is of concern, nourishing fluids should be advised. In cases where there is inability or reluctance to consume enough fluid, additional sources of fluid can be promoted, e.g. soup, sauces and gravy, jelly, milk puddings, custard and ice cream. Often an additional drink in the form of fruit juice is accepted at breakfast as well as tea or coffee. Drinks are often not taken towards the end of the day due to a perceived increase in micturition at night. If an

individual is concerned, encouragement should be given to maximise fluid intake during the day. Fluid intake is of particular concern in individuals who require thickened fluids (Whelan, 2001) (see Chapter 6.6).

Physical activity

Older people should be encouraged to maintain an active lifestyle where possible. Weight bearing exercise promotes bone health. Being active promotes weight maintenance, appetite, cardiovascular health and mental wellbeing as well as reducing falls (Health Education Authority, 1999).

Nutritional challenges in older people

Older people suffer from the same illnesses and nutritional assaults as younger adults. However, there are some conditions that present more often with advancing age, such as stroke, dementia and cognitive impairment, osteoporosis and falls. Older people may present with more diffuse symptoms such as falls, immobility, incontinence, acute confusion or weight loss, making diagnosis and treatment more difficult. There may also be a reluctance by an older person to visit their GP due to the misconception that disease is a natural part of ageing, not wanting to bother a busy health professional or thinking that there is nothing that can or will be done to help at their age. Often the biggest challenge when working with older people is to maintain adequate nutritional intake in the face of multiple factors conspiring to reduce appetite and food consumption.

Malnutrition

Malnutrition affects physical and mental function and the outcome of disease. These consequences of malnutrition include weight loss, reduced muscle strength, impaired immune response and delayed recovery from illness. The adverse effects of malnutrition in older adults are shown in Table 3.3.6 (NICE, 2006).

Table 3.3.4 Changes in energy requirements with age [based on SACN, (2011)]

Age (years)	Men (MJ/day)	Women (MJ/day)
45–54	10.8	8.8
55–64	10.8	8.7
65–74	9.8	8.0
Over 75	9.6	7.7

Table 3.3.5 Common causes of dehydration [based on Copeman & Hyland (1999)]

Pathological causes	Effects of ageing	Iatrogenic causes
Confusion – unable to ask for a drink, do not recognise thirst, may forget to drink	Altered thirst perception – thirst mechanism less sensitive so may not feel thirsty	Drugs, e.g. diuretics
Depression	Increased skin losses – thinner skin therefore more water lost via skin	Fluid restriction
Drowsiness	Reduced total body water	Institutionalisation – lack of availability of drinks
Decreased mobility or dexterity – unable to procure a drink or drink unaided. Lack of assistance given with drinking	Reduced renal function – kidneys not able to concentrate urine to the same degree as both renal plasma flow and glomerular filtration rate decrease with age	Physical environment, e.g. poor access to drinks, high room temperature
Conditions that affect fluid requirements or fluid losses, e.g. pyrexia or renal failure		Urinary incontinence or perceived increase in micturition after drinking, especially in the evening

Table 3.3.6 Adverse effects of malnutrition (NICE, 2006)

Adverse effect	Related consequences
Impaired immune response	Compounded by age related decrease in immunity Increased risk of infection including pneumonia and other respiratory tract infections Delayed recovery from infections
Muscle wasting	Decreased muscle strength and increased fatigue leads to delayed rehabilitation from illness Decreased mobility and increased risk of thromboembolism Decrease in ability to perform activities of daily living and increased burden on carers Increased risk of falls and consequent fracture more likely Increased risk of heart failure due to wasting of heart muscle compounding age related decline in cardiac function
Reduced respiratory muscle function	Increased breathing problems and less effective coughing mechanism Reduced cough pressure affects recovery from chest infection
Impaired thermoregulation	Increased risk of hypothermia
Impaired wound healing	Increased risk of wound infection and ununited fractures Increased risk of pressure sores
Psychological effects	Apathy, depression, anorexia, anxiety, fatigue and self neglect, impaired psychosocial function, low self esteem
Increased risk of vitamin and other deficiencies	Increased risk of refeeding syndrome Increased risk of specific nutrient deficiencies, e.g. iron deficiency anaemia
Overall	Delayed recovery from illness Greater risk of mortality

Table 3.3.7 Malnutrition prevalence rates in different settings [based on BAPEN (2010)]

Group	Rate of malnutrition
General population	5% (BMI <20 kg/m ²)
Free living older people	14%*
GP and outpatient attendees	18–30%*
Chronic disease	12% (underweight)
Care homes	16–29% (underweight) 20–50%*
Hospital admissions general	15–40%* (underweight)
Hospital admissions medical, surgical, elderly and orthopaedic wards	20–60%*

*using Malnutrition Universal Screening Tool ('MUST').

Groups of people who are more vulnerable to malnutrition include older people, and those with longstanding conditions, recently discharged from hospital, socially isolated or with a low income. Prevalence rates of malnutrition are shown in Table 3.3.7.

It has been shown using the Malnutrition Universal Screening Tool ('MUST') that older people at risk of malnutrition [body mass index (BMI) <20 kg/m²] have 25% more hospital admissions, 6% more GP visits and 9% more prescriptions than individuals within the normal weight range (BMI 20–25 kg/m²). For patients in hospital, it has been shown that those at risk of malnutrition have a significantly longer length of stay and are more likely to be discharged to a care destination other than their own

home (Elia, 2005). Risk of malnutrition increases with age. Older people may well have multiple factors that lead to inadequate nutritional intake and individual problems must be ascertained in order to develop a targeted nutritional care plan. Davies (1998) identified four types of malnutrition that are pertinent to older people and help to identify nutritional strategies to improve nutritional status:

- *Specific malnutrition* – a deficiency of a specific nutrient or nutrition related disease, e.g. scurvy or osteomalacia.
- *Long standing malnutrition* – often linked with general neglect. Clinical appearance of energy and nutrient deficiencies following period of inadequate intake.
- *Sudden* – a sudden marked change in food intake. Often after significant life event, e.g. major fall or bereavement.
- *Recurrent* – an older person with barely adequate nutritional status who, following a period of illness, enters a cycle of poor nutrition and repeated episodes of illness.

There are four main causes of malnutrition:

- Impaired intake.
- Altered nutrient requirements.
- Impaired digestion and/or absorption.
- Increased nutrient losses.

Specific factors affecting intake have been shown in Table 3.3.3 and factors affecting requirements, digestion and absorption and nutrient losses are shown in Table 3.3.8.

Table 3.3.8 Factors affecting nutrient requirements, digestion, absorption and nutrient losses in older people

Cause of malnutrition	Factors
Altered nutrient requirement	Increased energy requirements, e.g. due to involuntary movements or wandering, drug–nutrient interactions
Impaired digestion and/or absorption	Drug–nutrient interactions, polypharmacy, bacterial overgrowth, achlorhydria, medical or surgical problems affecting stomach, intestine, pancreas and liver
Increased nutrient losses	Gastrointestinal losses, e.g. vomiting; diarrhoea; fistulae, stomas, exudate from wounds or pressure sores.

Common issues

Osteoporosis is a common condition in older people. When assessing an individual nutritionally, their weight and level of physical activity should be taken into account. Being overweight can impair mobility and hence lead to increased risk of falls. However, being underweight also increases the likelihood of falling and consequent fracture.

Dementia and cognitive impairment are an important factor in nutritional problems. Individuals may have a number of challenging issues that impact on ability to prepare and consume food, and communicate thoughts and feelings related to food to other people. Food is an emotive issue for patients and carers and is seen as a very important part of the care process. Comprehensive and effective communication with patients and relatives is needed when addressing feeding difficulties in this area. Similarly, stroke also poses challenges to maintaining nutritional status.

Polypharmacy can compound the drug–nutrient interactions or side effects of a single medication. Older

people often take a range of medications, including prescribed, over the counter, vitamin and mineral supplements, and complementary remedies. It is important to take into account any implications of an individual's medication regimen when performing a dietetic consultation. Common side effects include nausea, dry mouth, altered taste sensation, constipation, diarrhoea and drowsiness.

Nutritional care planning

Older people often have multiple comorbidities. It is important to consider their combined effect on nutritional status and function when devising a nutritional strategy. Box 3.3.1 illustrates a checklist for good nutritional care of older people.

Free living and sheltered accommodation

The majority of older people live in the community. The aim of nutritional intervention is usually to promote independence for as long as possible and maintain nutritional

Box 3.3.1 Checklist for good nutritional care of older people

- Ensure that the patient is involved as far as possible with their nutritional care. Follow best practice in decision making if an older person does not have capacity regarding nutritional care
- Older people are a diverse population with a range of factors affecting nutrition. Ensure an individual's circumstances are fully explored when planning nutritional care
- Check that national regulatory standards for food, fluid and nutritional care are being adhered to
- There is a need for a local healthcare wide strategy for good nutritional care of older people
- Follow local policies for malnutrition or risk of malnutrition and appropriate prescribing of oral nutritional supplements
- Regular nutritional screening should occur in all health settings to identify those at risk of malnutrition. A validated screening tool should be used. Results of screening and nutritional care plans should be communicated across care settings. Ensure that there is regular monitoring of weight and food and fluid intake
- A food first approach to improving nutritional intake is advised where possible
- Work towards a positive mealtime experience in all settings. Food should be a highlight of the day
- In institutional care settings ensure protected mealtimes are implemented. Give consideration to timing of meals, appropriate menus and drink and snack provision
- Ensure modified texture meals are used only when appropriate
- Set realistic goals and desired outcomes
- Ensure adequate and effective training on nutritional issues for health and social care staff working with older people. Many health professionals and carers have had very little nutrition training other than education about healthy eating

Table 3.3.9 Risk factors for poor nutrition for older people living in the community [based on Davies (1981)]

Theme	Risk factor
Food habits	Fewer than eight main meals, hot or cold, eaten in a week Minimal consumption of milk, fruit and vegetables Wastage of food, even when supplied ready to eat Long periods during the day without food or drink
Physical or mental factors	Depression or loneliness Unexpected weight changes either up or down Indications in medical records of disabilities including alcohol abuse or dependence
Social	Problems shopping Poverty

status to avoid admission to hospital or another care setting. In the community, care is often provided informally by a relative or carer or by a paid care package. It is important to ensure that carers as well as older people themselves are given sufficient information about specific nutritional issues and strategies to enable them to provide appropriate care. There are some specific risk factors for poor nutrition that are particularly pertinent to older people living in the community [based on Davies, (1981)] and should be considered when assessing nutrition in older people (Table 3.3.9).

Community meals

There are no national standards for nutritional content of community meals. The National Association of Care Catering (2003) and the Caroline Walker Trust (2004) both give guidelines for meal specification, but they are not the same. Community meals should meet the dietary needs of a variety of groups of people, from traditional healthy eating, to energy and nutrient dense in a small serving, to modified texture and therapeutic diets. One meal a day should aim to provide 40–50% of daily nutrient requirements in a realistic volume. There should be sufficient variety to reduce menu fatigue. Some meals are very low in salt, which can reduce its tastiness, but if a meal is not eaten it provides no nutrition. The energy content of meals can also be low. Individuals should be easily able to choose suitable dishes to meet their needs. Provision needs to be made for those with reduced appetites to ensure that suitable meals are nutrient and energy dense.

It must be remembered that community meals only provide one meal a day and not always 7 days a week. Overall meal, snack and beverage provision must be taken into consideration when working with older people as well as the need for encouragement and assistance. The human contact involved in delivered hot meals is very important as for some people this may be the only contact

they have in a day. However, delivery staff need to be trained to support the older people to whom they deliver.

Cost is another factor in community meals and care packages in general. Some individuals will only order a meal every other day due to the expense. Food is not seen as sufficiently important as there is a widely held misconception that people will lose weight and become more malnourished as they get older, but this is not a normal part of ageing.

Institutions (care home and hospital)

Regulation and monitoring of food and nutritional care in hospitals and other care settings has changed and strengthened. In England this is monitored by the Care Quality Commission, with Outcome 5 of the Essential Standards for Quality and Safety (2010) relating to meeting nutritional needs. The Health Inspectorate Wales monitor this through dignity and essential care inspections. Healthcare Improvement Scotland monitors nutrition and runs the Improving Nutritional Care Programme. Standards of nutritional care for Scotland are laid out in Food Fluid and Nutritional Care in Hospitals (2003). In Northern Ireland the Regulation and Quality Improvement Authority has produced Minimum Standards for Care in Nursing Homes, Residential Care and Day Care settings, which include standards for nutrition (Department of Health, Social Services and Public Safety, 2008; 2011; 2012).

The recent Care Quality Commission report into Dignity and Nutrition (2011) found that in hospitals, where there were problems, the recurrent themes were:

- Patients were not given the help they needed to eat, which meant they struggled to eat or were physically unable to eat meals.
- Patients were interrupted during meals and had to leave their food unfinished.
- Needs of patients were not always assessed properly, which meant they did not always get the care they needed, e.g. specialist diets.
- Records of food and drink were not kept accurately, so progress was not monitored.
- Many patients were unable to wash their hands before meals.

These themes are not new and have been the subject of high profile campaigns and media coverage e.g. Hungry to be Heard (Age Concern, 2006) and Still Hungry to be Heard (Age UK, 2010).

Care must be taken to promote a positive approach to food and the mealtime experience in all healthcare settings. Table 3.3.10 lists some examples of factors that will contribute to positive nutritional care. There should be a team approach to caring for older people. Working with this group will often entail being part of one or more multidisciplinary teams. The exact make up of each team will vary according to setting, speciality and funding. Good, effective team working can improve patients' nutritional status as each team member understands the role

Table 3.3.10 Factors promoting nutritional care

Factor	Comment
Snacks	Snacks should be available between meals. Patients may often only be able to manage small portion sizes and rely on snacks to make up their nutritional deficit. Nourishing drinks should be available, e.g. milky drinks
Appropriate meals	Dishes, timings and dining arrangements should be appropriate to the population they are for. Routines should be flexible enough to be able to cope with individual needs. There should be a choice of portion sizes and the provision of seconds for those who are still hungry. A range of drinks should be available during and after the meal. Meals should be culturally appropriate and meet religious requirements where necessary. If required there should be the ability to fortify foods to increase nutritional content
Assistance	Appropriate assistance with eating and drinking should be available when needed from appropriately trained staff. The need for assistance should be assessed on admission and reviewed regularly
Team work	Nutritional care of patients is the responsibility of the entire health and social team. There should be effective communication between the team members and the patient and their relatives to ensure a consistent message
Eating area	Where there is a dining room it should be comfortable, clean and tidy and have appropriate furniture for the older people who will be using the room. Where there is no dining room, bed tables should be cleared and cleaned prior to meal times
Hygiene	People should be given the opportunity to use the toilet and wash their hands prior to meal service. Good oral hygiene should be promoted
Adaptations	Eating and drinking aids should be available for those people who require them. Modified texture diets should only be used where this will benefit the patient

Table 3.3.11 Range of services available in the community setting

Services to prevent hospital admission or provide support post discharge	Social services or private care packages Community meals – may be hot meals on wheels or regular delivery of frozen meals Rapid response teams to reduce admission Early supported discharge teams to provide immediate post discharge support and reduce readmission Intermediate care teams to provide rehabilitation at home Day hospital Respite care
Local community services	Over 60s clubs Retirement clubs Lunch clubs Community centres Day centres Cultural and religious activities
Shopping services	Dial a Ride Free bus laid on by supermarket Internet or telephone shopping and delivery
Voluntary services	Age UK Disease specific groups, e.g. Alzheimer's Society, Stroke Association and stroke clubs, Parkinson's Society Carers UK Citizens Advice CRUSE – bereavement care Ex services groups, e.g. Royal British Legion Admiral Nurses – Dementia UK

that they perform and the contribution to nutritional care that they bring.

Promoting independence and rehabilitation

There is a range of community based services to promote independent living for older people. Providers range from local authorities to private companies and the voluntary sector. The services available in any one area differ, as do access routes and eligibility criteria. Much support for older people is provided by family and friends who

may be of a similar age to the person they are helping. Table 3.3.11 shows the range of services available in the community setting.

People in low income groups

Rachel Barton and Diane Talbot

Key points

- The links between poverty, poor health and diet related inequalities in health are well recognised, and dietitians need to be aware of these.
- Dietitians need to understand the issues for people living in poverty and the impact on food choice when offering any dietary advice.
- Dietitians need to be involved in policy development in relation to food and health strategies. They have a role in helping to ensure that issues of poverty, and their impact on the ability to make healthier food choices, are understood and taken into account by policy makers.
- Working with individuals and communities living on a low income poses challenges for dietitians. These may require the dietitian to use new and varied ways of working, leading to the development of new skills and competencies, particularly in the field of public health.

Whilst the developed world does not experience the same level of poverty related malnutrition as the developing world, there are still clear links between diet and inequalities in health. This chapter considers why those with the lowest income have the poorest diet and examines some of the difficulties people on a low income encounter in relation to food. It discusses the size and nature of the problem; the barriers to eating a healthy diet and some of the ways in which the problems people experience may be overcome.

It is estimated that 60% of premature deaths in Britain are due to non-communicable diseases, including coronary heart disease and cancer. Poor nutrition is estimated to be a contributory factor in one-third of all cancers (Department of Health, 1998), nearly 30% of deaths from coronary heart disease (Peterson & Rayner, 2003) and 30% of years are lost due to disability or early death (WHO, 2002). The Department of Health has estimated that if diets followed nutritional guidelines, around 70 000 deaths in the UK could be prevented each year and that the health benefits [in terms of quality adjusted life years (QALYs)] would be as high as £20 billion each year (Cabinet Office, 2008).

Within the last two decades numerous policy documents, including *Choosing a Better Diet: A Food and Health Action Plan* (Department of Health, 2005a) and more recently *Healthy Lives, Healthy People: Our Strategy for Public Health in England* (Department of Health, 2010a) have highlighted areas for action to improve the

diets of individuals, and set out strategies to reduce fat, sugar and salt consumption, and to increase intakes of fruit and vegetables. All of these documents recognise the links between poor diet and deprivation.

The Marmot Review (2010) extensively highlighted a systematic pattern of declining health linked to socioeconomic status: the social gradient. Shorter life expectancy and greater disability are concentrated in some of the poorest areas of England. This means that people living in disadvantaged areas are more likely to bear a higher burden of ill health (Department of Health, 2010b). Inequalities are not limited to life expectancy and are also present for diseases and conditions that impact on a person's quality of life. Marmot (2010) noted a gap in life expectancy of 7 years between the richest and poorest neighbourhoods and a gap in disability free life expectancy of up to 17 years.

Whilst dietitians cannot alleviate poverty directly, they can, by means of sensitive and appropriate advice, help to minimise some of the nutritional consequences. Dietitians also have a responsibility to highlight to policy makers and planners the nutrition related inequalities in health that can result from low income.

Links between low income, diet and health

Evidence shows that there is a wide health divide between the richer and poorer sections of society in the UK (Acheson, 1998; Marmot, 2010). People in lower income

Physically inactive (%)	15	15	17	24	22	22

groups have a higher prevalence of diet related conditions such as obesity, hypertension, high serum cholesterol and anaemia, and are more likely to suffer a premature death from coronary heart disease or cancer (Table 3.4.1). Children from lower income groups are more likely to have a low birth weight, birth abnormalities, poor growth, poor oral health or die in the perinatal period (see Chapter 3.2). Data from the UK National Child Measurement Program 2009/10 showed an almost linear relationship between the prevalence of obesity in children and deprivation. Among children in the first year (reception) of school, obesity prevalence ranged from 6.6% in the least deprived tenth of the population to 12.2% in the most deprived tenth. In Year 6 (10–11 years), this range was 12.6–22.8% (Health & Social Care Information Centre, 2010).

While many factors contribute to the increased risk of certain diseases, it is now widely accepted that dietary factors play an important role. Many UK dietary surveys (Gregory *et al.*, 1990; 2000) show the same pattern: lower income groups consume a diet containing fewer essential nutrients but more fat and sugars than those in higher income groups. The more recent National Diet and Nutrition Survey (NDNS) (Henderson *et al.*, 2002) confirmed this and highlighted that people in receipt of benefit were less likely to eat oily fish, whole grain and high fibre breakfast cereals, and more likely to consume less healthy alternatives, such as chips, table sugar, burgers, kebabs, meat pies, pastries and whole milk.

Increased concern in relation to dietary intake and low income led to the commission of a nutritional survey specifically focusing on low income groups. The Low

Income Diet and Nutrition Survey (Nelson *et al.*, 2007a) included over 3600 adults and children from throughout the UK and living in households that fell into (approximately) the bottom 15% of the population in terms of material deprivation. The results were similar to those found in other surveys and broadly showed that those surveyed failed to meet population dietary targets, had poor micronutrient intakes, high body mass index (BMI) and blood pressure, and low reported levels of physical activity.

Size and nature of the problem

Unlike most other European countries, the UK does not have an official poverty line below which people are defined as poor. However, there are a range of measures that are frequently used to identify those in society with insufficient resources. While each measure of poverty has advantages and disadvantages, it is important to note that each often produces different estimates and identifies different groups as poor. *Minor changes in available income can be critical in determining how much households can afford for food, which is an essential but flexible budget item* (Dowler, 2008).

It would be wrong to assume that poverty is a static phenomenon and that the poor are a homogeneous group. There have always been groups in societies who are vulnerable, such as the elderly, disabled, chronically ill and those from ethnic minorities. Often these groups have fewer resources and many have struggled to make ends meet. However, over the last decade, the proportion of children and pensioners in poverty has fallen, while

the proportion of working age adults in poverty has remained unchanged. As a result, more than half the people who live in poverty are working aged adults (Palmer *et al.*, 2007) and 53% of children have one or both parents in work (Department of Works and Pensions, 2010). Research suggests that individuals or households may enter poverty either because they are excluded from employment or their wages are insufficient to provide their families with adequate resources. People move in and out of poverty; some experience repeated spells in poverty as, while they may move out of poverty, this escape is short lived and they oscillate between being in and out of poverty. This movement affects the financial and other resources to which individuals have access and in turn limits their opportunities for adopting a healthy diet.

There has been a rise in the number of poor people and a widening of the gap between the rich and the poor (Hills, 1995; Babb, 2005). A common threshold of low income is one <60% of the median income. In 2005–2006, approximately 13 million people (22% of the population) in Great Britain were living in households below this income threshold and until 2004–2005; about 15% of the population (nine million individuals) had been in this category for 2 of 3 years, i.e. living in what might be termed persistent low income poverty (New Policy Institute, 2008). Parents living in poverty are more likely to be experiencing poor mental and/or physical health, to be disabled or to be caring for a disabled relative; this has an impact on children's immediate health and future life chances.

Disabled adults are twice as likely to live in low income households. While the number of children living in poverty has reduced by 6% since 1998–1999, it was estimated that 20% of children (2.6 million) in the UK were living in low income households in 2009–2010 (Department of Work and Pensions, 2011). This may be an underestimate; e.g. the Children's Commissioner cited 3.5 million children in low income families in 2010. Ethnicity also plays a part in childhood poverty with 63% of children from Pakistani or Bangladeshi families living in poverty compared with 25% of white children. The average risk of a child being poor is 28%.

It is also important to note that while half of those people living on low income live in the most deprived areas of the country, the other half live outside these areas and may not benefit from policies that target poverty in areas of known deprivation. Although poverty levels have been falling in recent years, the difference between rich and poor households is still significant.

A number of studies have investigated the effects of living in poverty. A 2003 survey for the National Children's Home (NCH, 2004) found that:

- Almost half of parents (46%) had gone short of food during the previous 12 months to meet the needs of someone else in their family.
- Over one-third (36%) said that they had gone without food so that others in the family could eat.

- One in five (20%) families said that they did not have enough money for food, with a further 40% saying that they had only just enough money for food.
- Of the families on income support, several said that they had been so desperate for money they had considered doing something illegal.

In the UK, social security benefit levels are sometimes used as an indicator of those living on a low income as, in theory, they represent the safety net; the amount of income required to live on. In 2005, 4.25 million people were in families that were reliant on means tested benefits. However, the amount of income that a family living on benefit receives is not generous. This money has to cover all household and family expenses such as food, utility and other bills, school costs, travel, household consumables as well as larger items such as furniture, birthday and other celebrations, and presents. The Low Income Diet and Nutrition Survey (LIDNS) found the median spend on food was £28 per person per week, which included eating out, but excluded alcoholic drinks (Nelson *et al.*, 2007a). Given the limited income of families in this study, it is not surprising that they were unable to afford to follow healthy eating guidelines. *'Food poverty is worse diet, worse access, worse health, higher percentage of income on food and less choice from a restricted range of foods. Above all food poverty is about less or almost no consumption of fruit and vegetables'* (Lang, 2009).

Food poverty is defined as those households that *'do not have enough food to meet the energy and nutrient needs of all their members'* (DeRose *et al.*, 1998) and this is influenced not only by the cost of healthy food, but also the availability of healthy food in a local area as well. Evidence has shown that a healthy diet is more expensive than a diet that is based mainly on foods that are considerably higher in fats and sugars (Drenowski & Darman, 2005). It has also been found that the cost of a diet that adhered to nutritional standards was 88% more expensive in small local shops compared to the same diet bought in an out of town supermarket (O'Neill, 2005). Many people living on a low income rely heavily on local shops, as they cannot readily access out of town supermarkets. This illustrates an inequality in the affordability of healthy food for people living on a low income and thus a limited amount of money to spend on food, and is one of the reasons healthy eating guidelines are not followed (see Chapter 4.2).

Nutritional consequences of low income

The LIDNS (2007) set out to assess the diets of the low income population to determine the extent to which they vary from expert recommendations, whilst also providing data on height, weight and blood pressure for a representative sample of low income individuals and examining relationships between diet and risk factors in later life. The broad conclusions drawn from the study were that the dietary patterns of many low income households

were falling short of those recommended for health and that there were reasons to be concerned about the health consequences of following such a diet (Nelson *et al.*, 2007b). More detailed results are summarised below:

- The average number of fruit and vegetable portions eaten daily was: men 2.4, women 2.5, boys 1.6, girls 2.0.
- Compared with adult National Diet and Nutrition Survey (NDNS) data, adults in the LIDNS were less likely to eat wholemeal bread and vegetables, and more likely to drink more soft drinks (but not more low calorie diet drinks) and eat more processed meats, whole milk and sugar.
- Non-milk extrinsic sugars accounted for 14% and 17% of food energy for adults and children, respectively.
- Percentages of food energy from total fat were 35.9% (men), 35.2% (women), 36.1% (boys) and 35.7% (girls).

Average daily intakes of most vitamins and minerals from food sources were found to be above or close to the reference nutrient intake (RNI). There was a proportion of the population whose intake fell well below the RNI for iron, magnesium, potassium and zinc, and the intake for some was lower than the lower RNI. This was especially noticeable for iron.

The LIDNS was the first to use a food security questionnaire in a national survey. About 30% of households within this low income population lived in food insecure households, which meant they had reported that during the previous year their access to enough food that was both sufficiently varied and culturally appropriate to sustain an active and healthy lifestyle had been limited by lack of money or other resources. Thirty-nine per cent reported having worried that their food would run out before they had money for more and 22% reported that they reduced or skipped meals regularly because of lack of money, with 5% reporting not eating for a whole day because they did not have enough money to buy food.

Low income issues and dietetic practice

When working with low income households, dietitians have to address a very complex situation in which access to food and shops, prices, budgeting strategies, patterns of food choice as well as the need for social and cultural acceptability all interact. The challenge for dietitians is to find ways of maximising the opportunities available to people on a low income to incorporate a healthier diet into their daily lives. Dietitians must understand how these factors interact in order to ensure that the information and the advice that they give is appropriate, and that the particular individual or family has the resources to implement the guidance given. Dietitians working with low income groups should have a knowledge of available benefits and be able to direct clients as appropriate. The Citizen's Advice Bureau is a good starting place (www.adviceguide.org.uk).

The UK Child Poverty Action Group (CPAG) looked at the causes of food poverty (Dowler *et al.*, 2001) and

highlighted its complexity and the multifactorial nature of what determines food security for households and individuals within the UK (Figure 3.4.1). Factors that contribute to food poverty in people living on low income include:

- Food affordability.
- Food access and availability.
- Food access through institutions, e.g. schools.
- Food usage.

An earlier study by Dobson *et al.*, (1994) examined the food choices of families and identified some of the difficulties and barriers faced when eating on a limited budget. All families who participated in this study struggled to make ends meet and their main concern was feeding their families and preventing children from going hungry. They had all changed their food buying habits in an attempt to economise and the cost of food took precedence over issues of taste, cultural acceptability and healthy eating. The responsibility for budgeting and feeding the family rested with the mother. Many found themselves having to ration food to ensure that there would be enough. Families tended to shop little and often at local discount supermarkets as they could not commit income to buying in bulk or in advance from large supermarkets or food cooperatives. In addition, families resisted radical changes and tried to maintain conventional eating patterns, often eating cheaper versions of familiar mainstream meals. They had worked out that it was cheaper to buy prepared foods from discount supermarkets than to buy raw ingredients. A limited income also discouraged experiments with new foods in case children and partners did not like them and so refused to eat them. Parents were concerned that their children should not appear different from their peers; having crisps or chocolate to take to school was not seen as a luxury but as a way of participating in conventional behaviour. Families were aware of the need to eat healthily but the difficulty for many was how to achieve this given the constraints of a limited income. It was often considered infeasible to adopt advice on healthy eating or this advice could only be partially carried through. The advice that many families received would have involved making substantial changes to their diet, which few could risk or afford.

This study did not include travellers, the homeless or those living in temporary accommodation such as hostels or bed and breakfasts. For these individuals and families, the difficulties are even more severe as many will not have access to cooking or storage facilities. Therefore, the advice given to these groups needs to reflect the realities of their everyday life.

In order to work with groups to enable them to change their dietary behaviour, the complexities surrounding food choice and its multifactorial nature, as outlined earlier, must be acknowledged. Health behaviour is deeply embedded in people's social and material circumstances and their cultural context. In 2007, the National Institute for Health and Care Excellence (NICE) published guidelines on promoting health related

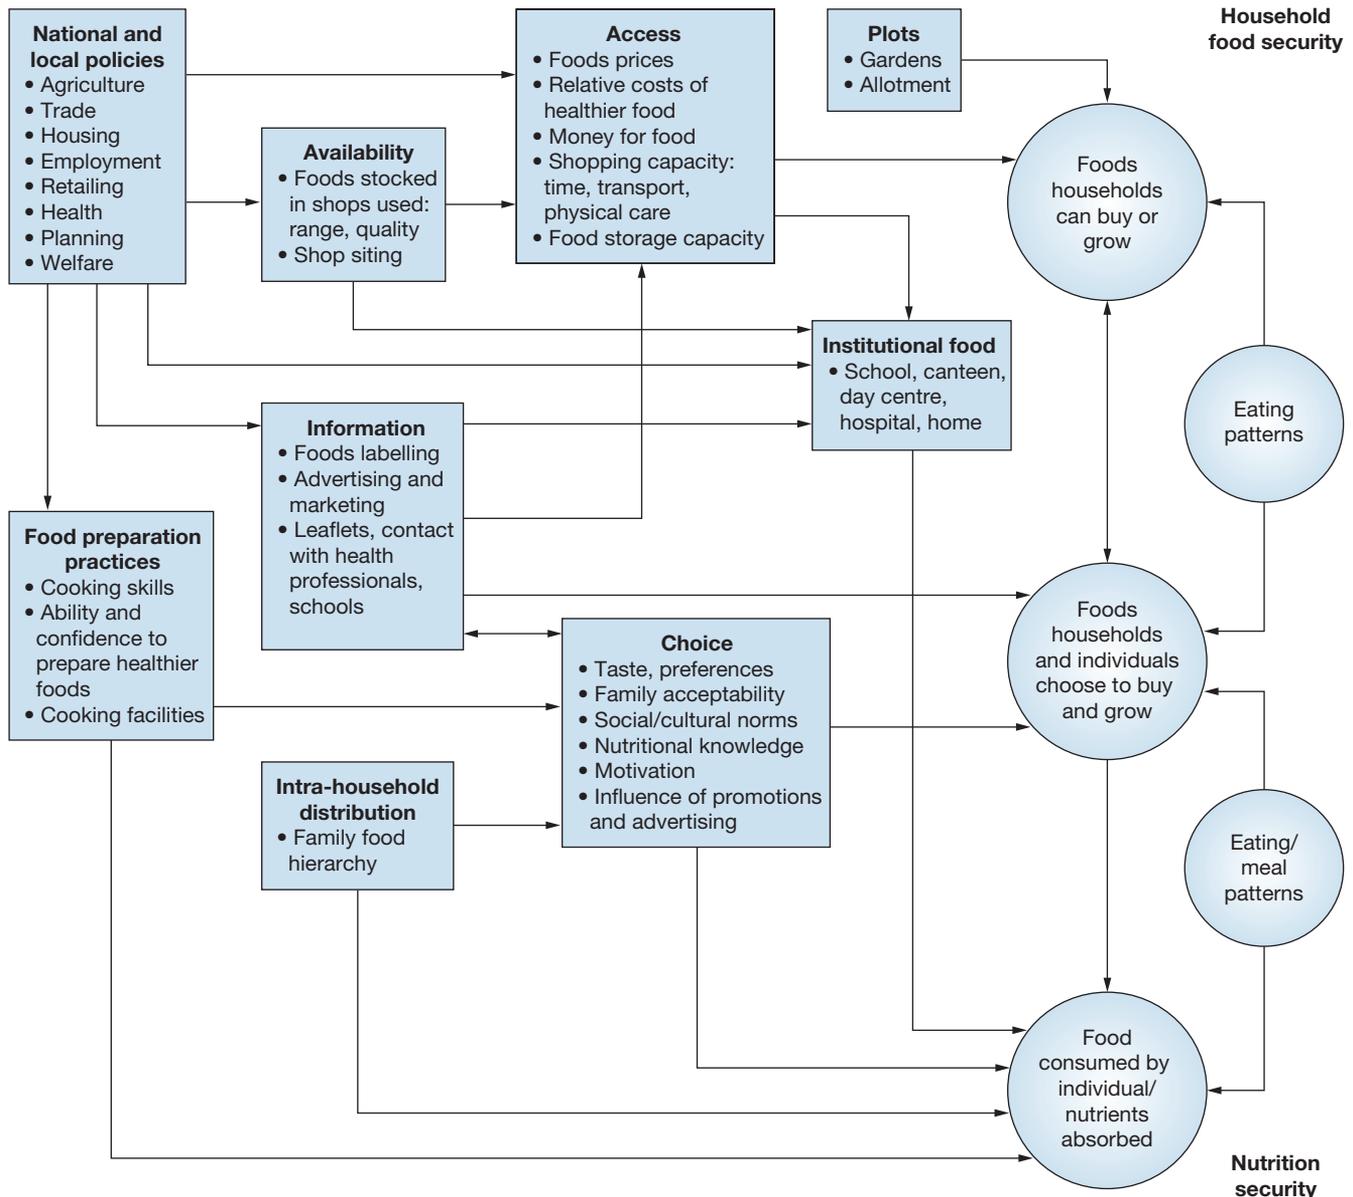

Figure 3.4.1 Framework of the barriers to healthy eating on a low income [source: Dowler *et al.* 2001. Reproduced with permission of the Child Poverty Action Group (CPAG)]

behavioural change. The guidance is for interventions at population, community and individual level. It identifies certain features that should be characteristic of interventions designed to promote health related behaviour change:

- They should be based on a needs assessment or knowledge of the target audience.
- They should take into account the circumstances in which people live, especially the socioeconomic and cultural context.
- They should be tailored to tackle the individual beliefs, attitudes, intentions, skills and knowledge associated with the target behaviour, e.g. healthy eating.
- Work should be developed in collaboration with the target population and take into account lay wisdom about barriers and change.

- Messages should be consistent with other national and local interventions.
- Key life stages or times when people are more open to change (such as pregnancy, starting or leaving school and entering or leaving the workforce) should be used.

Policy response to low income issues

The link between diet, poverty and health has been well documented, together with overwhelming evidence that a poor diet increases the risk of certain diseases. In addition, Marmot (2010) recently recognised the need for ensuring a healthy standard of living for all in order to reduce health inequalities. The NHS Plan (Department of Health, 2000) referred directly to the need to increase the intake of fruit and vegetables by improving availability

and affordability; it launched the 5 A DAY programme. The programme included:

- School fruit and vegetable scheme.
- Local 5 A DAY initiatives.
- 5 A DAY programme, including a communications programme.
- Work with industry.

In 2004, the government launched Healthy Start as a replacement for the welfare food scheme, which targeted low income families and provided milk and vitamins to expectant and nursing mothers, babies and children under the age of 5 years. A review of the original scheme carried out by the Committee on Medical Aspects of Food and Nutrition Policy (Department of Health, 1999) concluded that the scheme did not meet the wider nutritional needs of pregnant and nursing mothers and young children. It concluded that the original scheme acted as a disincentive to breast feeding by providing up to twice as much infant formula as a 6–12-month-old baby required, and also provided more milk than children aged 1–5 years required. The current scheme targets pregnant women and families with children under the age of 4 years who are in receipt of some key means tested benefits and all pregnant women under the age of 18 years. Recipients now receive weekly vouchers to exchange in registered shops for modest quantities of milk, fresh fruit or vegetables or infant formula, and for vitamin supplements from health distribution points (Department of Health, 2004) (see Chapter 3.2).

Recognition of the impact of diet related inequalities in health led to the UK government including improving nutrition within low income and socially excluded groups as a key commitment in tackling health inequalities (Department of Health, 2003; 2005b; 2005c). These policies recognised the role that all government departments can play in tackling inequalities in health. Alongside this, the Department of Health Food and Health Action Plan was published (Department of Health, 2005a). Although there was no explicit focus on inequalities, population wide interventions were advocated, including social marketing, public food procurement, food labelling, restrictions on food marketing to children and processed food reformulation, which potentially benefit low income households alongside the majority (Dowler, 2008). In 2004, the National Heart Forum produced a tool kit *Nutrition and food poverty* (Press, 2004) that was aimed at supporting people who were developing or implementing local nutrition and poverty strategies.

Dietitians have increasingly looked for alternative ways of encouraging people to make changes to their diets since empirical research has shown that, for low income groups, nutrition education has a limited role (Kennedy *et al.*, 1999). The reasons for this are summarised in Box 3.4.1. A number of community projects involving dietitians have adopted a community development approach or have used methods such as social marketing to ensure local communities are involved in the development of project methodology more commonly seen within social

Box 3.4.1 Reasons for the limited role of nutrition education for low income groups [Kennedy *et al.* (1999)]

- Traditional approaches to nutrition education have shown limited success in changing food consumption patterns of low income households
- The main barrier to change is not ignorance of nutrition but the sum effect of social, cultural and economic factors
- The unidimensional model of knowledge, attitudes and behaviour is too simplistic
- The combination and interrelationship of factors has a more powerful effect on the individual's ability to exercise informed choice
- Nutrition education is clearly only part of the solution
- Even using more contemporary methods of nutrition education, people with limited resources are less likely to adopt recommended dietary changes unless other barriers to healthy eating are also dealt with
- More comprehensive approaches are needed
- Evaluation of the effectiveness of nutrition education and health promotion work at the community level is urgently required

sciences. Community development is an interactive and iterative process that should involve genuine partnership between local people, local workers and professionals. It is a process that has been described as '*working to stimulate and encourage communities to express their needs*' and then to work with all those concerned to address these needs (Ewles & Simnett, 1995).

Dietitians have used community development to ensure initiatives include the needs and food concerns of local people. Community based food projects use familiar foods that are available locally and dietitians work with local people to identify dietary changes that they can achieve, afford and are acceptable to the whole family (Dobson *et al.*, 2000).

An interesting development has been the use of non-dietetic workers in food projects, i.e. members of the communities in which the projects are based. The emergence of these new practitioners has necessitated the development of training programmes to enable these workers to go into communities and work with local people to address their food concerns (Le Cornu *et al.*, 2010; Kennedy *et al.*, 2008). Their involvement has included running a number of different sessions including 'cook and eat' and food tastings, as well as providing healthy eating advice and supporting food related community activities.

In recent years the Department of Health (2011) has introduced social marketing to facilitate change in health behaviours. Health related social marketing is the systematic application of commercial marketing concepts and

techniques, such as insight generation and customer segmentation, to promote healthy behaviour in an appropriate way to the appropriate group of people. Essentially, social marketing is about understanding people's starting point in relation to an issue, e.g. healthy eating (Medical Research Council, 2007). The key questions are:

- What in their behaviours places them at risk?
- What drives their current behaviours?
- How might they be motivated to change?
- Who might be able to influence them?
- What might act as barriers to change?

Examples of using social marketing to change behaviours in relation to childhood obesity are the Change4Life project in the UK and the EPODE (Ensemble, Prévenons l'Obésité des Enfants or 'Together, let's prevent obesity in children) programme in France. The Change4Life campaign developed tools and messages aimed at specific groups of families identified as at risk of childhood obesity. Using research into food and physical activity behaviours (insight generation), families were split into six distinct groups, each with different characteristics, including socioeconomic class, age of mother, awareness of risk and intent to change (customer segmentation). Specific campaigns were developed using this insight generation and customer segmentation, which could be used by local health workers, businesses and community groups (Department of Health, 2008). The Change4Life evaluation indicated that 30% of mothers with children aged 2–11 years claimed to have changed at least one thing in their children's diets and activity levels as a direct result of Change4Life (Department of Health, 2010c). Dietitians can incorporate these techniques into targeted interventions with hard to reach groups, including those living on a low income. The EPODE programme in France used a whole town approach to social marketing and, alongside school based activities, different promotions were designed for different locations across the town but all with the same message. Over the course of 5 years, children aged between 5 and 12 years were weighed and measured. Results from the programme showed a reduction in mean BMI in participating towns compared with control towns (Ramon *et al.*, 2009).

Although community development and social marketing offer dietitians innovative ways to work with local people to change eating behaviour, they also present them with a number of challenges that must be addressed if these approaches are to prove effective. Dietitians need to be involved in the development of policy to address food security and food poverty work with communities and within public health departments and settings.

3.5

Dietary patterns of black and minority ethnic groups

Aruna Thaker

Additional contributors: Heidi Chan, Ruth Kander, Christina Merryfield and Elzbieta Szymula

Key points

- The traditional diet of first generation Black and minority ethnic groups was well balanced, high in fibre and low in saturated fats.
- Most migrants adopt western eating habits, whilst maintaining some of their traditional eating habits.
- Over the years, the adoption of unhealthy western eating patterns and changes in lifestyle has resulted in a rise of chronic diseases in ethnic groups.
- There is robust evidence that diet, with other lifestyle changes, plays an important part in maintaining optimum health and in the treatment of chronic disease, but no systematic research has been undertaken for Black and minority ethnic groups in the UK to support this.
- Dietitians need to make a careful individual assessment of where a client is in the process of dietary acculturation before tailoring dietary advice.

The UK is a multicultural, multiracial society. Over many years, migration to the UK, mainly from Europe, was driven by political upheaval or war. However, during the 1950s and 1960s, due to expansion in different manufacturing and infrastructure sectors, young men were systematically recruited from British colonies such as the West Indies, India, Pakistan, Bangladesh, China and Hong Kong to fill an increasing shortage of labour that was created by the Second World War. Due to their status as British subjects, these young men settled with their families in the UK. Migration of Black and minority ethnic (BME) groups peaked during 1970s, as there were changes in the migration law and deportation of South Asians from Uganda, a former British colony. It has been shown that these migrants have contributed to the economic development of the UK over the last 60 years. For example, the British curry industry, which is Bangladeshi dominated, contributes approximately £4.5 billion to the British economy (Federation of Bangladeshi Caterers, 2008). In recent years, many cultural groups have arrived from the European Union as well as war zones of the world as asylum seekers or refugees, e.g. Tamils, Somalis and Iranians.

In the 2001 census, the size of the BME population in the UK was 4.6 million (7.9% of the total population) (ONS, 2004a). The largest category was South Asians, accounting for 2 million people or 3.6% of the UK population. The second largest group was comprised of 1.0%

Black Caribbean and 0.8% Black African people. Their geographical distribution in England was uneven with most living in Greater London, the West Midlands and other metropolitan counties (ONS, 2004a,b). The first generation of migrants mostly stayed within their communities in the large cities, as there were ample job opportunities. However, the second generation, who were born and educated in this country, are much more mobile and are more willing to move to different parts of the UK where there are job prospects.

The profiles for Scotland, Wales and Northern Ireland differ substantially from England. In Scotland, the BME population is just over 2%, with the main concentrations in the four largest cities. The South Asian population totals nearly 1% of the Scottish population, whilst the next largest BME group is Chinese at 0.3% (ONS, 2004a,b).

It is now acknowledged that the BME population is generally disadvantaged in terms of health (Erens *et al.*, 2001; Balarajan & Raleigh, 1995). The prevalence of disorders such as diabetes, heart disease, hypertension, stroke, cancer and mental illness tends to be higher in BME groups; good nutrition is important in the prevention of these diseases. Despite increased health needs, uptake of healthcare services tends to be low. Health problems are often compounded by factors such as poverty, unemployment, poor housing, communication difficulties and social isolation, in particular for women. Figure 3.5.1 shows the deprivation index of some BME

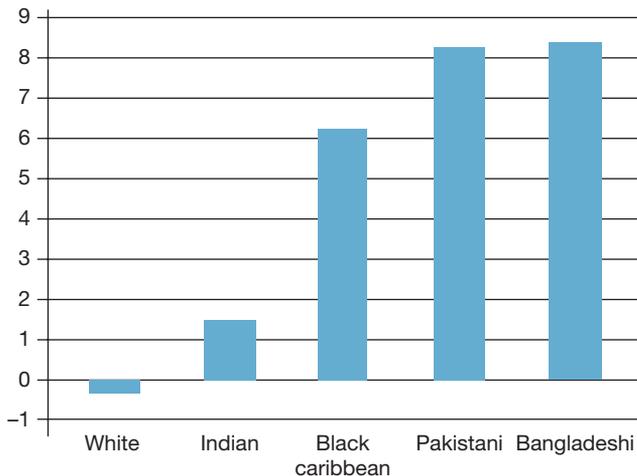

Figure 3.5.1 Relative deprivation of some ethnic groups in the UK (source: Cabinet Office Strategy Unit, *Ethnic Minorities and the Labour Market: Final Report*, 2003, figure 2.1, p. 15. Reproduced with permission under the Open Government Licence v2.0)

groups in the UK. This index combines several indicators, including unemployment rate, children in low income households, households that lack amenities (bath/shower/toilet) or a car, children in unsuitable accommodation and educational participation (Cabinet Office, 2003).

About half of those of BME origin were born in the UK, a proportion that will steadily increase and, as a result, western influences have affected traditional eating patterns to a considerable extent. Some people consume a diet that is no different from that of their indigenous peers, while others, particularly older people or those who have recently migrated, retain their traditional eating practices. This presents a major challenge in the UK, as there is enormous diversity in culture, traditions and food habits, both between and within different ethnic groups, and within a single family.

Dietitians are well placed to advise ethnic minority patients. It is erroneous to make assumptions about an individual's food habits simply based on their ethnic origin. Dietary needs should be tailored to take account of cultural factors, such as food preferences, religious dietary requirements and spoken and written language. It is vital that dietitians understand and are familiar with these factors when offering dietary guidance.

Collecting information

Dietitians can enhance their understanding by collecting information about and familiarising themselves with different ethnic groups and foods. The later section on Arabic diets should be used as an example of how to gather this information. It is important to find out about traditional foods, and the availability and affordability of the following:

- Starchy foods.
- Fruit and vegetables.
- Meat, fish, pulses, dals, nuts and seeds.
- Fats and oils.

- Milk and dairy foods.
- Sugary and fatty foods.

It is important to also consider these points:

- Try to be objective about the quality of the diet and recognise the healthy aspect of traditional foods.
- Try to find out the ethnic names of the traditional foods that form a normal part of the diet.
- Try to find out how migration, religion and culture has affected food choices, e.g. fasting and alcohol intake, as well as smoking and physical activities.
- Try to find out who is responsible for making decisions about the diet at home, e.g. shopping, different cooking methods and portion size.
- Suggest healthier acceptable western foods, which can be cheaper as some of traditional foods in the UK may be quite expensive, e.g. tropical fruit and vegetables.
- Find out how much the client is motivated to make changes and what support is received from the family members, especially, if living within an extended family.
- Find out what are the barriers for making dietary and life style changes and how these can be overcome.
- Find out what is the best way to get your message across effectively so that adherence to dietary changes is more effective and easier to achieve.
- Find out which language the client fluent in and what resources are available.
- Do not be reluctant to question the client if you are unsure about any foods or if any clarification is needed.

The aim of this chapter is to provide a short introduction to well established cultural groups, some which have only recently arrived in the UK, and to describe how to find out relevant information about these ethnic groups before consultation. This chapter can only give an introduction to this topic and more detail can be found in Thaker & Barton (2012). The cultural groups' diets that are covered are:

- South Asian sub-continent: Gujarati, Punjabi, Pakistani, Bangladeshi, Sri Lanka.
- Arabic.
- Jewish.
- African–Caribbean.
- West African.
- Chinese.
- Polish.
- Turkish.
- Greek.

South Asian sub-continent

The term South Asian defines many ethnic groups with distinctive regions of origin, languages, religions and customs, and includes people born in India, Bangladesh, Pakistan and Sri Lanka (Fox, 2004). Figure 3.5.2 shows the cultural and religious diversity of South Asians living in the UK.

The Indian sub-continent was considered the jewel in the crown of the British Empire and young Indian men were recruited to different parts of the British Empire as

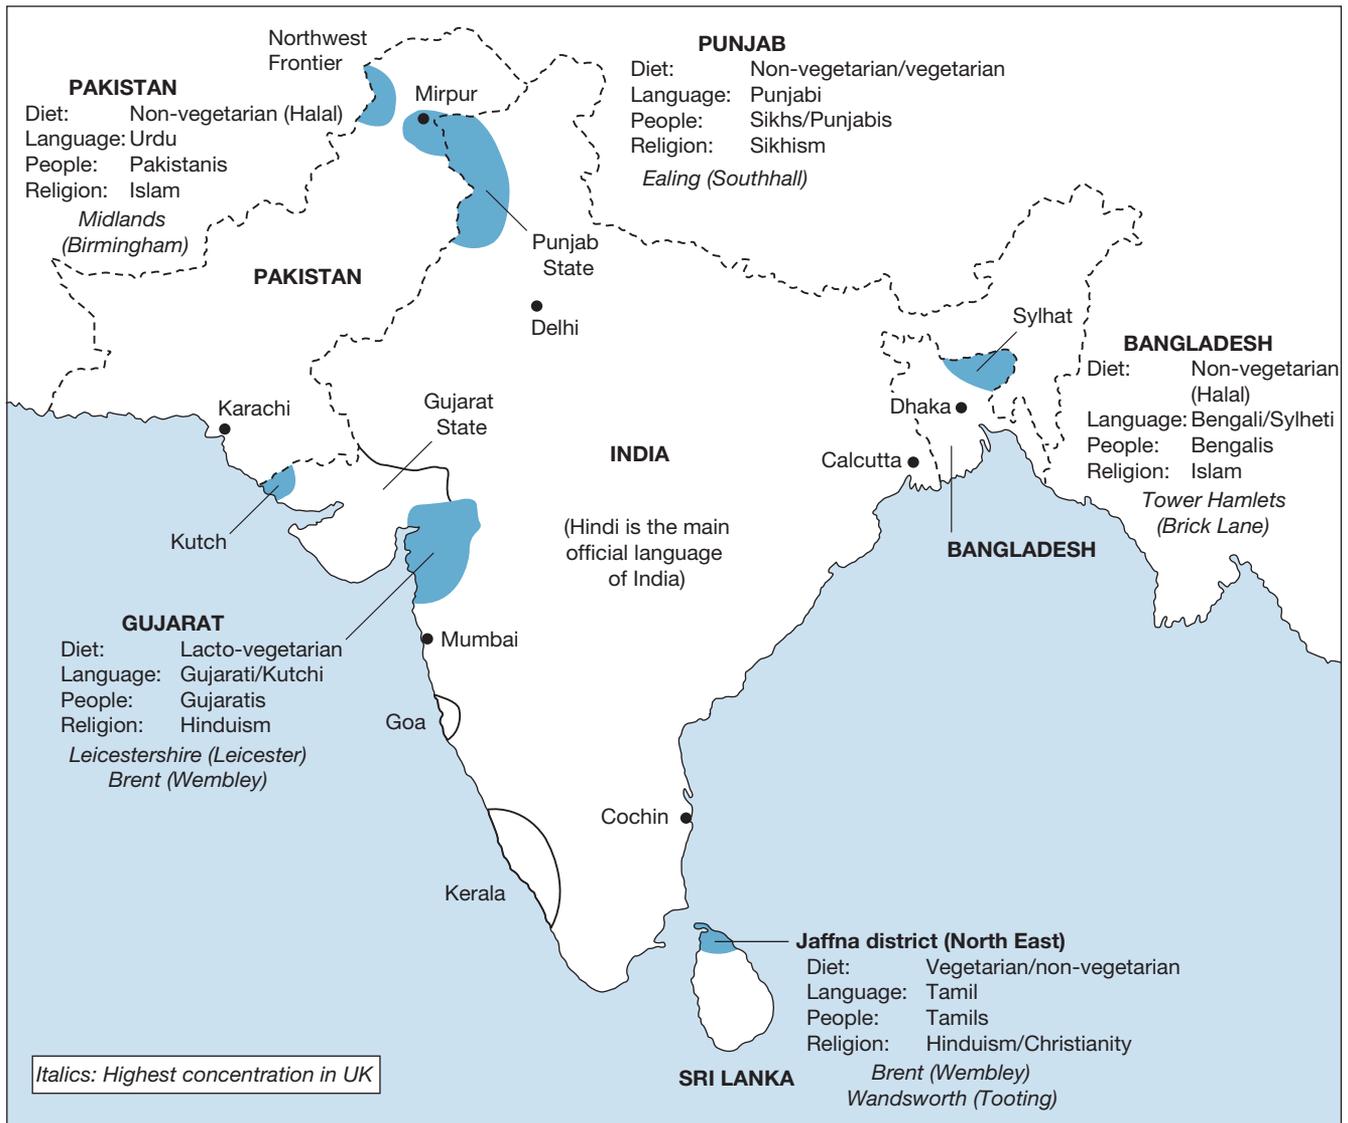

Figure 3.5.2 Cultural and religious diversity of South Asians living in the UK ([source: Thomas B, Bishop J (eds). (2007, Fig. 3.10.1, p. 361) *Manual of Dietetic Practice*, 4th edn. Oxford: Blackwell Scientific. Figure reproduced with permission of A. Thaker])

work force to develop the British colonies. In early 1900, young men from Gujarat and Punjab were recruited to lay a railway line from Mombasa in Kenya to Kampala in Uganda. After the completion of the line, these men settled with their families and helped in the development of these East African countries (Figure 3.5.3). They were able to maintain their culture and traditions in East Africa, as they were a very close knit community. In 1960, East African countries were granted independence, but after the deportation of South Asians from Uganda in 1972, the South Asians in other African countries felt unsafe and as a result many subsequently migrated to the UK. Young men from Pakistan and Bangladesh came directly to the UK after 1950. After 1980, many Tamil families migrated to the UK as refugees because of the civil war in Jaffna, the northern most region of Sri Lanka.

Due to the heterogeneity of diets consumed by South Asians, it is impossible to generalise about the nutritional

implications. These will vary from person to person depending on the nature of the diet and the extent to which it meets individual nutritional needs and provides overall dietary balance. In the UK, older South Asian people are more likely to be first generation immigrants and follow traditional customs, although this is now happening to a lesser extent. Some may not read or speak English. In contrast, the younger generation may have adopted many aspects of the westernised way of life, including dietary habits.

Religious influences on diet

Religion is an integral part of the life of South Asians and each religion has its specific dietary restrictions. The four main religions of South Asians living in the UK are Hinduism, Sikhism, Islam and Buddhism. Table 3.5.1 shows the traditional diets of the South Asian ethnic groups.

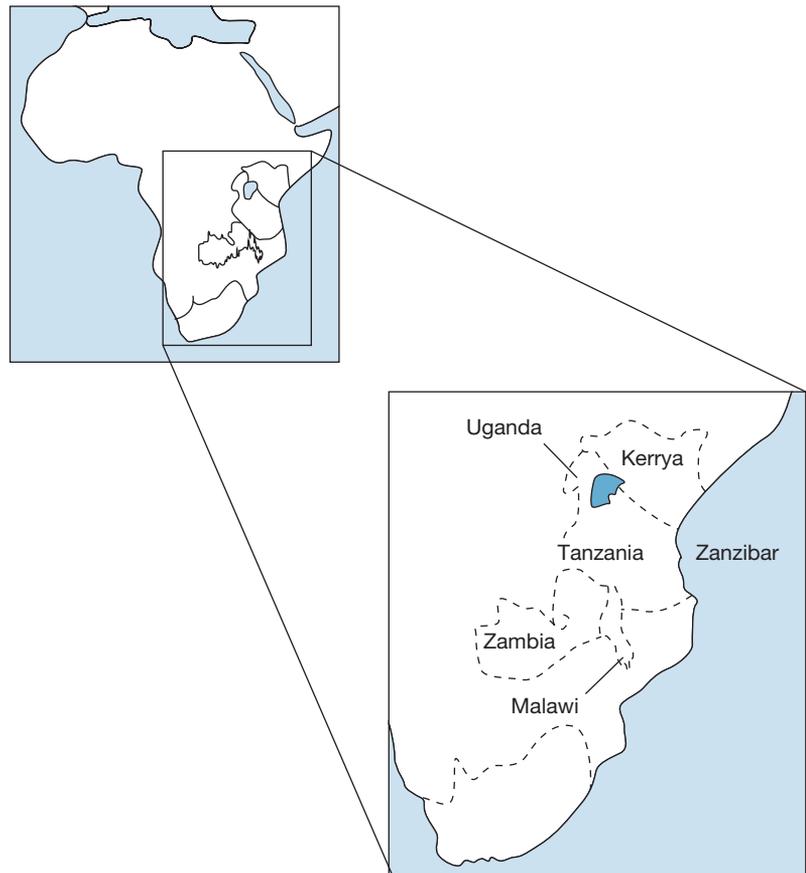

Figure 3.5.3 African origins of South Asian migrants to the UK [source: Thomas B, Bishop J (eds). (2007, Fig. 3.10.2, p. 353) *Manual of Dietetic Practice*, 4th edn. Oxford: Blackwell Scientific. Figure reproduced with permission of A. Thaker]

What is a curry?

In the UK, many people now enjoy eating South Asian foods including curry, which has become a household name. This is one of the most institutional and best loved foods in the UK but there is no dish in the Indian, Pakistani, Bengali or Sri Lankan home called curry. Curry is an Anglicised version of the Tamil word *kari*, which refers to a dish made with vegetables or meat cooked in spices with or without a sauce in the south of India. The way it is pronounced is the most likely derivation of the word curry. Curry is now generically used to describe a variety of spiced dishes from the Indian sub-continent.

It is also likely that the word was adopted during the British Raj in India when British personnel stationed in India acquired a taste for the spicy foods. These dishes and recipes were brought back and adapted to suit the British palate and personal taste. A typical British curry originally included ingredients such as sultanas, spices and sugar in a sauce and was very mild in comparison with its Indian counterpart.

The first appearance of curry on a menu in the UK was at the Coffee House in Norris Street, Haymarket, London in 1773, but the first establishment dedicated to Indian cuisine was the Hindostanee Coffee House at 34 George Street, Portman Square, London in 1809. In <200 years this industry has grown from one restaurant to approximately 9500 restaurants with a £3.2 billion annual turnover (www.tandoorimagazine.com).

India consists of 28 states, all of which have their own regional cuisine, and people who migrated from the Indian sub-continent to the UK brought their traditional local dishes with them and these are recognised by specific names in South Asian households. As previously stated, the word curry is not used in South Asian homes.

In Hindi, this dish is known as *masalaydar*, which indicates that fresh herbs and spices (*masala*) are used in the cooked dish. *Masala* is a shallow fried mixture, cooked in fat or oil, that consists of cumin seeds, onions, ginger, green chillies, garlic, tomatoes and spices, such as turmeric (*haldi*), chilli powder, *garam masala* and salt. This was one of the cooking methods used to preserve food due to the hot climate of the Indian sub-continent. Dishes that are dry are *sukhi* and those that are liquid are *tari*. These dishes will include vegetables, pulses, dals, meat, poultry, seafood and paneer (unprocessed cheese). The precise name of the dish is dependent on which of these main food ingredients is used. The following terms are used:

- Gujarati dish made with vegetables – *shaak*:
 - Dry vegetable dish – *koroo shaak*.
 - With sauce – *rasa varoo shaak*.
 - Stuffed – *bhareloo shaak*.
 - Fried – *tareloo shaak*.
 - Potatoes – known as *batata* and according to the way it is cooked, e.g. *batata nu karoo shaak*, *batata nu rasa varoo shaak* or *batata nu bharelloo shaak*.

SECTION 3

Table 3.5.1 Traditional diet of South Asian ethnic groups (from Thomas B, Bishop J (eds). (2007, Fig. 3.10.1, p. 354) *Manual of Dietetic Practice*, 4th edn. Oxford: Blackwell Scientific)

	Gujarat	Punjab	Pakistan	Bangladesh	Sri Lanka
Main staple cereals	Hindus Rotli made from whole wheat flour Millet/lowar/cornflour White rice	Muslims Chapattis/roti made from whole wheat flour or corn flour	Hindus Chapattis/roti made from whole wheat flour or corn flour	Muslims White rice Rice flour	Christians Buddhists Hindus Red rice Red rice Flour Whole wheat flour White rice
Vegetables and fruit	Vegetables cooked in oil with spices Raita/pickles Fresh fruit	Vegetables cooked in oil with spices Raita/pickles Fresh fruit	Vegetables cooked in oil with spices Raita/pickles Fresh fruit	Vegetables cooked in oil with spices Salad/pickles Fresh fruit	Vegetables cooked in oil with spices Salad/pickles Fresh fruit
Meat	No beef Might eat meat	No beef Mainly chicken and mutton	No beef Might eat meat	No pork Halal meat: chicken, mutton, lamb	Pork Chicken Mutton Lamb Or lacto vegetarian diet
Fish	White fish	–	–	White/oily/dried	White/oily
Eggs	Not eaten by strict lacto vegetarians	Not a major part of the diet	Not eaten by strict lacto vegetarians	Usually hard boiled, shallow fried or omelette	Hard boiled or omelette
Pulses and dals	Major source of protein	Major source of protein	Major source of protein	Important	Major source of protein
Dairy products	Semi-skimmed milk, yoghurt, paneer	Semi-skimmed milk, yoghurt, paneer (used for making savoury dishes)	Semi-skimmed milk, yoghurt, paneer	Full fat milk or semi-skimmed milk, yoghurt	Full fat milk or semi-skimmed milk, yoghurt
Fats/oils	Ghee Butter Groundnut/sesame oil	Ghee Butter Mustard oil	Ghee Butter Mustard oil	Ghee Butter Groundnut/mustard oil	Ghee Butter Coconut/sesame oil
Cooking methods	Breads are cooked in a frying pan or on a griddle (tava) Shallow frying Deep frying Steaming Baking	Breads are cooked in a frying pan or on a griddle (tava) Shallow frying Deep frying	Breads are cooked in a frying pan or on a griddle (tava) Shallow frying Deep frying	Breads are cooked in a frying pan or on a griddle (tava) Shallow frying Deep frying	Breads are cooked in a frying pan or on a griddle (tava) Shallow frying Deep frying Steaming

Fresh herbs and spices are used by all the cultural groups in cooking and as garnish

Note: South Asian communities in East Africa follow the traditional diet that is largely based on the area of the sub-continent from which they emigrated but might include some African starchy foods, e.g. green banana (matoke) and cassava in their diet.

- A Punjabi dish – sarson ka saag – is made with spinach and mustard leaves and served with corn flour chapatis (makke di roti).
- A Pakistani dish made with vegetables is sabji and saalan is made with meat, e.g. mutton or chicken.
- Rasam or saaru is a South Indian soup which is dal based and served with boiled rice.
- Jhol – the Bengali dish usually made with seafood or fish.

Gujarati diet

Gujaratis constitute the largest cultural group of South Asians in the UK. They migrated from Gujarat on the Northwest coast of India, but significant numbers also came via East Africa where Gujaratis became prominent in the business community. Idi Amin expelled a large number of Ugandan Gujaratis in 1972, and the majority came to the UK. Gujarati or Kachi is likely to be their first language. Most Gujaratis follow the Hindu religion and the remainder are Muslims following Islam.

Hindu religion

The Hindu religion (Dharma) is the oldest religion in the world, having existed for over 5000 years. Hinduism is founded on reverence for life, non-violence and a belief in reincarnation. Dietary restrictions were laid down in the Hindu holy book, the *Bhagavat Gita* (chapter 17, verses 2–22).

Dietary restrictions

The Hindu dietary restrictions are:

- Hindus like Buddhists and Jains are lacto vegetarians and believe in Ahimsa, meaning non-violence to all forms of life. They avoid beef, as cows are sacred, and other meat and fish. They do not eat eggs since they are potentially a source of life.
- Animal derived fats such as dripping or lard are not acceptable. Foods that contain animal products are not eaten, e.g. rennet and gelatine.
- Milk, yoghurt, paneer and butter are consumed because they do not involve killing an animal. Paneer and yoghurt are made at home with full fat milk.
- Cooking with ghee (clarified butter) is believed to sanctify food. Fruit and cooked foods, especially sweet dishes (prasad) that are offered to the deities in the temples, are made at home with ghee. Ghee and vegetable oils are used in cooking and frying.
- Alcohol is forbidden, but is consumed by some.
- Strict Hindus will be unwilling to eat food unless they are certain that the utensils used in its preparation and service have not been in contact with meat or fish.
- Less strict Hindus may eat lamb, chicken or white fish.

Festivals

The Hindu festivals and religious days are:

- Mahashivratri – the birthday of Lord Shiva (March).
- Holi (March).
- Ram Navmi – the birthday of Lord Rama (April).

- Janmastami – the birthday of Lord Krishna (August).
- Raksha Bandhan (August).
- Navaratri – nine nights (October).
- Diwali – festival of lights and New Year (October/November).

NB: all dates in this chapter are approximate as they are based on the lunar calendar.

Special sweet and savoury dishes are prepared during festival days and shared with friends and families.

Fasting

Some devout Hindus will fast regularly during the week and on religious days; it is mostly a matter of individual preference. The fast will be observed usually for a single day (24 hours) from dawn to dusk or for several days. Fasting is willingly abstaining from some or all food, drink or both. Some may have one cooked meal a day or only eat *pure* foods such as yoghurt and fruit, whilst others forego all food and may take fluids only.

Punjabi diet

Most Sikhs in Britain originate from the Punjab in India and like Gujaratis most came to the UK via East Africa. Many Sikhs came to the UK after the partition of India and there are now second and third generations in the UK. The mother tongue is Punjabi, but most Sikhs in the UK speak English and many can also converse in Hindi or Urdu.

Sikh religion

Sikhism is a reform movement, which is an offshoot of Hinduism and Islam and has developed into a religion in its own right. It started nearly 300 years ago. Guru Nanak, the first of 10 Sikh Gurus, founded Sikhism. Sikhs believe in one God. A Sikh Gurdwara (place of worship) traditionally serves meals (langar) to anyone at any time regardless of their caste, religion or class. In the UK, langar is cooked on Saturdays and served after evening prayer.

The three main principles of Sikhism are:

- Nam Japna (reciting God's name, e.g. prayers).
- Kirat Karna (honest earning).
- Vand Chhakna (helping the needy or less fortunate people, i.e. charity).

In 1699 the 10th Guru baptised the Sikhs and ordered the baptised Sikhs to wear five Ks, which are Kesh (uncut hair), Kanga (comb) Kara (steel bangle), Kirpan (small sword) and Kachhera (special shorts). Sikh men are meant to wear turbans and grow a beard; however, the majority are now clean shaven.

Dietary restrictions

Sikh dietary restriction include:

- The main food restriction is that Sikhs are not allowed to eat halal or kosher meat.
- For Sikhs this is a matter for each individual's conscience. As a group, they are less strict than Hindus and

Muslims, but for each Sikh their own self imposed restrictions are binding.

- They are unlikely to eat pork, and beef is forbidden as the cow is considered a sacred animal.
- On the Indian sub-continent, chicken, lamb and sheep are killed by the jatka method (at one stroke); however, this practice is not common in the UK.
- Meat and eggs are included in the diet; however, after the Amrit (baptism) ceremony, individuals will revert to a lacto vegetarian diet.
- It has retained many features of Hinduism, e.g. women still follow a lacto vegetarian diet, even though they cook meat dishes for family members.
- Fasting is forbidden but many Sikhs still practice this Indian tradition and women may fast in the same way as Hindus.
- Alcohol, smoking and taking recreational drugs are also prohibited, although in practice alcohol consumption by men can sometimes be excessive.

Festivals

There are three main festivals in the Sikh calendar:

- Baisakhi – the Sikh New Year's day (April).
- Diwali – the Festival of Light (October/November).
- Birth of Guru Nanak – the founder of Sikhism (November).

Pakistani and Bangladeshi diet

The South Asian Muslim community in the UK came mainly from Pakistan, Bangladesh and East Africa. However, some Muslims in the UK will have originated from the Middle East, Malaysia, Indonesia, Sri Lanka and Africa. Many Muslims of Asian origin will speak Urdu, Punjabi, Mirpuri or Bengali. Muslims who have come from India or via East Africa may also speak Gujarati; they do not speak Kachi.

Islamic religion

The religion of Muslims is Islam; the word Islam is an Arabic word meaning submission. All Muslims acknowledge the obligation to signify their submission in terms of the five pillars of Islam. These are:

- Belief in one God (Allah) and that Mohammed is his true messenger.
- Prayer – five times a day.
- Zakat – giving 2.5% of wealth to the poor and needy.
- Pilgrimage – once in a lifetime Muslims should make a pilgrimage to Mecca if they can afford it.
- Fasting – complete abstention from food and drink from dawn to sunset in the month of Ramadan.

Dietary restrictions

Muslim dietary restrictions laid down in the Holy Qur'an are:

- Animals to be ritually slaughtered while reciting the name of Allah and then blood being allowed to drain (halal meat). (Kosher meat may be acceptable.)

- All wholesome foods are halal unless it is declared unlawful (haram). Unlawful (haram) foods are:
 - Foods and food products from the pig and foods containing ingredients or additives derived from the pig, any animal that has not been ritually slaughtered or any Haram source. Strict Muslims will eat outside home provided it is halal. Halal food is now available in institutions such as schools and hospitals. Ready made halal frozen foods are produced and sold in shops. Catering organisations, e.g. restaurants or other eateries, serve halal foods.
 - In practice, this means that a wide range of manufactured foods containing gelatine, animal fats or emulsifiers derived from animal sources will be avoided.
 - Alcohol, including that used in cooking or for medicinal purposes.
- A Muslim might refuse a food if they cannot be sure that it does not contain unlawful ingredients. Similarly, a devout Muslim will be concerned that the dishes used for cooking have not been in contact with unlawful foods.
- Fish is acceptable providing it has fins and scales and for Bengali Muslims both white and oily fish forms part of the diet.

The Muslim Food Board (UK) produces a regularly updated halal food directory listing halal manufactured foods available in the UK.

Festivals

There are two major festivals in the Muslim calendar:

- Eid-al Fitr (little Eid) marks the end of the fasting month of Ramadan and celebrations are held both in the community and at home.
- Eid-al Adha (big Eid) commemorates the pilgrimage to Mecca that concludes the Hajj.

Both Eids are marked with prayers in addition to the regular daily prayers, mutual visiting by family and friends and celebratory meals. Muslims are required to sacrifice a lamb, sheep, cow or goat after Eid-al Adha. During the celebration this meat is shared amongst family, friends and the poor. In the UK Muslims may contribute financially so that an animal is slaughtered by a halal butcher in the UK or abroad and then distributed to the needy.

Fasting

Muslims are required to fast from dawn to sunset during the month of Ramadan, which is the ninth month of the Muslim (lunar) calendar. Fasting involves abstinence from all food and drink and some Muslims might also stop smoking. It is considered one of the highest forms of worship as it enables people to practise self discipline, and it helps them to appreciate and share the feelings of the poor and hungry. Muslims should rise just before sunrise (sehri), have a meal similar to breakfast and then break their fast again at sunset (iftari). Feelings of weakness and lethargy can occur because of this abstinence and, to help overcome this, some Muslims rise early and eat a substantial high carbohydrate, high fat meal before dawn. Another heavy meal is then taken after sunset.

Elderly people and children under 12 years are exempt from fasting. Women who are pregnant, breastfeeding or menstruating and people who are ill or travelling during Ramadan are also exempt, but are expected to compensate by fasting at some other time. Chronically ill people, such as those with diabetes or heart disease, for whom fasting would be physically harmful, are exempt. However, many Muslims still choose to fast and should be advised accordingly (see Chapter 7.12). Devout Muslims may also fast once or twice a week in addition to Ramadan.

Arabic diet

Arab is the generic term applied to inhabitants of the Middle East and North Africa whose mother tongue is Arabic and who are Muslims. Arabic foods were originally the food of desert nomads. It was simple and carried during travels from one area to another, such as settled farming areas and oases. Animals such as goats and camels travelled with nomadic people and provided meat and milk, often cooked over camp fires. Foods such as flour, dates, spices and vegetables were collected on the way from farms and incorporated into various dishes including bread. Although there are still nomadic people having traditional diets, food consumption has changed to incorporate foods from different parts of the world, including aspects of a western diet. Urbanisation has also played a dramatic role in changes in food consumption patterns and dietary habits.

Traditional foods groups

Bread, rice, potatoes and other starchy foods

Bread (houbus – traditional flat bread made with white wheat flour), rice (roz), couscous and potatoes are all available from supermarkets. Cassava, millet or yam is often pounded into a porridge consistency. Cassava can be made into flour to be used in sauces with meat and vegetables or fried. These are the more traditional foods from North Africa and are now available in most UK supermarkets and ethnic stores.

Fruit and vegetables

Commonly eaten vegetables include aubergines, carrots, onions, okra, courgettes, spinach, green beans and salads (lettuce, tomatoes and cucumber). These are all available, although aubergines and okra may be expensive. Commonly eaten fruit include melon, pineapple, mangoes, grapes, citrus fruit and pomegranate. Most tropical fruit, while available, tend to be expensive. Dried fruit, particularly dates (tamour) and figs, are abundant in most Arabic countries, but although available, again are more expensive in the UK.

Meat, fish, eggs, beans and other non-dairy sources of protein

Meat (lahm) – lamb, mutton and chicken (dajaaj) – are available as halal. However, other meats that are traditionally eaten are not always available in the UK; these include goat and camel.

Many varieties of fish (samak) are eaten, especially in countries such as the Gulf States that are situated on the coast. Salmon, sardines, mackerel (oily fish), prawns and other shellfish are readily available in the UK. However, others are not so available and are likely to be expensive, these include monkfish, mullet, bream and trevally, which are all white fish.

Eggs (baydh) are frequently consumed at meal times, especially breakfast.

Pulses and beans are consumed frequently in main dishes, particularly split lentils in stew (mujaddarah), chickpeas that may be whole or puréed (hummus), broad beans (fool), white kidney beans (fasulya beyda) and green beans (fasulya). A variety of beans or individual pulses may be used in one dish, such as ground broad beans (fool) and ground chickpeas (hummus). Many of these are available in the UK, although ready made foods such as fool and falafel (made from ground chickpeas, sometimes added potato, onion and flour and usually fried) will be more expensive.

Nuts and seeds are a permanent feature on the table, especially pistachios, walnuts, cashews, sunflower and pumpkin seeds (salted). These are often consumed as snacks between meals. Sesame seeds are often added to bread and pastries, often with thyme.

Milk and dairy foods

Arabs consume either full-fat or semi variety cow's milk in the UK; traditional milk is from the goat, sheep and camel. Goat's milk has become more popular in the UK and is available in supermarkets; however, sheep's milk is harder to obtain and more expensive and camel's milk is virtually impossible to buy in the UK. Powdered milk in many Arabic countries is full fat; condensed and Carnation milk (normal or light) are also used, particularly in tea.

The most commonly eaten cheeses (jebnah) are haloumi and feta, which are both usually made from a mixture of sheep's and goat's milk. Haloumi has a high melting point and can be grilled or fried whilst feta cheese is usually eaten cold with salads; both can be quite salty.

The consistency of natural yoghurt (lebneh) is between yoghurt and soft cheese. Strained yoghurt is prepared by removing the whey. This may be made at home or bought and is mostly spread on bread. Full cream cow's or camel's milk is often used.

Foods and drinks high in fat and/or sugar

Sugar (sukkar) and honey (aasat) form the basis of pastries and are used to sweeten drinks (tea and coffee). These are readily available but are often cheaper in Arabic countries. Honey is seen as having health benefits and frequently consumed. Mostly olive and sunflower oil are used in cooking but groundnut, sesame oil and ghee may also be used.

Traditional diet of first and second generation Arabs

The diet of first generation Arabs is more traditional and second generation people will include more western foods.

First generation

Breakfast may be eaten quite late (around 10–11 am) and can include many of the following items:

- Fruit juice – various.
- Eggs (fried or boiled) one or two.
- Salad such as onions, tomatoes and olives.
- Flatbread with honey or natural or strained yoghurt.
- Cereal – often cornflakes.
- Ground broad beans (fool made with garlic, olive oil and lemon).

Lunch may be eaten at about 2–3 PM and is often the main meal of the day. This is usually a mezza, which is a selection of several dishes. Bread is usually eaten with the main meal or as a starter with ground chickpeas (hummus), natural yoghurt, cracked wheat and parsley (taboulleh), ground aubergine (baba ghannou) or vine leaves stuffed with onion, garlic, tomato, rice, herbs and often minced meat (usually lamb). The meal is usually based on starchy foods, particularly rice (roz); this may be boiled or have meat juices and fat added. Other starchy foods may be specific to specific dishes, such as potatoes, cassava, yam (boiled or fried) and couscous.

Vegetables and meat, fish and pulses, such as chickpeas (hummus), lentils (aadas), broad beans (fool) and peas (basilla), are often mixed with the rice to form a stew-like dish. A salad of leaves, tomatoes, and cucumber is usually included; dressings may simply be lemon juice, garlic and olive oil.

Desserts are mixed fresh fruit or a milk pudding (rice or semolina based; mahalabia) and may be followed by (usually many) dates, often stuffed, or pastries filled with nuts and coated with honey/sugar syrup (baklava), both usually eaten with coffee.

The evening meal may be consumed late (8–9 PM) and is usually a light meal: bread (flat or sliced, white or brown) and cheese made into a sandwich or flat traditional bread filled with red or white meat eaten with cracked wheat, tomato, parsley (tabouli) and a sauce, such as sesame based one (sharwama). Meat or vegetables (usually potato; kibbeh) may be eaten. Salad (tomatoes, lettuce and olives) will accompany the meal.

Fruit juices (aasir), water, tea (shay) or Arabic coffee (ground coffee beans brewed with boiling water to which saffron, ginger and cardamom may be added) tend to be the main fluids consumed. Coffee is usually consumed in small cups and accompanied by dates or other snacks. Tea usually has moderate amounts of sugar added to it.

Second generation

If meals are not be consumed with the rest of the family, they may be skipped. A consequence of meals being eaten outside the family home (often with friends or work colleagues) has been a significant increase in intake of fast foods.

Breakfast may be a traditional breakfast or a croissant. Lunch is commonly fast foods such as, pizza, fried chicken, chips and burgers. Foods from other cultures such as pasta dishes and Chinese food have become more popular.

Desserts may include ice cream, cakes and chocolate. Chocolate bars and crisp are eaten as snacks and fizzy drinks (many diet or low calorie varieties are not available in Arab countries) may be consumed during the day. There has also been the introduction of accompaniments such as ketchup, mayonnaise, chocolate and vegetables such as mushrooms

The evening meal may be eaten with the family and this is likely to be a traditional light or main meal. However, it is common to see many Arabic people eating out with friends and to incorporate fast foods, similar to those constituting lunch. Alternatively, traditional Arabic foods may be consumed at a restaurant.

Diet quality

Healthy aspects of traditional Arabic food habits include:

- Generally meals are not skipped, i.e. three meals a day, with lunch being the main meal.
- Vegetables and/or salad included as part of main meal.
- Pulses included in dishes – olive oil may be added liberally to dishes such as hummus and fool.
- Fruit usually as a dessert, including dried (dates and figs).
- Variety of fish, including oily fish (salmon, mackerel and sardines) particularly in coastal areas. This is usually shallow fried, but oven baking is becoming more frequent.
- Dressings on salad, with the exception of olive oil, are usually low fat (lemon and garlic).
- Particularly with traditional diets, snacks include high fibre foods, e.g. nuts, dates and fruit.

Religion, culture and migration affect food choices and physical activities, e.g. fasting, alcohol intake, smoking and exercise.

Religion

Most of the populations of Arab League countries are practising Muslims, divided mainly into Sunnis and Shia. There are different branches and denominations of Islam, each with its own traditions and practices. However, the basic practices of Islam are universal. There are some Christians in some countries, such as Jordan, Lebanon, Djibouti and Sudan. Restrictions on what Muslims can eat are laid down in the Qur'an and are regarded as the direct command of Allah, as discussed earlier.

Alcohol consumption has increased due to availability and peer pressure; it is not uncommon for many Arabic people to drink alcohol at home or socially. It is unusual for Arabic women to drink alcohol. In many Arabic countries, the prevalence of men smoking cigarettes appears to be higher than among women; however, the Shisha (pipe) may be smoked by men and women and is often seen as a fashionable thing to do and less stigma is attached to women smoking this.

Many people are put off exercising (men and women) due to the hot weather; generally, physical activity is low

or not common. Physical activity may be reduced, particularly for women, who cover themselves with the hijab and who may be conscious about wearing sports clothes.

Decisions about the diet at home

These will include shopping, cooking methods and use of herbs and spices. The main female person in the household, wife or mother, usually makes the decisions. If there is more than one wife, the first wife of the household will decide about diet at home. Cooking may be carried out by the main female of the house or by maids. Often Arabic families will have maids who do the shopping and cooks who prepare the food (especially in the Gulf States). Many of these domestic helpers are from Indian or Sri Lanka and hence they may introduce the influence of Indian foods such as biryani. In the UK, women mostly do the cooking; it may be cooked daily (especially if cooks are available) or in bulk. Shallow frying is used frequently for cooking, e.g. for pastries, vegetables such as aubergines, and falafel. Many main dishes use boiling as a cooking method. However, the fat from meats is not removed in this process and other foods will be added to the dish to make stews. There appears to be healthier, low fat methods of cooking in the younger generation. Frequently used seasonings include salt (mileh), mint (nana), parsley (badoonis), nutmeg (basbasa), tumeric (kurkum), cardamom (hail), cinnamon (qurfal), black pepper (filfil aswad) and coriander (kuzbara).

Traditionally, foods such as fruit and vegetables are bought in bulk from market stalls; in the UK, traditional foods may not always be available. Arabic foods will be bought from Arabic shops and other shopping is done from supermarkets.

Dietary components

Some of the following foods tend to be more significant in the diet in Arabic countries compared with the diet in the UK:

- Portions of starchy staple foods such as rice and bread tend to be large. It is not unusual for a portion of rice to cover a full dinner plate, along with bread as an accompaniment, and meals are based around these. Due to social events and hospitality it is usual to have food available and large 'spreads'.
- Dates – these are often consumed in large amounts, e.g. five to 10 may accompany coffee that is more than once a day, usually between or after meals.
- Eggs are consumed frequently at breakfast (boiled or fried); this may be amount to one to two daily.
- Fluids – fruit juices and sugary carbonated drinks in hot climates; sugar free (low calorie) varieties may not be available.
- Fruit – particularly grapes, pineapple, melon and mangoes; however, in some countries fruit may not be widely available.
- Salads are often preferred to cooked vegetables.

Fewer if the following foods may be consumed due to the lack of availability in Arab countries:

- Fruit and vegetables may not always be available, or are seasonal; this includes frozen or tinned.
- Low fat dairy products, particularly milk, may not be available; an alternative to fresh milk may be condensed or powdered milk.
- Sugar free varieties of drinks.

In some countries multicultural outlets have increased the variety of dishes, including Italian, Chinese and Indian foods, as well as western fast foods. In the first generation low fat and sugar free foods may not be accepted, but there is greater acceptance in the second generation.

Cooking methods

Traditionally fat or juices from meat are used in stews and added to rice. Second generation Arabs appear to use less fat in cooking, although the intake of fast foods containing fats can be greater. Olive and vegetable oil are mainly used, although ghee is used for some specific dishes. With education refrying has reduced but may still be carried out by the first generation.

Dietary advice

Healthier western foods should be suggested as traditional foods in the UK are quite expensive. These include:

- Low fat milk and dairy products.
- Oils higher in monounsaturated fats, e.g. olive oil, and polyunsaturated fats, e.g. corn, sunflower and sesame oil.
- Fruit and vegetables in their frozen or tinned form, such as pineapple, mangoes, peas, various beans and tomatoes.
- Sugar free beverages.

The barriers to healthier dietary changes include:

- Eating late – lunch may be around 2–3 PM and the evening meal also late, with food spread out during the evening.
- Misconception that some foods such as honey are good for health and therefore added liberally to foods and beverages.
- Large consumption of dates in some countries due to their availability and the tradition for eating them with coffee.
- Social obligations, visiting friends and being hospitable and generous when friends visit. Welcoming people with food is a common tradition.

The following may help to improve compliance with and ease of dietary changes:

- Diet sheets to reinforce the message – bilingual diet sheets in Arabic and English are very useful as they allow family members to share the information. It is worth noting that a proportion of patients, particularly Bedouin and nomads, may be unable to read and then

visual diet sheets portraying foods and portion sizes are very useful.

- Discuss portions visually – use hands to demonstrate appropriate portion sizes.
- Quantities in spoons and cups may be better than in grams.

The following changes to the diet may be agreed with the client:

- Reducing the amount of starchy food at the main meal (rice, bread, potatoes, which can be eaten in large quantities) and replacing these with larger portions of vegetables and salad.
- White bread is predominant in Arabic countries; however, in the UK patients should be encouraged to choose wholemeal varieties.
- Although there are alternative high fibre cereals, cornflakes are widely consumed and it is worth educating patients about the availability of and types of cereals higher in fibre.
- Reducing the amount of oil in cooking (measuring oil before using) and changing to one higher in monounsaturated fats and polyunsaturated fats.
- Avoiding the fat and juice of meat in stews and rice and looking at low or non-fat cooking methods, such as oven baking, grilling and boiling foods containing fat (such as meat) initially and discarding the fluid before other ingredients are added to make stews.
- Replacing meat dishes (often lamb is used) with dal or fish. Removing visible fat from meat and skin from chicken before cooking and smaller portions.
- Changing to low fat milk and dairy products.
- Choosing sugar free carbonated drinks and reducing intake of sugar and honey.

African-Caribbean diet

African-Caribbean collectively refers to people of African descent from the many West Indian islands. The majority of people from the Caribbean, notably Jamaicans, moved to the UK during the 1950s and 1960s.

Religion

Religious beliefs influence food choice, preparation and cooking methods. Although African-Caribbean people are generally Christian, there are many faiths in the Caribbean. The two main religions that affect dietary practice are Seventh Day Adventism and Rastafarianism.

Seventh Day Adventists are often vegetarian. If meat and fish are eaten, pork is avoided, as are fish without fins and scales. Alcohol and other stimulants, e.g. coffee and tea, are avoided.

The degree of dietary restriction observed by Rastafarians depends upon the individual; many are vegetarian or vegan. The majority of followers will only eat *ital* foods, which are foods considered to be in a whole and natural state. Processed or preserved foods are excluded. Specific foods not consumed are pork, fish without fins

and scales, vine fruit and stimulants such as alcohol, coffee and tea.

As with people of South Asian origin, it is important to remember that the dietary customs of people from the Caribbean are not uniform and food habits and their cultural context play an important role in every island, with clear differences between islands. The dietary traditions of each island have been influenced by different historical, political, social and geographical factors; the development of the sugar colonies, for example, brought many different cultures to the Caribbean (HEA, 1993). As a result, dietary practices can vary considerably and dishes with similar or the same name can contain different ingredients. Alternatively, the same dish may have several names, e.g. Journey cakes are also called Jonny cakes (Douglas, 1987). There will also be variation in the degree to which individuals follow traditional eating habits; some people will consume a diet indistinguishable from the typical UK diet.

Meal pattern

The meal pattern varies with the individual or family. Traditional dishes may take a long time to prepare and are more likely to be eaten at weekends and evenings. At weekends there is a tendency towards eating two meals, omitting lunch. Popular cooking methods include stewing, braising, steaming, frying and roasting, and very often involve the use of added fat. Food is highly seasoned. Desserts are traditionally only eaten on special occasions, although this trend appears to be changing. Foods such as fruit, fruit salads and ice cream may be eaten quite commonly and other items such as apple pie and gateaux are being increasingly consumed.

Within the African-Caribbean community, beliefs about diet and health may influence dietary practices, e.g. use of herbal (bush) teas as a cure for disease.

West African diet

The majority of West Africans in the UK originate from Nigeria and Ghana and have settled in the major cities.

Traditional dietary practices

The diet consumed by West Africans is generally similar to that consumed by African-Caribbean people, but there are some differences in both food choice and cooking methods (Bailey *et al.*, 2012).

Bread, cereals and other starchy foods

Cassava, green bananas, yam, cocoyam, plantain and sweet potatoes are usually boiled, roasted or fried. Fufu is made by pounding cooked tubers like cassava, yam and cocoyam, and then dried in the sun. These ready made flours are now available in the UK. Other starchy foods include rice, corn, cornmeal millet and sorghum.

Fruit and vegetables

Commonly eaten fruit and vegetables are oranges, pawpaw, mango, ugu (pumpkin leaves), green leafy vegetables and okazi.

Meat, fish and alternatives

Meat, fish and seafoods are eaten at each meal. Among Nigerians, black eyed beans are cooked as a stew. Melon seeds (egusi), pumpkin seeds and groundnuts (peanuts) are used in cooking or as snacks.

Milk and dairy foods

Evaporated, condensed and powdered milk are used in tea and coffee.

Other dietary practices

Other dietary practices are:

- One pot meals (stew) are the most common cooking method and can include meat or fish.
- Stew is served with cassava, yam or plantain (possibly pounded), which are mostly boiled but also can be fried.
- Vegetable stew or soup is also served with starchy foods.
- Palm oil is used in cooking to give flavour and colour to the dishes.
- Nuts and seeds, e.g. Ghanaians use peanut butter to make soups.
- Nigerians eat peanuts (roasted or boiled) and cashew nuts as snacks.
- Desserts are not usually served.

Common health problems

The incidence of type 2 diabetes, hypertension and obesity is high in the West African community (Erens *et al.*, 2001). General weight reducing dietary advice is often necessary and aspects that need to be highlighted are:

- Reducing the amount of oil used in stews. Palm oil and palm nut oil are commonly used but are saturated fats; if possible, a limited amount of sunflower, corn or groundnut oil should be used instead.
- Reducing the amount of peanut butter used in soups.
- Reducing the amount of fried foods such as fried fish or meat.
- Fish, e.g. snapper, may be stewed or baked instead of being fried.
- Portion size of green bananas, yam, ground rice and other starchy foods is often quite substantial and may need to be reduced.
- Frequent use of glucose drinks such as Lucozade and other sugar rich drinks should be discouraged.

Chinese diet

The majority of Chinese people in the UK originate from Hong Kong and arrived in the UK in the 1950s and 1960s. This was partly in response to the collapse of traditional

agriculture there and partly because of the boom in the Chinese restaurant trade in Britain. Other Chinese people migrated from mainland China, Taiwan and Vietnam; Chinese people from Vietnam came as refugees (boat people) mostly after 1978.

In 2009, the estimated Chinese population in England and Wales exceeded 451 000, which accounted for 0.8% of the total population (ONS, 2009). They had the highest average growth rate compared with all the other ethnic groups at 8.6% annually. The Chinese and white population was the highest amongst Other Mixed descriptors at 10%, whereas Asian and Chinese and Black and Chinese were both reported to be <1% (ONS, 2006). There has been a 21.1% and 3.6% increase in the number of students from China and Hong Kong, respectively, in higher education in the UK (HESA, 2000).

Traditional dietary practices

Although coming from various countries such as China, Taiwan, Hong Kong, Singapore and Malaysia, Chinese people or their ancestors all originate from China. Food has a prominent position in Chinese culture and is used as a to mark family, religious and social events. The dietary pattern is believed to be an important determinant of the body's balance and state of health, and manipulations of this pattern to restore equilibrium lost as a result of disease or changes in physiological status may have considerable influence on food habits.

Festivals

At the beginning of the year, Chinese celebrate their lunar New Year, which is sometime in late January or early February depending on the lunar calendar. A mid Autumn festival usually takes place in late September or early October to coincide with the end of the harvest year. Feasting demands the preparation and consumption of highly calorific foods that people at other times may not be able to afford.

Food preparation

Most of the staple foods in the Chinese diet, e.g. rice or wheat dumplings, are cooked by boiling. Other prominent dietary components such as soups and stews will also be boiled for several hours before serving. More delicately flavoured items such as seafood and dim sum are more likely to be steamed, usually by placing them on slatted wooden or bamboo trays over boiling water. Roasting is used as a cooking method for items such as pork, chicken and duck.

Baking has become more common in areas exposed to western influence with items such as cakes, tartlets and buns being produced. However, in northern China, where wheat consumption has always been common, buns made from wheat flour and sesame seeds have traditionally been baked by sticking them to the sides of a large pot or pot shaped oven. Fried foods are commonly stir fried, although some dishes will be deep fried. Oil is

heated until it smokes; meat and vegetables sliced into small pieces are tossed in it and rapidly stirred around the hot wok so that the food cooks without being burnt. This usually only takes a few seconds. Larger pieces of fish, poultry and egg may be cooked for longer with more oil and less stirring.

It is also a common practice to cook a food item by sequential methods. For example, a food may be smoked, then boiled and finally stir fried. Alternatively, it may be partly boiled, then set aside until needed and the cooking process completed by further additional boiling as part of another dish, or by another cooking method.

Meal pattern

Depending on their degree of acculturation, migrant Chinese adopt certain western eating habits while maintaining other traditional Chinese eating habits. For example, in a Chinese American study (Pan *et al.*, 1999), it was noted that rice continued to be an important staple but other traditional foods were replaced by cereal, bread, sandwiches, milk and soft drinks. The evening meal remained the most traditional meal. Breakfast, lunch and snack items were more likely to be replaced by foods more commonly consumed by Americans.

Most children and young adults will consume a western style breakfast and lunch, and only the evening meal is likely to be typically Chinese. Popular foods are white bread, burgers, pork chops, ham, bacon, peas, butter, crisps, chips and those from fast food outlets. Lamb and frozen vegetables are less commonly eaten. Older adults are more likely to maintain traditional customs. Elderly people still consume the more traditional diet but often incorporate western foods such as white bread and breakfast cereals for convenience at breakfast (Chan, 1991). Men are more likely to change their food habits than women as the latter have more experience of preparing traditional cuisines (Pan *et al.*, 1999).

Jewish diet

Many Jewish people were born in the UK and for the majority English is the native language. Jewish people are very diverse, reflecting differing degrees of assimilation and religious observance of Judaism, an ancient religion.

Dietary restrictions

Jewish people, like all other people, have food customs traditionally associated with their daily lives, holidays and festivals. These are in addition to detailed dietary laws (Kashrut) that date back to the Old Testament and define the selection, preparation and consumption of permitted (kosher) food. Self discipline and preservation of Jewish spirituality and religious identity underlie these laws, which are:

- Meat and poultry must not be cooked with milk or milk derivatives, or be served at the same meal. Utensils,

crockery, pots and pans used for milk and meat must be stored, washed and dried separately.

- All meat and milk products must be bought from a kosher shop bearing a kosher stamp.
- Permitted animals are quadrupeds that chew the cud and have cloven hoofs, such as sheep, goats and cattle. All others, including pigs, are forbidden.
- Poultry such as chicken, duck, goose, turkey and some game birds are permitted. Most others, including birds of prey and ostrich, are forbidden.
- Animals and birds must be slaughtered by shechita. This procedure, considered the painless means of slaughtering the animal, must be carried out by a trained and authorised person and entails a rapid cut with a sharp knife to sever the jugular vein and carotid artery. The meat must then be salted and soaked in water to remove the blood and render it kosher (permitted).
- Only fish with scales and fins, such as cod, plaice, salmon, tuna, etc., are allowed. Eels, shark, monkfish and all shellfish are forbidden.

The modern orthodox Jew will follow similar rules but is more integrated with the general population. It is important to establish the level of observance at the time of consultation.

The variety of kosher low fat, low sugar dairy foods are limited. During Shabbat and festivals, high calorie foods are served. Shabbat and festival foods from the Ashkenazi tradition (that of families from Eastern Europe and Russia) tend to be higher calorie than traditional Sephardic foods (those of families from Southern Europe, the Middle East and Asia) due to the different climates where the recipes were developed. A traditional Ashkenazi diet uses large amounts of chicken fat (schmaltz) and may require different dietary modification from that of the traditional Sephardic diet.

Social restrictions

In the ultra orthodox Jewish community a woman runs the house and looks after the children and the husband goes to work. One of the many laws that exists regarding behaviour is that men and women should not mix together or have any bodily contact apart from with their husband, brother or child. If a male dietitian is seeing an ultra orthodox female, she will not want to shake hands or have any contact with him and may feel uneasy being in the same room with him and vice versa.

Festivals and fasting

The seventh day of the week is the Sabbath (Shabbat), a day of prayer at the synagogue and complete rest from work from sundown on Friday to Saturday evening. Writing, operating any electrical equipment, cooking and travelling are amongst the tasks that are forbidden during the Sabbath and many festivals. All food preparation is done in advance and large family meals are traditionally eaten.

The Jewish year is based on lunar calculations. The New Year (Rosh Hashanah) is celebrated in September/October. Ten days later is the Day of Atonement (Yom Kippur), which is the holiest day of the Jewish calendar. It is also a fast day; no food or drink is permitted for 25 hours (from sunset the evening before to sunset the next day).

Passover, which commemorates the exodus of Jews from Egypt, is celebrated for 8 days in April. No foods made with, or in contact with, wheat, barley, oats or rye may be eaten. Unleavened bread (matzo) is eaten in place of normal bread. Cooking and eating utensils that are reserved only for Passover are used.

Polish diet

Slavic and many other culinary traditions, including German, Austro-Hungarian, Jewish, Turkish, French and Italian, have influenced Polish cuisine over several centuries.

Festivals and feasting

The majority of the population, approximately 90%, are Roman Catholics who observe varying degree of strictness. Christmas and Easter are the most celebrated religious festivals. Some people abstain from alcohol or meat during Lent; others may fast on Great (Good) Friday and until late afternoon supper on Christmas Eve. Many people traditionally eat fish on Friday.

Traditional dietary practices

Polish cuisine is abundant in meat and sausages of all kinds, as well as different kinds of pickles, dumplings and pasta shapes, most notably Polish ravioli (pierogi) and kasha (kasza).

Bread, rice, potatoes, pasta and other starchy foods

Many types of bread (chleb) are eaten but the most popular include mixed rye and wheat bread (chleb pszenno-żytni), wheat (pszenny) bread, rye (żytni) bread and wholegrain (pelnoziarnisty) bread. Traditionally, bread is made with a sour dough starter. Poppy, sunflower and caraway seeds are added to some breads and rolls. Potatoes are the most popular accompaniment to the main course. Kasha (kasza), which is made from buckwheat, cracked pearl barley or millet, is an alternative accompaniment to the main course. It is also used in soups, cakes (semolina) or boiled with milk as a type of porridge (millet or semolina). Oats are eaten with milk or can be added to bread. Breakfast cereals, often sugary varieties, are consumed more often nowadays. Rice is used in soups such as tomato or sour cucumber soup, and in stuffed cabbage parcels.

Pasta is eaten in a variety of ways. Pasta shapes are added to soups, e.g. chicken consommé, tomato or mushroom soups; eaten as pasta salads and most importantly as Polish ravioli or stuffed dumplings (pierogi). Pierogi can be filled with a variety of fillings. Savoury fillings include farmer's cheese and potatoes – Russian style,

minced meat, cabbage and mushrooms. Sweet fillings include sweetened farmer's cheese or fruit, e.g. apples, wild blueberries, cherries and plums. Pierogi are usually eaten boiled or boiled and then fried. They are served with a variety of toppings such as melted butter, fried onion, fried chopped bacon, sugar and cream. Other types of pasta include dumplings made with flour and potatoes mixed together e.g. kopytka and pyzy. These can be stuffed with meat or served plain. Ready made pierogi and dumplings sold in Polish shops are a quick and easy meal to prepare and hence are very popular with Polish people.

The following foods should be encouraged:

- Wholegrain bread and cereal, e.g. rye bread (chleb żytni), wheat-rye bread (chleb pszenno-żytni), pumpernickel (pumpernikiel), graham or razowy (wholemeal), wholegrain (pelnoziarnisty) and sunflower seed bread (chleb z ziarnami słonecznika).
- Breakfast cereal such as porridge, branflakes or any other unsweetened wholegrain variety, rather than cornflakes.
- Kasha are a good source of soluble fibre but should not be topped with bacon or other fat.
- Pierogi can be served with kefir or maslanka (low fat soured milk drinks) or a small amount of melted vegetable based spread/olive oil with stir fried onion topping instead. Mushroom (grzyby), cabbage (kapusta), Russian style (ruskie) and fruit (owoce) fillings should be encouraged in preference to a meat filling (farsz miesny).

Meat, fish, eggs, beans and alternatives

Meat (pork, beef and lamb in some regions of Poland), sausages and offal are consumed in great amounts in Poland. Fish, both white and oily, is available. Herrings, mackerel, trout, sprats, sardines, tuna, cod and hake are most commonly eaten. Carp is eaten mostly at Christmas. Herrings are usually preserved in oil or vinegar marinade, often consumed with sour cream with the addition of onion, apple, gherkins, dill and spices. The majority of sausages and hams, and some fish, are smoked. Pulses are not eaten to a great extent but are used to make soups or as a main meal accompaniment. Nuts and seeds are used in baking, bread making or as a sweet or savoury snack. Eggs are eaten at breakfast, added to soups and salads.

The following foods should be encouraged:

- To increase the consumption of pulses, the following could be suggested: bean soup (zupa grochowa, fasolowa), adding beans to other vegetable soups and stews to replace some meat, serving beans as a side dish more often, a butter bean casserole in tomato sauce Bretagne style (fasolka po bretonsku) and trying baked beans in tomato sauce. Bean soup and casserole should be made with a limited amount of lean bacon, good quality lean sausage or without meat altogether, and no roux.
- Instead of ordinary sausage (zwyczajna), country sausage (wiejska), grilling sausage (grilowa), pâté (pasztet),

Frankfurters (parówki), bacon (boczek) and black pudding (kaszanka), choose lean ham or pork loin (chuda szynka lub poledwica), chicken or turkey (szynka z kurczaka lub indyka).

- Choose low fat dairy, e.g. cottage cheese (serek ziarnisty) or Polish low fat (ser biały chudy) or reduced fat white cheese (ser biały półtusty) and low fat milk (mleko chude).
- Avoid using cream, sour cream, butter, roux (zasmażka), bacon, ribs or sausages in food preparation, e.g. in soups, sauces and pierogi. Try to use substitute with the following as appropriate: low fat milk (mleko chude), buttermilk (masłanka) or kefir (a type of sour milk, usually low fat) and vegetable oils, including spreads. For example, beetroot soup (barszcz czerwony) can be served clear with boiled egg or mushroom ravioli and sour rye soup (żurek) with boiled egg and/or potatoes, and without roux. Chicken soup is healthier if the skin is removed prior to cooking and more vegetables and herbs can be used to improve flavour.

Fruit and vegetables

Commonly consumed vegetables are beetroot, cabbage including sauerkraut, cucumbers, tomatoes, peppers, beans, lettuce, onion, leek and mushrooms. Fruits include apples, pears, plums, cherries, berries, bananas and citrus fruit.

Milk and dairy products

Full fat milk (mleko tłuste) is often chosen over low fat. Cream and sour cream are commonly used in soups, sauces, and vegetable and herring salads. Condensed milk is used in baking and creamer in coffee. Hard cheese, often referred to as yellow cheese (ser żółty), and full fat (tłusty) farmer's cheese, referred to as white cheese (ser biały), have been traditionally eaten. Nowadays, reduced and low fat equivalents, as well as a whole range of foreign cheeses, are widely available. Buttermilk (masłanka) and a medium to low fat soured milk (kefir) are consumed especially in summer months; they go well with pierogi. They can be used as a low fat alternative to cream in soups and salads. Similarly, low fat yoghurt could replace sour cream in vegetable and herring salads.

Food and drinks high in fat, sugar or salt

Poles tend to consume large amounts of sugary snacks, sweetened fruit juice drinks, e.g. Kubuś or Tymbark, honey, fruit compote and soft drinks. Energy drinks, coke or Sprite are also often used as mixers in cocktails. Polish fruit compote is a sweet drink made by boiling fruit in water with added sugar. This is traditionally served with main meals.

The following foods should be encouraged:

- Healthy alternatives, including vegetable juice, no sugar added squashes, herbal teas and water could be recommended.
- Vegetable juices, e.g. carrot (sok z marchwi) or tomato juice (sok pomidorowy) could provide an alternative.
- Tinned fruit in fruit juice rather than in syrup.

Ready meal consumption

Polish ready meals are widely available in Polish shops and some supermarkets in the UK. They often contain a high level of fat and salt. Some popular examples of Polish ready meals are Hunters' stew (bigos – sauerkraut and cabbage stewed with a variety of meats, sausages, bacon and spices), stuffed cabbage parcels (gołąbki – cabbage stuffed with rice and pork filling) and meatballs in tomato sauce (pulpety or klopsy). Ready made soups and dumplings also feature heavily on the shelves in Polish delis and some supermarkets. Home made varieties can be made healthier; however, they often require fairly long preparation time and therefore ready made alternatives make an easy option.

Food production and preservation

A wide variety of herbs and spices are used in meal preparation, e.g. dill, parsley, marjoram, paprika, black, cayenne and herb pepper, bay leaf, all spice, caraway seed, cinnamon, nutmeg and cloves. Bacterial and yeast fermentation are widely used in food production and preservation.

Turkish diet

There is a significant Turkish community in the UK; it is the third largest in Europe. Most Turks are Muslim and as such will follow the religious customs and dietary restrictions as described earlier. The Turkish diet is essentially a Mediterranean diet, which may reduce the risk of some non-communicable diseases. However, with acculturation, some Turks, especially those who are second or third generation, are adopting a more western diet.

The main meal is eaten in the evening and traditionally fingers are used instead of cutlery, although cutlery is widely used in the UK. Food is often prepared over a few days due to this being labour intensive and time consuming. The traditional Turkish diet will include a lot of vegetables and fruit. Many traditional varieties are available in the UK, although they may be more expensive. Despite most Turks being Muslims, there is a tradition of starting a meal with mezze, which is eaten with wine or raki (the anise flavoured national drink of Turkey). Dessert is often fresh fruit; desserts most associated with Turkish cuisine are baklava, a sweet filo pastry dish, and milk desserts (muhallebi), which are made with rice flour.

A glossary of Turkish foods, a list of traditional Turkish foods and example meal plans, with examples of the effect of migration, are given by Mirza & Sarwar (2012).

Greek diet

Many Greek emigrants arrived in the UK after the Second World War, with most coming from Cyprus. Most Greek speaking people live in and around London with communities in other large English cities, e.g. Liverpool. The Greek Orthodox Church, a Christian religion, is the main religion of the Greek community and on 180–200 days of

the year there are specific dietary restrictions or fasting. These restrictions include:

- Avoiding fish, eggs, meat, cheese and olive oil on Wednesdays and Fridays (except during the week following Christmas, Easter and Pentecost).
- There are three fasting periods:
 - 40 days before Christmas – eggs, dairy products and meat are not allowed. White fish and olive oil are allowed except on Wednesdays and Fridays.
 - Lent – 48 days preceding Easter, which varies each year depending on the time of the full moon on or after the vernal (spring) equinox. Fish is only allowed on the 25th March and Palm Sunday.
 - The Assumption – 15 days in August. The same rules as at Lent apply, except that fish is only allowed on 6th August.

Festivals

The main festivals are Easter, Christmas and New Year. Traditionally, specific foods are associated with each festival including:

- Easter – Easter bread (tsoureki) eaten with boiled eggs that are dyed, Easter soup (mayeritsa) and Easter savoury pastries (flaounes).
- Christmas – rich, sugary cakes are made (e.g. kourabithes) but other food choices will vary. These may include meat in aspic (saladina). Christmas food is plentiful and shared with family members.
- New year – a vasiloptia cake is made and shared amongst the family.

Like the Turkish diet, the Greek diet is a Mediterranean diet and is therefore associated with reduced risks of some non-communicable diseases, e.g. type 2 diabetes. A glossary of Greek foods, a list of traditional Greek foods and example meal plans, with examples of the effect of migration, are given by Petrides (2012). In addition, advice on foods to be encouraged and discouraged in the Greek diet are listed.

Conclusion

The ethnic and cultural mix of the UK is constantly changing, partly due to the migration. The population of any specific city or location may also change and it is therefore important that dietitians stay abreast of the diversity in the locality in which they work. One example of this is the influx of Somalian migrants to London and other large communities including Liverpool and Cardiff. Details of the diet eaten by Somalian people and some other groups can be found in the *Multicultural Handbook of Food, Nutrition and Dietetics* (Thaker & Barton, (2012)). The resources at the end of this chapter will assist dietitians in finding information relevant to working with specific cultural groups.

Additional resources

A number of UK dietetic departments have produced excellent dietary resource material for use with BME groups, often in a variety of languages. Details of material currently available and contacts are available to BDA members from the Multi-Cultural Nutrition Group (www.bda.uk.com).

The British Heart Foundation has developed free booklets and DVDs in English and five South Asian Languages (www.bhf.org.uk).

Diabetes UK produces a number of resources for people with diabetes from BME groups and have resources available in different languages (www.diabetes.org.uk).

The Food Standards Agency has translated diet sheets (www.food.gov.uk).

Local resources

Local community and religious leaders may be able to help with general information, translation of leaflets and the establishment of contacts with relevant individuals or groups. Local temples and religious establishments or local council offices may be a useful starting point of contact.

Local public health departments may have produced resource material relevant to local ethnic minority groups.

Local voluntary organisations in different areas of the UK run lunch-club clubs for local relevant communities.

3.6

Vegetarianism and vegan diets

Elaine Gardner

Key points

- Well balanced vegetarian diets are appropriate for all ages.
- Vegetarians consume widely divergent diets; a well balanced vegetarian diet can offer potential health benefits over non-vegetarian diets.
- A vegetarian eating pattern is associated with a lower risk of death from ischaemic heart disease.
- Vegetarians and vegans tend to have a lower body mass index (BMI) than omnivores.
- There is an increased risk of nutrient deficiencies when consuming a vegan diet compared with a vegetarian diet.
- Vegetarian and vegan diets have the potential to be used as treatment for chronic diseases such as type 2 diabetes and metabolic syndrome.

The Vegetarian Society (UK) defines a vegetarian as *'someone who lives on a diet of grains, pulses, nuts, seeds, vegetables and fruits with, or without, the use of dairy products and eggs. A vegetarian does not eat any meat, poultry, game, fish, shellfish or by-products of slaughter'* (www.vegsoc.org). The Vegan Society (UK) defines veganism as *'excluding all animal flesh and animal products, including milk, honey, and eggs and may also exclude any products tested on animals, or any clothing from animals'* (www.vegansociety.com). A number of other definitions are available but these are not *true* vegetarianism or veganism as they include animal consumption in some format. For completeness they are included in Table 3.6.1.

Individual consumers may have their own definitions and understandings of these terms, which can vary depending on their country of origin, culture, views on animal welfare and other factors. If appropriate and practical, especially when consulting with individuals, it is recommended to clearly define any parameters of reference. The UK National Diet and Nutrition Survey 2008/9 reported that 2% of both adults and children reported being vegetarian (Bates *et al.*, 2010). This is lower than previously reported in the Consumer Attitude to Food Standards Survey (FSA, 2003), which reported that 6% of households contained at least one vegetarian member. In 2001, 0.3–0.4% of the UK population was reported as being vegan (FSA, 2006a).

Alternatives to unacceptable foods for vegetarians and vegans

There are a number of alternatives to unacceptable foods, as shown in Table 3.6.2 and Table 3.6.3. These foods are generally found within supermarkets, with the more unusual items available for purchase from health food shops or online shopping.

The labelling of foods as *suitable for vegetarians* or *suitable for vegans* has increased and is making it easier, in some cases, to identify acceptable products (although there are still some problems, e.g. welfare issues such as whether eggs used are free range). Guidance on these terms is provided by the Food Standards Agency (FSA, 2006b) as the labelling is not mandatory and falls under several pieces of legislation (see Chapter 4.5).

Reasons for following a vegetarian or vegan diet

Religion

Some religions advocate avoiding animal products, either partially or fully (see Chapter 3.5 for more details).

Parental and peer influence

Vegetarianism is becoming more common among teenagers, especially among girls. The National Diet and Nutrition Survey of 4–18-year olds found that one in 10 girls

Table 3.6.1 Broad definitions regarding vegetarianism and vegan diets

	Meat and meat products	Fish, seafood and their products	Milk and milk products (including cheese and yoghurt)	Eggs and egg products	Other food items that are unacceptable	Comments
Vegetarian [Vegetarian Society (UK)]	×	×	√ Cheese needs to be animal rennet free	Free range eggs only		Sometimes referred to as lacto-ovo-vegetarian
Vegan [Vegan Society (UK)]	×	×	×	×	Honey, beeswax, some alcohol and all products tested on animals	Many products can have hidden animal ingredients so it is recommended to contact the Vegan Society or to use the Vegan Shopping Guide
Lacto-vegetarian	×	×	√ Cheese needs to be animal rennet free	×		
Ovo-vegetarian	×	×	×	Free range eggs only		
Piscatarian	×	√	√ Cheese needs to be animal rennet free	√		

Table 3.6.2 Alternative foods for vegetarians^{1,2,3}

Unacceptable foods	Possible vegetarian alternatives
Meat, fish and poultry, and products containing these like pies, sausages	Nuts, seeds, free range eggs, pulses and beans, sprouted beans and seeds, root vegetables, seaweed Soya, ⁴ tofu, Quorn, TVP (textured vegetable protein) Cereal based foods such as bread, pasta, noodles, couscous, quinoa, rice, bulgar wheat, barley, buckwheat, spelt, millet
Meat and fish stocks, soups and gravies	Vegetable stock, yeast extracts, vegetarian gravy mix
Animal fats and fish oils	Trex, Pura, 100% vegetable oils and margarines, vegetariaSuet, Trex, Pure, Vitalite, 100% vegetable oils and margarines, vegetable suet. Plant sources of n-3 oils, e.g. hempseed, rapeseed and flax oils
Fish oils, foods that are 'n-3 enriched by fish oils'	
Gelatine and its products, including aspic, jelly, marshmallows, jelly type sweets, gelatine thickened yoghurts	Agar agar, Gelozone, carrageen, pectin
Animal based flavourings, e.g. some brands of Worcester sauce	Yeast extracts, soya sauce, miso, herbs and spices, vegetarian Worcester sauce
Cheese made with animal rennet, including Parmesan, Grana Padano, Gorgonzola	Vegetarian cheese
Animal sources of E numbers: • E120 – cochineal/carmine (from crushed insects) • E452 – edible bone phosphate (from animal bones) Some E numbers may be derived from either plant or animal sources. The Vegetarian Society (UK) provide an online, up to date factsheet.	Foods without animal sources of E numbers
Eggs from caged hens and products prepared with these, e.g. quiche	Free range eggs and products prepared with these
Alcoholic drinks that have been clarified using animal derived products, e.g. chitin, gelatine, isinglass. This includes the majority of real ales; bottled naturally conditioned beers; some ciders; some fortified wines and some wines	Majority of keg beers and lagers, canned beers Ciders that have been produced without gelatine Majority of organic wines and those produced using non-animal alternatives Majority of spirits and liqueurs. Vegetarian alcoholic drinks

¹The labels and ingredients of all manufactured products must be read carefully.

²Care must be taken in the storage and preparation to ensure that the ingredients used do not come into contact with animal products.

³Vegetarian foods should not be cooked in oils that have been used for frying animal products.

⁴The term 'soya' is used throughout the chapter; however, it should be noted that in the US they commonly use the term soy.

Table 3.6.3 Alternative foods for vegans^{1,2,3}

Unacceptable foods	Possible vegan alternatives
Meat, fish and poultry, and products containing these like pies, sausages.	Nuts, seeds, pulses and beans, root vegetables, sprouted beans and seeds, pure nut and seed butters, seaweed Soya, TVP (textured vegetable protein), tofu Vegan meat substitutes, e.g. vegan sausages, vegan bacon rashers, mock duck Cereal based foods such as bread, pasta, plain noodles, couscous, quinoa, rice, bulgar wheat, barley, buckwheat, spelt, millet
Eggs and cheese and products made from these, e.g. Quorn, mayonnaise, quiche, cakes, egg noodles, pesto	Vegan mayonnaise, vegan cakes, vegan biscuits, rice noodles, vegan pesto
Meat and fish stocks, soups and gravies	Vegetable stock, yeast extracts, miso
Animal fats and products made from these, e.g. chocolate	Vegan chocolate, carob 100% vegetable oils, e.g. soya, sunflower, rapeseed, olive Vegetable suet
Fish oils, foods that are 'n-3 enriched by fish oils'	Plant sources of omega-3 oils, e.g. hempseed, rapeseed and flax oils
Margarines that contain milk products and/or vitamin D3	Pure dairy free spreads, e.g. Vitalite, Pure
Ghee	
Gelatine and its products, including aspic, jelly, marshmallows, jelly type sweets, gelatine thickened yoghurts	Agar agar, Gelozone, carrageen, pectin
Animal based flavourings, e.g. Worcester sauce	Yeast extracts, soya sauce, herbs and spices, vegan worcester sauce, miso
Animal milks, cheese, yoghurt, cream, ice cream	Soya, nut and cereal based milks (vitamin and mineral fortified products are strongly recommended)
Products made from these or manufactured products containing whey powder, casein or lactose, e.g. some crisps	Soya cheese and alternatives made from nuts and seeds. Nutritional yeast flakes for 'cheese' sauces and for sprinkling on savoury dishes Soya yoghurt, soya based desserts, soya ice cream. Non-dairy creams e.g. soya, nut and rice
E numbers from unacceptable sources (approx. 35 possible E numbers). The Vegan Society (UK) provides online, up to date information	Foods without unacceptable sources of E numbers
Honey, cereal bars containing honey, some breakfast cereals that contain honey/milk/vitamin D ₃	Maple and agave syrup, sugar, jams. Vegan cereal and fruit bars, pure breakfast cereals not enriched with vitamin D ₃ and honey
Alcoholic drinks that have been clarified using animal derived products, e.g. chitin, gelatine, isinglass. This includes the majority of real ales; bottled naturally conditioned beers; some ciders; some fortified wines and some wines	Majority of keg beers and lagers, canned beers Ciders that have been produced without gelatine Majority of organic wines and those produced using non-animal alternatives Majority of spirits and liqueurs Vegan alcoholic drinks

¹The labels and ingredients of all manufactured products must be read carefully.

²Care must be taken in the storage and preparation to ensure that the ingredients used do not come into contact with animal products.

³Vegan foods should not be cooked in oils that have been used for frying animal products.

aged 15–18 years reported that they were vegan or vegetarian (Gregory *et al.*, 2000). Support for vegetarian practices from mothers and classmates has been shown to be high, although many adolescents reported finding it difficult to avoid eating meat at home (Trew *et al.*, 2006). There are associations between vegetarianism and anorexia nervosa (Aloufy & Latzer, 2006), but while being vegetarian does not cause disordered eating, it may be used to camouflage an existing eating disorder.

Animal welfare

Issues concerning animal welfare that may lead to the adoption of a vegetarian or vegan diet include:

- Conditions in which animals are kept, e.g. restricted space.
- Use of antibiotics and growth promoters to maintain and increase production.
- Intensive breeding and culling programmes.
- Production and killing of animals and fish solely for food purposes.

Environmental issues

Resources required for animal food production have a higher environmental impact than those for growing food from plant sources. With world food security an issue, this inefficient use of land may be viewed as non-sustainable.

In addition, the increased water needs for the production of food from animal as opposed to plant sources is also causing concern. The impact on the environment also encompasses the following issues:

- Quantity of greenhouse gases produced by animals.
- Damage to ecosystems, the environment and other animals.
- Water contamination.
- Higher carbon footprint.

Health reasons

Vegetarians appear to be more health conscious than non-vegetarians (Bedford & Barr, 2005) and a vegetarian eating pattern is associated with a lower risk of death from ischaemic heart disease (Craig *et al.*, 2009; Key *et al.*, 2006). An evidence based review by the American Dietetic Association (Craig *et al.*, 2009) found that vegetarians compared with non-vegetarians had lower:

- Low density lipoproteins (LDL) cholesterol levels (Ferdowsian & Barnard., 2009).
- Blood pressure levels.
- Rates of hypertension.
- Rates of type 2 diabetes (Tonstad *et al.*, 2009. Zaman *et al.*, 2010).
- Risk of metabolic syndrome (Rizzo *et al.*, 2011).
- Body mass index (BMI) (Sabate & Wien, 2010. Tonstad *et al.*, 2009).
- Overall cancer rates and risk (Lanou & Svenson, 2010a).

These findings are supported by the European Prospective Investigation in Cancer (EPIC) and Nutrition Oxford Study that included approximately 65 000 participants of whom 31 000 were non-meat eaters (Key *et al.*, 2009; Spencer *et al.*, 2003, Appleby *et al.*, 2002; Davey *et al.*, 2002).

Bone fracture risk among vegetarians, meat eaters and fish eaters was similar if they consumed at least 525 mg/day of calcium, as measured over a 5.2-year follow-up period in the EPIC Oxford study (Appleby *et al.*, 2007), and normal bone mass has been reported for vegetarians (New, 2004). However, it is acknowledged that there are large variations in factors that may impact on, this including dietary components and lifestyle factors.

Features of a vegetarian diet that may reduce the risk of chronic diseases include lower intakes of saturated fat and a higher consumption of fruit, vegetables, whole-grains, nuts, soya products (the term *soya* will be used throughout this chapter, rather than *soy*), fibre, some vitamins and minerals, and phytochemicals (Craig, 2010; Craig *et al.*, 2009). The overall antioxidant status is similar between vegetarians and omnivores, but vegetarians have a 15% higher level of plasma carotenoids (Halder *et al.*, 2007). However, it should be noted that vegetarians consume widely divergent diets and only a well balanced, vegetarian diet offers potential health benefits.

Other lifestyle practices, including activity levels, smoking and drinking habits, may also have an impact on the positive health benefits. Alewaeterers *et al.*, (2005) reported that vegetarians smoked less, drank less alcohol

at the weekends and were engaged in more intensive physical activity compared with a reference population. In the EPIC Oxford study, however, such differences in lifestyle factors accounted for <5% of the difference in mean age adjusted BMI between meat eaters and vegans, whereas differences in macronutrient intake accounted for approximately half of the difference (Spencer *et al.*, 2003).

There have been suggestions that the term *vegetarian*, often used in research, is not specific and requires fuller clarification. Studies have found that some people who classify themselves as vegetarian actually occasionally eat meat (Haddad & Tanzman, 2003). Robinson-O'Brien *et al.* (2009) found that approximately one-quarter of those who classified themselves as current vegetarians ate chicken. Inconsistencies in this description may have led to anomalies in findings between studies, such as the differences in the rates of colorectal cancer between British vegetarians and other populations (Key *et al.*, 2009; Sanjoaquin *et al.*, 2004), and as a result findings might need to be interpreted cautiously (Fraser, 2009).

Compared with other vegetarian diets, vegan diets tend to contain less saturated fat and cholesterol and more dietary fibre, but there is an increased risk of nutritional deficiencies (Craig *et al.*, 2009; Key *et al.*, 2006). Lower BMI levels and rates of type 2 diabetes have been seen in those consuming vegan diets as compared with vegetarians and non-vegetarians (Zaman *et al.*, 2010; Spencer *et al.*, 2003). There is, however, a higher fracture risk for vegans, probably as a consequence of lower calcium intakes (Ambroszkiewicz *et al.*, 2010; Appleby *et al.*, 2007).

Nutritional adequacy of a vegetarian or vegan diet

Protein

Vegetarians and vegans in the UK, Europe and North America consume adequate energy as derived from protein, albeit at lower levels than omnivores (Craig *et al.*, 2009; Cade *et al.*, 2004; Davey *et al.*, 2002). The source of protein is important as this dictates its digestibility. Soya protein can meet needs as effectively as animal protein, whereas wheat protein, for example, eaten alone may result in reduced efficiency of nitrogen utilisation. Requirements may therefore vary depending on food selection. Kniskern & Johnston (2011) have suggested that the dietary reference intake (DRI) should be increased to 1.0g/kg (from 0.8g/kg) when consuming <50% of protein from animal sources. While it was once thought that combinations of plant foods had to be eaten at the same meal to ensure a sufficient intake of amino acids, it is now known that if energy intake is adequate and a mixture of plant proteins are eaten over the course of the day, requirements for essential amino acids will be met.

Fatty acids

The consumption of alpha-linolenic acid (ALA), an n-3 fatty acid obtained from plants, is relatively low in vegetar-

ian and vegan diets compared with n-6 polyunsaturated fatty acids intakes, mainly linoleic acid, from seed oils (Sanders, 2009; Kornsteiner *et al.*, 2008). This results in an unbalanced n-6 to n-3 ratio in vegetarians and vegans, which may inhibit endogenous production of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Little, if any, EPA and DHA are obtained from a vegetarian or vegan diet (as they are mainly obtained from fish sources, although some spreading fats, soups and sauces have been found to be the major sources in vegetarians) (Welch *et al.*, 2010; Sanders, 2009). Studies have shown that tissue levels of long chain n-3 fatty acids are depressed in vegetarians and particularly in vegans, irrespective of the duration of the diet (Kornsteiner *et al.*, 2008; Rosell *et al.*, 2005).

This is compounded by an inefficient conversion of ALA by the body to the more active longer chain metabolites (<5–10% for EPA and 2–5% for DHA) (Davis & Kris-Etherton, 2003). Total n-3 requirements may therefore be higher for vegetarians and vegans than for fish and meat eaters as they must rely on conversion of ALA to EPA and DHA. However, Welch *et al.* (2010) found that, although non-fish eating meat eaters and vegetarians have much lower intakes of EPA and DHA than fish eaters, their n-3 status is higher than would be expected, which suggests a greater conversion of ALA to circulating long chain n-3 fatty acids in non-fish eating groups. As yet, there is no documented evidence of adverse effects on health from the lower DHA intake in vegetarians.

The American Dietetic Association (Craig *et al.*, 2009) recommends that '*vegetarians should include good sources of ALA in their diets like flaxseed, walnuts, canola [rapeseed] oil and soya. Those with increased requirements of n-3 fatty acids such as pregnant and lactating women, may benefit from DHA rich microalgae*'.

Iron

Vegetarian diets contain mainly non-haem sources of iron, and the iron from these is less efficiently absorbed than haem iron of animal origin. They have generally higher intakes of inhibitors of iron absorption such as phytate, but evidence suggests that the overall effect of enhancers and inhibitors on iron absorption is considerably less than predicted and do not substantially influence iron status (SACN, 2010). Soya contains iron mostly in the form of ferritin, which is easily absorbed despite the presence of phytate, and so iron absorption may be higher than previously thought (Lonnerdal *et al.*, 2006). The Scientific Advisory Committee on Nutrition (SACN, 2010) reviewed a number of studies and found that dietary iron intakes of vegetarians are on average similar, or sometimes higher, than those of non-vegetarians. This is also consistent with regards to vegans in the EPIC study (Davey *et al.*, 2003), for whom intake was higher (14.1 mg/day) than for meat eaters (12.6 mg/day), fish eaters (12.8 mg/day) and vegetarians (12.6 mg/day).

Haemoglobin concentrations in vegetarians and non-vegetarians are similar, but although serum ferritin con-

centrations can be consistently statistically significantly lower in vegetarians, they are usually within the reference ranges (Haddad *et al.*, 1999). In western societies, incidence of iron deficiency anaemia among vegetarians is similar to that among non-vegetarians, although iron stores are often lower (Hunt, 2002).

Zinc

In the EPIC Oxford study (Davey *et al.*, 2003), vegetarians had lower intakes of zinc than meat eaters (7.67 mg/day versus 9.16 mg/day for women and 8.44 mg/day versus 9.78 mg/day in men), with vegans consuming even lower intakes (7.22 mg/day and 7.99 mg/day for men and women, respectively). The UK Women's Cohort Study (Cade *et al.*, 2004) confirmed this, with vegetarians consuming 10.2 mg/day versus meat eaters consuming 12.0 mg/day, a finding consistent with studies in other countries (de Bortoli & Cozzolino, 2009; Tupe & Chiplonkar, 2010; Chiplonkar & Agte, 2007; Haddad *et al.*, 1999).

The effect of phytates and folic acid on zinc bioavailability also causes concern with regards to vegetarian and vegan diets (Craig, 2009; Chiplonkar & Agte, 2006; Kristensen *et al.*, 2006; Hunt, 2003; Gibson, 1994). Suitable zinc rich foods for vegetarians and vegans include legumes, nuts and soya products. Soaking and sprouting seeds can increase zinc bioavailability. There no evidence has been found for any impact or adverse health effects of these lower intakes and biochemical stores on functional immunity (Hunt, 2003; Haddad *et al.*, 1999).

Iodine

The iodine content of food of plant origin may be lower than that of animal origin due to lower iodine concentration in the soil in some geographical areas. A number of studies have looked at the iodine content of vegetarian and vegan diets and all have found that there is a high potential for deficiency, especially in vegan diets (Leung *et al.*, 2011; Waldmann *et al.*, 2003; Krajcovicova-Kudlackova *et al.*, 2003; Remer *et al.*, 1999; Lightowler & Davies, 1998). Where iodine containing foods are consumed, however, mean iodine intakes can be greatly in excess of the RNI, e.g. if some types of seaweeds are eaten (Lightowler & Davies, 1998). Iodised table salt is a useful contributor to total iodine intake (Davidsson, 1999) and those who do not eat seaweed should be encouraged to consume this, kelp fortified yeast extracts or iodine supplements.

Selenium

Concerns have been raised about the selenium status of non-meat eaters, as the consumption of red meat is a major determinant of serum selenium (Letsiou *et al.*, 2010). Selenium status in vegetarians in studies by De Bortoli & Cozzolino (2009) and Gibson (1994) found that selenium blood levels were adequate. There is, however, currently insufficient evidence to assess the usefulness of

biomarkers of selenium status and results as to whether vegetarians and vegans may be selenium deficient or not may depend on the biomarker chosen (Hoefflich *et al.*, 2010). Cereals, nuts and seeds are all suitable sources of selenium, but the actual content will vary depending on the soil in which they are grown.

Calcium

Calcium intakes for vegetarians are similar to those for meat eaters for men and women (Cade *et al.*, 2004; Davey *et al.*, 2003). Intakes of calcium by vegans are much lower, with a mean intake for men of 610 mg/day for men and 582 mg/day for women (Davey *et al.*, 2003), and may fall below the recommended intakes. Calcium enriched soya products are excellent sources of bioavailable calcium for vegans alongside kale and pak choi, tofu, brown and white bread (legally fortified with calcium), sesame seeds, tahini, nuts and dried fruit such as apricots and figs. Some green vegetables such as spinach and Swiss chard are high in calcium, but the calcium is bound to oxalate which makes it poorly absorbed.

Vitamin D

The richest sources of vitamin D are animal foods (with the exception of fortified products), so there is a potential for vegetarians and vegans to be deficient. There are conflicting results with regard to vitamin D status from different populations. The Adventist Health Study-2 found that there was no significant difference in serum 25-hydroxyvitamin D status (Chan *et al.*, 2009), but the EPIC Oxford study found that serum 25-hydroxyvitamin D was lower in vegetarians and vegans than meat eaters (Crowe *et al.*, 2011). A small study from Finland concluded that dietary intake of vitamin D in vegans was insufficient to maintain levels within normal ranges in the winter months at northern latitudes (Outilia *et al.*, 2000). For those with low sun exposure or consuming low intakes of vitamin D, fortified foods (such as margarine, some breakfast cereals and soya milks) or vitamin D supplements are recommended. Vitamin D₃ (cholecalciferol) is obtained from foods of animal origin but vitamin D₂ (ergocalciferol) is obtained from yeast which is an acceptable to vegans.

Vitamin B₁₂ (cobalamin)

Vitamin B₁₂ occurs in substantial amounts only in foods from animals. There are issues with diagnosing vitamin B₁₂ deficiency, but low circulating concentrations and low intakes have been recorded in numerous studies of vegetarians and vegan diets (Gilsing *et al.*, 2010; Waldmann *et al.*, 2003; Herrmann & Geisel, 2002). Megaloblastic anaemia, a symptom of vitamin B₁₂ deficiency, can be masked by high intakes of folic acid, with symptoms only detected at a neurological stage. In the EPIC Oxford cohort study, folate concentrations were highest among vegans, intermediate amongst vegetarians and lowest amongst omnivores (Gilsing *et al.*, 2010). Vegetarians can

obtain vitamin B₁₂ from dairy foods or eggs, but the only reliable source for vegans is fortified foods such as some breakfast cereals, yeast extracts, some plant milks and some soya products (approximately three portions are required per day). Alternatively, a daily supplement can be taken.

Retinol

Retinol is found only in animal foods and intakes for vegetarians and vegans are low (Davey *et al.*, 2003). Intakes of dietary carotenoids enable vegans to obtain an adequate supply of vitamin A, even though the bioavailability of beta-carotene from foods is variable. The most concentrated sources of carotenoids are carrots, red peppers, dark green leafy vegetables, tomatoes and yellow coloured fruit.

Vegetarian or vegan diets as a treatment for chronic diseases

Weight management

Vegetarians tend to have a lower BMI than non-vegetarians (Sabate & Wien, 2010; Appleby *et al.*, 1998) and weight gain over time is lower on a vegetarian diet (Rosell *et al.*, 2006). As vegetarian diets are nutritionally adequate (Farmer *et al.*, 2011), it has been proposed that a vegetarian diet may be a possible approach to treating obesity and weight management. A randomised clinical trial of 176 overweight or obese adults examined whether a prescribed calorie controlled, vegetarian diet had any significant benefits over a prescribed calorie controlled, omnivorous diet (Burke *et al.*, 2007). The vegetarian diet group showed a significant reduction in monounsaturated fat and a marginally significant reduction in total fat intakes at 18 months. Both groups, however, had significant reduction in total energy and fat intakes with reduced body weight, so as yet the evidence for prescribing vegetarian diets *per se* for weight management is inadequate. However, a low fat vegan diet has been compared with the National Cholesterol Education Program (NCEP) on weight loss maintenance and was found to produce significantly greater weight loss (Turner-McGrievy *et al.*, 2007).

Metabolic syndrome and type 2 diabetes

There have been suggestions that a vegetarian or vegan dietary pattern is an appropriate form of treatment for metabolic syndrome and type 2 diabetes (Marsh & Brand-Miller, 2011; Trapp *et al.*, 2010; Trapp & Barnard, 2010; Barnard *et al.*, 2009a). It is believed that the effects are mainly due to the accompanying weight loss, as well as reduced intakes of saturated fats and high glycaemic index food sources, and increased intakes of dietary fibre and vegetable protein.

In a small 24-week trial, 37 patients with type 2 diabetes received a vegetarian, calorie restricted diet and a matched number were assigned a conventional calorie restricted, diabetic diet (Kahleova *et al.*, 2011). Results showed that

43% of participants in the vegetarian group and 5% of participants in the traditional diabetic diet group reduced their antidiabetic medication. Also, body weight decreased more in the vegetarian group than in the traditional group (−6.2 kg versus −3.3 kg), even though the diets were isocaloric. The inclusion of exercise training further improved the outcomes with the vegetarian diet. A similar study with 99 participants compared a low fat vegan diet with a diet following the American Diabetes Association (ADA) guidelines (Barnard *et al.*, 2006). Both diets improved glycaemic control (as measured by HbA1c measurements), and promoted a reduction in body weight and LDL cholesterol levels, but the those on the low fat vegan diet showed greater improvements than those on the diet based on ADA guidelines. Questionnaire responses rated both diets as satisfactory (Barnard *et al.*, 2009b). To assess the quality of the diets, nutrient intake and Alternate Healthy Eating Index (AHEI) scores were collected at baseline and at 22 weeks; the vegan group improved its AHEI score whereas the ADA recommended diet group's AHEI score remained unchanged (Turner-McGrievy *et al.*, 2008).

Cardiovascular disease

Vegetarian and vegan diets have been suggested to be an effective tool for the management of cardiovascular disease (Lanou & Svenson, 2010b). A review by Ferdowsian & Barnard (2009) of both observational and intervention studies concluded that plant based dietary interventions, often in the form of portfolio diets, are effective in lowering plasma cholesterol concentrations to a greater extent than NCEP diets. In conjunction with increased exercise, stress management and group support, a vegetarian diet consumed for 1 year was shown to meet key heart health characteristics (fibre intakes >25 g/day, LDL cholesterol <10 mg/mL, BMI <25 kg/m², blood pressure <140/90 mmHg) and reduce risk markers (Marshall *et al.*, 2009). It has been suggested that, if maintained, such an intervention could result in substantial reductions in cardiovascular disease events.

Dietary considerations for different population groups

Pregnancy and lactation

Well planned vegetarian and vegan diets can be adequate in maintaining the health of both mother and child during pregnancy and, in some cases, may even have advantages over omnivorous diets. Gestational weight gain in pregnancy above the recommended ranges can be related to adverse pregnancy outcomes, but consumption of a vegetarian diet is associated with less gestational weight gain (Streuling *et al.*, 2011).

Additionally, vegetarians consume higher intakes of magnesium due to their plant based diet, which can result in slightly improved magnesium status during pregnancy compared with an average western diet (Koebnick *et al.*, 2005). Magnesium is important as a cofactor for many enzyme systems and has a critical role in cell division.

Plasma and red blood cell (RBC) folate concentrations have also been shown to be higher in pregnant vegetarians (probably due to long term, high vegetable intakes) than in those eating an average western diet. This can reduce the risk of folate deficiency if an adequate vitamin B₁₂ supply is ensured (Koebnick *et al.*, 2001).

Pregnant vegetarian (and vegan) women, however, are at greater risk of vitamin B₁₂ deficiency (Koebnick *et al.*, 2004) and there have been numerous cases cited of severe vitamin B₁₂ deficiency with neurological damage in the infant as a result of maternal strict vegetarian/vegan diets (Erdeve *et al.*, 2009; Roed *et al.*, 2009; Mariani *et al.*, 2009; Mathey *et al.*, 2007; Weiss *et al.*, 2004; Smolka *et al.*, 2001). An adequate maternal dietary supply of vitamin B₁₂ or a daily supplement is recommended.

A low consumption of red meat was marginally associated with anaemia in pregnant women in Pakistan (Baig-Ansari *et al.*, 2008), but in India there was no significant difference in the prevalence of iron deficiency anaemia between pregnant vegetarians or meat eaters (Sharma *et al.*, 2003). In both studies, prevalence of anaemia was very high in over 95% of the cases. Reference intakes for iron during pregnancy are the same as those for non-pregnant women in the UK (Department of Health, 1991), whether vegetarian or not. The Scientifics Advisory Committee on Nutrition (SACN, 2010) suggested that the high proportion of females with intakes of iron below the lower reference nutrient intake (LNRI) might mean that the iron dietary reference value (DRV) may be set too high. Iron intake recommendations and/or supplements should be based on the standard recommendations for pregnant women (see Chapter 3.2) and be food appropriate.

Vegan diets are devoid of DHA and vegetarian diets that include dairy foods and eggs only provide about 20 mg of DHA/day (Sanders, 2009). Pregnancy is a developmental period during which the n-3 fatty acid supply to the foetus is critical to ensure the optimal development of the brain and visual systems, with the balance between n-3 and n-6 fatty acids present in the perinatal period affecting the development of systems regulating immune function, fat deposition and metabolism (Gibson *et al.*, 2011). The fatty acid composition of breast milk reflects that of the maternal diet and is a major determinant of the n-3 status of a breastfed infant and subsequent immune function (Lauritzen & Carlson, 2011). It has been recommended that all pregnant and lactating women should aim to achieve an average daily intake of at least 200 mg of DHA (Koletzko *et al.*, 2008). Pregnant and lactating vegetarian/vegan women may benefit from DHA rich supplements due to their low intakes and increased requirements.

The American Dietetic Association (ADA, 2009) (now the Academy of Nutrition & Dietetics) has published an evidence based review with regards to vegetarian nutrition in pregnancy with the following summaries in addition to the above:

- Pregnant vegetarians receive statistically lower levels of protein than pregnant non-vegetarians (although none

report a protein deficiency), but consume statistically higher levels of carbohydrates (Grade III – limited evidence (see Chapter 1.1)).

- No research was identified with regards to macronutrient intakes among pregnant vegans.
- There are no significant health differences in babies born to non-vegan vegetarian mothers versus non-vegetarians (Grade III – limited evidence).
- No research was identified that focussed on the birth outcomes of vegan versus omnivorous mothers.
- Intakes of vitamin B₁₂, vitamin C, calcium and zinc were lower among vegetarians than non-vegetarians. Vegetarians did not meet the dietary standard for vitamin B₁₂ and zinc (in the UK), iron (in the US) and folate (in Germany) (Grade III – limited evidence).
- The micronutrient content of a balanced maternal vegetarian diet does not have detrimental outcomes for the health of the child at birth (Grade III – limited evidence).
- Vegetarian diets can be nutritionally adequate in pregnancy and can lead to positive birth outcomes.

Pregnant and lactating vegetarians need to pay attention to the nutritional adequacy of their diets, particularly with regards to vitamin B₁₂ and zinc and be mindful about intakes of iron and folate. Supplements normally advised for pregnant women (400 µg folic acid in the first trimester and 10 µg vitamin D) also apply to vegetarians and vegans. There is currently no evidence as to the adequacy of a vegan diet or birth outcomes in pregnant vegans. It has, however, been noted (Amit, 2010) that:

- The calcium content of breast milk is unaffected by a vegan diet in the mother.
- The breast milk from vegan mothers does not contain an adequate amount of zinc for infants after the age of 7 months.
- Soya formula is the only option for non-breastfed vegan infants.

Childhood and adolescence

A review by Sabate & Wien (2010) of the anthropometry of vegetarian youngsters found conflicting data on the height of vegetarian children, with one study finding that vegetarian children were taller than their omnivorous classmates (Sabate *et al.*, 1991), while another showed that they were shorter (Sabate *et al.*, 1990). One study of predominately vegetarian adolescents showed that they had a significantly lower BMI, waist circumference, total cholesterol to high density lipoprotein (HDL) ratio and LDL concentration than their omnivorous classmates (Grant *et al.*, 2008).

There is evidence, however, of inadequate intakes of vitamin D and calcium in vegetarian children aged 2–10 years compared with omnivores, with subsequent lower levels of biochemical bone turnover markers (Ambroszkiewicz *et al.*, 2007). In a small study (n = 56), vitamin B₁₂ intake was found to be lower in vegetarian preschool children and their parents compared with omnivores, but both had similar serum vitamin B₁₂ concentrations (Yen

et al., 2010). SACN (2010) reported that in young people aged 4–18 years there was no association between a vegetarian diet and lower than average iron intakes, but that girls aged 15–18 years in general, (whether vegetarian or not) were at risk of iron deficiency anaemia. Research from Sweden also found this to be the case for adolescent vegans (Larsson & Johansson, 2002). They did, however, also find that the adolescents had dietary intakes lower than average requirements for riboflavin, vitamin B₁₂, vitamin D, calcium and selenium.

The Canadian Paediatric Society has issued a position statement on vegetarian diets in children and adolescents (Amit, 2010) and concluded that '*a well-balanced vegetarian diet can provide for the needs of children and adolescents*'. It did, however, raise concerns in the following areas:

- Restrictive vegan diets may cause energy deficits (due to low energy density and bulk), which present challenges in feeding smaller children. The inclusion of soya products, nuts (age appropriate) and nut butters can be useful.
- Due to the lower digestibility of plant proteins, some studies have suggested that protein intake may need to be increased for vegans (an increase varying from 30% to 35% for infants up to 2 years of age, 20–30% for 2–6-year olds, 15–20% for those >6 years). Combinations of protein sources from different food groups (nuts and seeds, cereals, legumes) need to be encouraged, but combining complementary proteins at each meal is not believed to be necessary.
- Due to lower bioavailability of iron and increased needs for iron in children, especially during rapid growth periods, it is prudent to ensure that good sources such as fortified cereals are included and supplementation is considered particularly in times of higher needs.
- Zinc requirements in vegans may be higher than in omnivores, due to differences in bioavailability, but additional supplementation is not recommended. Good sources of zinc such as pulses, nuts (age appropriate), yeast leavened bread, fermented soya products and sprouted seeds should be included in the diet.
- Calcium intakes below recommendations have been noted in vegan children and it is essential to ensure an adequate intake of calcium rich and calcium fortified foods (such as soya products, cereals, low oxalate green vegetables). Supplementation may be required.
- Adequate sources of linolenic acid (the precursor of EPA and DHA) are required and supplements may need to be included in the diets of vegetarian and vegan children.
- Supplementation of vitamin B₁₂ or a good intake of fortified foods (at least three servings of vitamin B₁₂ rich foods per day) is recommended for vegetarian and vegan children. Infants of vegan mothers are particularly at risk from vitamin B₁₂ deficiency.

In line with all children who do not consume sufficient vitamin D enriched foods or have limited exposure to sunlight, supplementation is recommended.

Three servings of dietary carotenoids per day (from fruit and vegetable products) are recommended for vegan children. Fibre intake should be monitored to avoid dilution of energy and interference with essential minerals, particularly in young children with potentially high intakes.

The Position Statement from the American Dietetic Association (Craig *et al.*, 2009) supports these points. Guidelines are available for children being weaned onto a vegetarian diet (Di Genova & Guyda, 2007) that reflect these recommendations. The Vegan Society (UK) (www.vegansociety.com) gives details about the introduction of solid foods for vegan children.

Older adults

In ageing, there is a decreased energy need but increased requirements and/or decreased absorption for some nutrients. This combined with a smaller appetite and the physical limitations that may increase with age means that nutrient dense, vegetarian or vegan acceptable foods should be eaten in line with nutritional requirements (see Chapter 3.3). When dietary selection is limited, nutrient supplementation with a low dose multivitamin and mineral supplement can be useful in meeting recommended intake levels.

A study in community living elderly vegetarians in Taiwan found they had significantly lower daily total energy, lower cholesterol, a higher percentage of fat as polyunsaturated fatty acid (PUFA), higher calcium and higher fibre intakes compared with omnivores. Vegetarian diets in this group contained more potassium, calcium, magnesium and fibre than vegan diets (Huang *et al.*, 2011). In China, community living, elderly women consuming a vegetarian or vegan diet had significantly lower bone mineral density at some sites in the hip (although bone mineral density at the spine was similar between vegetarians and omnivores) (Lau *et al.*, 1998). Due to possibly very different types of food consumption, these results should be viewed cautiously and further research is warranted. There appears to be little difference in the dietary intakes, blood values and physical characteristics between the institutionalised vegetarian and non-vegetarian elderly (Deriemaeker *et al.*, 2011).

Athletes

There is no reason why a vegetarian or vegan athlete will perform differently from omnivore athletes as long as they are consuming a well balanced diet. As yet, there is no evidence that a vegetarian or vegan diet will improve performance either (Fuhrman & Ferreri, 2010). There are a number of concerns that vegetarian and vegan athletes must be aware of to ensure optimum intake as an athlete may require more protein than non-athletes, but this generally should not cause any problems unless the diet becomes too bulky. However, vegetarian athletes may be at risk for low intakes of energy, fat, vitamin B₁₂, riboflavin, vitamin D, calcium, iron (particularly in women and during adolescence and pregnancy) and zinc (Rodriguez

et al., 2010). There is no current evidence regarding the adequacy of the nutritional intake of vegan athletes (see Chapter 4.3).

3.7

People with learning disabilities

Siân Burton, Anne Laverty and Marjory Macleod

Key points

- People with a learning disability are nutritionally vulnerable and their needs should be assessed on an individual basis.
- Dietary guidance for clients should be clear and concise with no more than three key messages or dietary goals at a time.
- Issues of client consent and involvement in the decision making process must be considered.
- Multidisciplinary and multiagency collaborative working is essential to ensure consistent messages and continuity of care.
- Guidelines for the nutritional management of specific learning disabilities, e.g. Down's syndrome and Prader–Willi syndrome, should be used.

NB: The guidance within this chapter is not applicable for people who have a higher level autistic spectrum disorder (ASD) such as Asperger's or other specific learning difficulties (SpLD), e.g. attention deficit disorder (ADD), attention deficit hyperactive disorder (ADHD) dyslexia, dyscalculia, dyspraxia and speech and language delay.

Government policy is aimed at encouraging people with a learning disability (LD) to access mainstream services (Rutter & Carmichael, 2011). Therefore, healthcare professionals (HCP), including dietitians, are more likely to encounter people with a LD in general clinics within primary and secondary care (Powrie, 2003; Sowney & Barr, 2004; Edwards, 2007). There has also been a major move away from institutionalised care so that people with a LD are enabled to live within the community, supported by a variety of healthcare and/or social care services as dictated by individual need. The unforeseen increase in the level of obesity, however, as a consequence of the change in domicile is impacting on people's health and quality of life (Robertson *et al.*, 2000; Emerson, 2005; Yamaki, 2005; Ito, 2006; Rimmer & Yamaki, 2006; Henderson *et al.*, 2008; Melville *et al.*, 2008).

People with a LD experience a higher burden of ill health than the general population, and are more than twice as likely to suffer health problems and four times as many die from preventable diseases (Disability Rights Commission, 2006). The range of health needs includes mental illness, epilepsy, an array of physical and sensory limitations (including impaired sense of touch, tempera-

ture, pain, taste and smell), dental disease, thyroid disorders, heart disease, alopecia, binge eating disorder (BED), dysphagia, undernutrition and obesity [Kennedy *et al.*, 1997; Bryan *et al.*, 2000; Hove, 2004; National Patient Safety Agency (NPSA), 2004; Bernall, 2005; Melville *et al.*, 2005; Wali *et al.*, 2006; Department of Health, 2007; 2009a; Wallace & Schluter, 2008; Carnaby, 2009].

The health gains associated with good nutritional care include enhanced quality of life and improved disease outcomes (Astor & Jeffreys, 2000; Department of Health, 2004). People with a LD must be enabled, as much as possible, to make informed decisions and steps must be taken to ensure that this client group has access to both mainstream and specialist services as and when required (Burton *et al.*, 2011).

Definition of learning disabilities

A universally accepted definition of LDs is not available; however, there is general agreement that the term includes a group of conditions that, as a result of factors occurring prior to birth, at birth, during childhood or up to the age of brain maturity, affect intellectual development and are life long (WHO, 2010). The following definition includes all the requisite dimensions and is useful for practitioners (WHO, 1992):

- A significant intellectual impairment with an intellectual quotient (IQ) of >2 standard deviations below the general population, i.e. <70 on a recognised IQ test.

- Deficits in social functioning or adaptive behaviour that significantly impact on how well a person's coping skills allow for everyday social demands that present within their environment.
 - Formal psychological assessments may include the Vineland Adaptive Behaviour Scales and the AAMR Adaptive Behaviour Scales.
- Are present before 18 years and are life long.

There will be local variations of this definition and it must be remembered that the use of IQ alone is not sufficient to define this population (Health Inspectorate Wales, 2007).

All children and adults with profound and multiple learning disabilities (PMLDs) need high levels of support with most aspects of daily life. They are among the most marginalised people in society, have some of the highest support needs and are the most reliant on services (Pawlyn & Carnaby, 2009). People with PMLDs:

- Have more than one disability.
- Have a profound learning disability.
- Have great difficulty communicating.
- May have additional sensory or physical disabilities, complex health needs or mental health difficulties.
- May have behaviours that are challenging.

All people with a LD have an expectation and a right to access core services as well as specialist LD teams [Scottish Executive, 2000; Learning Disabilities Advisory Group (LDAG), 2001; Bamford, 2005; Department of Health, 2007; 2009b]. Whether living at home, with parents, in supported or assisted accommodation or residential setting, appropriate support should be available from specialist teams that help clients live an ordinary life

within their local community. The division of what is considered core or specialist is not (or indeed should not be) clear cut, and robust working relationships between teams are essential for the provision of a seamless service for this client group; the dietitian is pivotal to service provision.

People with a LD are more nutritionally vulnerable than the general population for a number of reasons, including:

- Restricted income or poverty.
- Inappropriate or poor living conditions.
- Poor or limited availability in disadvantaged areas.
- Difficulties with travel and transport.
- Social isolation.
- Social exclusion.
- Limited training for healthcare staff about LDs.
- Limited nutritional knowledge of person with a LD and their carers.
- Limited budgeting or cooking skills of person with a LD and their carers.
- Reduced ability to understand and apply health messages, and read or understand food labels.
- Reduced ability or opportunity to make informed choices.
- Dependence on others for eating and drinking.

Physiological anomalies, polypharmacy, diagnostic overshadowing, multiple diagnoses and dysphagia are also common amongst this client group (Department of Health, 2007). Additionally, people with PMLDs are totally dependent on a range of carers, many of whom do not have the knowledge or skills to enable them to provide a well balanced diet for their clients (Melville *et al.*, 2009). Figure 3.7.1 shows the factors to consider when assessing

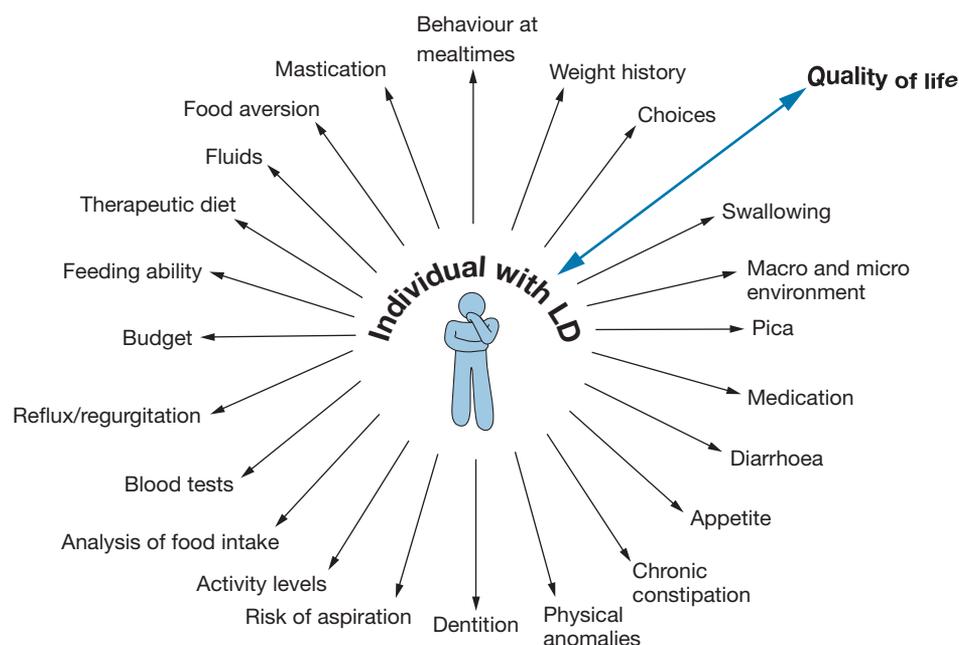

Figure 3.7.1 Factors to consider when assessing nutritional requirements for people with a learning disability (LD) [source: Thomas B, Bishop J (eds). (2007, Fig. 3.12.1, p. 391) *Manual of Dietetic Practice*, 4th edn. Oxford: Blackwell Scientific]

the needs of LD clients; these will also impact on the given intervention.

Capacity to consent

Consent must always be obtained before dietary interventions. When dealing with the general population, consent is customarily obtained verbally; however, for clients with cognitive impairment the issue of capacity to consent needs to be explored fully. In determining capacity to consent, it is essential to involve both clients and carers in the assessment and treatment process, and to communicate openly.

Assessments can be carried out without considering whether the client has the ability to give consent to treatment, but their capacity must be determined if treatment is to be given. Determining capacity to consent must always be time and decision specific. A person should not be viewed as unable to make a decision unless all practicable steps to help them do this have been taken without success. This includes employing alternative forms of communication such as symbolised information or signing. Legislation exists to provide a legal framework for decision making on behalf of adults who lack capacity to make specific decisions. It also provides the means for adults with the capacity to plan ahead in the event of future incapacity. Legislation differs slightly between countries; the relevant legislation for the UK is:

- Scotland – The Adults with Incapacity Act (Scottish Parliament, 2000).
- England and Wales – The Mental Capacity Act (MCA) (Department of Health, 2005).
- Northern Ireland – Seeking Consent [Department of Health, Social Services and Public Safety (DHSSPS), 2003].

Relevant excerpts from the legislation are included here as it is core to the care for a person with a LD. *The Short Reference Guide for Psychologists and Psychiatrists* (British Psychological Society, 2007) is recommended as a brief guide to its implementation for clinicians. This guide is applicable to England and Wales and also reflects the principles underpinning the Scottish Act. The guide includes the following:

- A person must be assumed to have capacity until it is established that they lack capacity.
- A person is not to be treated as unable to make a decision unless all practicable steps to help him or her to do so have been taken without success.
- A person is not to be treated as unable to make a decision merely because they makes an unwise decision.
- When decisions are made on behalf of someone who lacks capacity, they must be made in that person's best interests.
- When decisions are made on behalf of someone who lacks capacity, the less restrictive alternative must be considered to attain the goal specified.

The MCA defines capacity as: an adult can only be considered unable to make a particular decision if:

- They have 'an impairment of, or disturbance in, the functioning of the mind or brain', whether permanent or temporary.

and

- They are unable to undertake any (one or more) of the following steps:
 - Understand the information relevant to the decision.
 - Retain that information (despite use of prompts).
 - Use or weigh that information as part of the process of making the decision.
 - Communicate the decision made (whether by talking, sign language or other means).

A functional approach must be taken so that someone's ability to make a decision is determined by assessing whether they can undertake the steps above; it is not determined by their diagnosis or by the apparent wisdom of their decision. Decision making capacity is decision and time specific.

The functional approach (best interests)

In considering what is in someone's best interests when making a decision, the following should be taken into account:

- Whether and/or when the person is likely to regain capacity and whether the decision or the act to be undertaken can wait.
- How to encourage and optimise the participation of the person in the decision.
- Past and present wishes, feelings, beliefs and values of the person and any other relevant factors.
- Views of other relevant health, family, carer and social representatives. The decision should be perceived to be in the best interest of the client and not that of the family or carers.

When a person lacks the capacity to make decisions and has no family or friends, there is a duty to appoint an Independent Mental Capacity Advocate (IMCA) to help inform the determination of best interests. The dietitian should consult with paid and unpaid carers, and the client's general practitioner (GP) to determine if a dietetic treatment specific or overarching certificate of incapacity has been completed. The latter has generally been put in place for people with PMLDs, as many have permanent cognitive impairment. In some instances the client may have an advocate. It is also recommended that relevant professionals, whose core skills include assessment for capacity, from the specialist community learning disabilities team (CLDT) are approached, e.g. speech and language therapist (SLT), clinical psychologist, psychiatrist, LD community nurse and care manager. In many cases the issue of capacity is generally decided by multidisciplinary working.

If a client does not have capacity to consent, then whether the carer, relative or social worker has legal guardianship or power of attorney, which entitles them

to consent on specific issues on behalf of the client, should be considered. In Scotland a welfare guardian may be appointed, who may be granted full or partial powers under the act (Scottish Executive, 2000). If there is no welfare guardian, the GP, in consultation with the team, may complete an Adults with Incapacity form, which enables treatments to take place. In emergency situations the doctor can act without consultation of the team. In Northern Ireland, those close to the incapacitated individual should be involved in the decision making process (DHSSPS, 2003). In instances where there is no legal guardian, the decision should be reached with consultation of all health, family, carer and social representatives. Convening of a multidisciplinary or multiagency meeting is good practice to allow all to participate in decision making; this must be documented as well as any decisions made. The key documents for carers on the issue of consent are:

- *Scotland* – Caring and consent: information for carers (NHS Scotland, 2009).
- *England and Wales*:
 - Making Decisions: A guide for family, friends and other unpaid carers (Department for Constitutional Affairs, 2005a).
 - Making Decisions: A guide for people who work in health and social care (Department for Constitutional Affairs, 2005b).
- *Northern Ireland* – Seeking Consent: Working with people with learning disabilities (DHSSPS, 2003).

Role of advocacy

An advocate enables clients to get their views across and may be a friend, family member or independently appointed representative following a referral to an advocacy group, service or statute. Anyone can advocate on behalf of an individual, but emotional involvement with the client may make impartiality impossible. The advocate should contribute to the decision making process on the client's behalf. Where conflict occurs it should be remembered that their views, whilst listened to, have no legal status in relation to consent. In some cases their views may conflict with others who are involved in the decision making process. As the client's representative, they should be included in client specific multidisciplinary or agency meetings to discuss what is perceived to be in the client's best interests.

In England and Wales statutory Independent Mental Capacity Advocates (IMCAs) undergo formal training as stipulated by legislation (Department of Health, 2005) to enable them to assist with decision making in the best interests of clients who cannot make decisions by themselves or who have no family or friends. In Scotland a Mental Health Officer may be involved in this decision making process. In Northern Ireland family and carers involved with a particular client meet with the relevant health and social care professionals to act in the client's best interests.

Ethical issues

It is essential that any concerns raised about the ethical approach of managing a nutritional intervention in any adult with a LD should be discussed fully at a multidisciplinary/agency meeting. Where appropriate this should include key family members and an advocate to ensure that all are working in a consistent manner to meet the 'best interests' of the client at all times. All discussions and decisions must be fully documented.

Specific health needs of people with learning disabilities

Clinical syndromes associated with LDs include Down's syndrome and Prader–Willi syndrome.

Down's syndrome

Down's syndrome, also known as trisomy 21, is the most widely recognised chromosomal disorder and most common genetic cause of LD. The incidence is approximately 1 in 600–1000 live births with increasing prevalence rates due to increased life expectancy as the result of advancing medical knowledge and improving care. In addition, later pregnancies are increasingly common and the incidence of Down's syndrome rises with increasing maternal age. There are significant differences between various racial and social groups (Shin *et al.*, 2009).

Approximately 12% of neonates with Down's syndrome display congenital gastrointestinal anomalies, which require immediate surgical intervention to facilitate nutrition. Congenital heart disease occurs in approximately 40% of infants and may cause faltering growth. Following surgical repair of heart defects, these children's nutritional status will improve. Hypotonia (poor muscle tone) together with a small oral cavity, enlarged tongue and poor suck reflex can lead to initial feeding difficulties and delayed weaning (see Chapter 3.8.21).

Thyroid dysfunction is more common in people with Down's syndrome, with the incidence increasing with age. Hypothyroidism is most frequently reported but hyperthyroidism can also occur. Thyroid function should be checked every 2 years throughout life (Levy *et al.*, 2006). Obesity is common, but not inevitable, especially among the female population (Melville *et al.*, 2005). Growth retardation, short stature, hypotonia and a low resting metabolic rate (RMR) may all contribute to the problem. Other factors include poor eating behaviour, excessive energy intake and low exercise levels. Individuals should therefore be encouraged to follow healthy eating guidelines and participate in regular physical activity. People with Down's syndrome have an increased incidence of developing type 1 and type 2 diabetes and coeliac disease (Cohen, 2006). Diarrhoea, constipation, abdominal bloating, dyspepsia, mouth ulceration, mood change, arthritis, general fatigue and mild anaemia are common in Down's syndrome.

Nutritional management

Children and adults with Down's syndrome need the same range of nutrients as the general population. Energy intake estimates based on age groups are not appropriate in Down's syndrome and need to be tailored to height, weight and physical activity (Murray & Ryan-Krause, 2010). Growth charts specifically for Down's syndrome have been developed; standard charts are inappropriate due to developmental delay (Down's Syndrome Medical Interest Group, 2000).

Individuals have been found to be at greater risk of reduced bone mineral density as they age, possibly as a consequence of their small stature and sedentary lifestyle (Center *et al.*, 1998). For this reason a healthy balanced diet rich in calcium containing foods, regular weight bearing activity and a safe level of sunshine exposure in the summer months is recommended.

Dental anomalies include changes in tooth structure, reduced total number of teeth and delayed or abnormal eruption, as well as the physical abnormalities of the facial appearance and oral cavity, can impact on feeding. Dental disease is common because teeth are more at risk of wear through bruxism (teeth grinding) and decay due to enamel fragility. In addition, gingivitis (gum disease) and oral infections due to mouth breathing can lead to tooth loss and looseness (Hennequin *et al.*, 1999). A healthy balanced diet that avoids snacks and fizzy drinks can help preserve teeth.

Problems relating to premature ageing with Alzheimer-like changes in the brain have become more apparent as people with Down's syndrome are living longer. Between the ages of 40 and 50 years some individuals display a rapid deterioration in cognitive function. Possible explanations for this are being linked to the extra genetic material on chromosome 21. Low levels of vitamin E have been found to be associated with dementia in individuals with Down's syndrome, but more research is required into the possible effects of supplementation. In order to increase antioxidant intake, a diet rich in fruit, vegetables and oily fish is recommended. Features of rapid ageing in Down's syndrome include weight loss, reduction in appetite and problems with chewing and swallowing (Lazenby, 2008). If Alzheimer-like symptoms develop, it is important that steps are taken to ensure adequate nutrition and hydration (see Chapter 7.10.2). An individual may lose interest in food, forget to eat or may no longer recognise food or feeding utensils. The following points may help maximise food intake:

- Give assistance with feeding where appropriate but maintain independence for as long as possible.
- Give small frequent meals and snacks.
- Offer food that the individual is familiar with; items should be appetising and of appropriate consistency.
- Offer dessert later rather than present it with the main course, as many will reject savoury foods in preference for sweet items.
- Avoid external distractions and maintain a peaceful quiet environment at meal times.
- Avoid food that is too hot or too cold.

- Do not fill cups, beakers or plates to capacity to avoid spillage.
- Use food fortification for extra nutrition.

Most people with Down's syndrome live in the community, some with parents or carers, but adults often live independently or semi independently and many are able to learn about healthy eating and manage their own diet. A dietitian's role is likely to encompass not only individual assessment but also teaching and educating people with Down's syndrome as well as their parents, carers and other professionals.

Prader–Willi syndrome

Prader–Willi syndrome (PWS) is a relatively rare genetically determined neurodevelopment spectrum disorder with symptoms varying in severity and occurrence. It is believed to be caused by dysfunction of the hypothalamus, which controls bodily functions including hunger and satiety, temperature and pain regulation, fluid balance, puberty, emotions and fertility (van Mil *et al.*, 2000a; Whittington *et al.*, 2001; Vogels *et al.*, 2004; Lindmark *et al.*, 2010). It occurs in approximately 1 in 22 000 births, affecting males and females with equal frequency and all races and ethnicities (Prader-Willi Syndrome Association UK, 2010b). This genetic abnormality involves the absence of expression of one or more genes on chromosome 15 and definitive diagnosis is now based on genetic testing. Clients present with mild to severe LD; verbal skills are often better than functional skills. Obsessional characteristics include food related hoarding, ritualistic behaviour and an insatiable appetite, which drives the client to seek food (and sometimes fluids) and means they never feel full even after a large meal. This leads to severe hyperphagia (overeating), which is driven by a physiological abnormality and is highly resistant to motivational change. Prader–Willi syndrome is recognised as the most common genetic cause of life threatening obesity. Physical characteristics in PWS include:

- Short stature.
- Obesity.
- High vomiting threshold, possibly due to poor muscle tone.
- High pain threshold.
- Poor temperature control – erratic behaviour may occur during very cold or very hot weather.
- Decreased motor skills, hypotonia and poor balance.
- Bowel irregularities.
- Dental abnormalities.
- Abnormally thick and sticky saliva, especially in children.

The approach required in PWS is unique and requires close involvement of the multidisciplinary team (MDT). To work effectively with the client, clear boundaries are required, and due to the nature of the syndrome and the inability to self regulate, external management of the eating disorder is mandatory. The ethics of this situation have been fully explored in an application submitted for

guardianship within the Adults with Incapacity Act (Scotland), to ensure protection of the client (Healy, 2005). Long term structures and routines in relation to food and behaviours are essential for effective management. This can be seen to be in conflict with the prevailing health and social care ethic, which favours individual choice and decision making, but too much choice in particular situations can be counterproductive and may result in adverse outcomes. People with PWS can usually cope with a choice of two food or drink items at one time; more will lead to uncertainty and heightened anxiety, hampering not only decision making but also general behaviour, and is not recommended. People with PWS do not like sudden change or new experiences; therefore, incremental changes should be made to routines to allow adjustment and acceptance to take place. In order to establish and maintain a successful clinical relationship, the practitioner must give the client:

- Clear expectations and messages: leave no room for misinterpretation.
- Consistent routine and structure that must be followed by everyone.
- Specific feedback.
- Positive reinforcement to help establish new behaviours.
- Avoid confrontation, use eye contact and a gentle manner and wherever possible include the client in decision making.

Medications include growth hormone, which aims to improve growth velocity, and increase lean mass and physical function and ability (van Mil *et al.*, 2001; Haaq *et al.*, 2003; Carrel *et al.*, 2004) and appetite suppressants. However, there is no published evidence that demonstrates their effectiveness.

Nutritional management

The obesity associated with PWS is the result of a chronic imbalance between energy intake (due to hyperphagia) and reduced energy expenditure (due to decreased physical activity as a result of hypotonia and reduced metabolic rate). Individuals have a high ratio of body fat to fat free mass (FFM), where body fat can account for up to 50% of body weight (Butler *et al.*, 2007). Where the appropriate height to weight ratio is satisfactory, body fat can account for up to 40% (Schoeller *et al.*, 1988). As metabolic rate is related to FFM these abnormally high levels of fat result in significantly reduced metabolic rate and therefore energy requirements. Dietitians must structure weight reducing plans reflecting this.

Predictive formulae for estimating basal metabolic rate (BMR) in the general adult population have been shown to overestimate BMR in some populations (Ramirez-Zea, 2005; O'Riordan *et al.*, 2010) and this is further distorted in adults with PWS. Additionally, the standard approach to calculating requirements by subtracting 400–1000 kcal for a decrease in energy stores will not necessarily be effective in PWS. Research suggests that energy requirements in adults with PWS are up to 50% less than those of healthy age matched controls (Schoeller *et al.*, 1988;

Table 3.7.1 Height based energy prescription for Prader–Willi clients aged >16 years [from Hoffman *et al.* (1992)]

Outcome to be achieved	Energy/cm height
Weight loss	7–8 kcal (29–33 kJ)
Weight maintenance	10–14 kcal (42–59 kJ)

van Mil *et al.*, 2000a; Butler *et al.*, 2007). A height based energy prescription for adults with PWS is a practicable guide, as shown in Table 3.7.1. In predicting the energy requirements from BMR equations, the energy expenditure of physical activity should also be considered. The underdevelopment of muscle and any excess weight limits physical activity. One study in children and adolescents reported a mean physical activity level (PAL) of 1.33 (van Mil *et al.*, 2000b). This is significantly lower than that for obese controls and lower than the PAL of 1.4 previously used in calculating estimated average requirements (EAR) for energy in the UK population (Department of Health, 1991).

Predictive energy equations should be used with extreme caution in people with PWS. The recommended energy intake for adults with PWS is around 800–1200 kcal/day, reducing to 800–1000 kcal/day for weight loss (Heinemann, 2010; International Prader-Willi Association, 2010; Prader-Willi Syndrome Association, 2010a,b). At these levels of energy the diet should be planned using low energy, nutrient dense foods to ensure optimal vitamin and mineral intake (Lindmark *et al.*, 2010). As osteoporosis and low bone mineral density are common in PWS, calcium and vitamin D supplementation should be considered (van Mil *et al.*, 2001).

Adherence to dietary regimens may present many challenges. The dietitian should work closely with the MDT, client and carers to overcome obstacles; this may involve the training of all staff in the management strategies that are required to support PWS clients. All involved must adhere strictly to the prescribed diet, agreed structures and routines, which are required for life and cannot be relaxed even when weight is being maintained.

Clear straightforward language is required and the judicious use of terminology, e.g. *free fluids* will be understood literally by the client and may result in fluid intoxication. If food seeking/stealing behaviour is an issue, the team should work together to seek resolutions. Sanctions may be appropriate but at no time should blame be directed towards the client. The need for rules and routines is inherent in this syndrome (Holland *et al.*, 2003) and can be used advantageously in positive reinforcement of healthy eating behaviours and regular exercise plans.

Clients with PWS have particular difficulties with short term memory and processing spoken information, and tend to display rigid thinking. Forward planning for all changes in routine is therefore an essential component to minimise anxiety and associated challenging behaviour. The dietitian plays a pivotal role when working with

these clients as they have the knowledge and skills necessary to guide the management of this disorder.

Other syndromes that cause learning disabilities and their nutritional consequences are shown in Table 3.7.2.

Conditions associated with learning disabilities

Autism

Autism is a spectrum of lifelong neurodevelopmental disorders with onset noted in early childhood (see Autism in Chapter 3.8.6). Social and communication skills are affected and there is often, but not always, some degree of LD. The spectrum ranges from those who are high functioning (often referred to as Asperger's) to people who are severely disabled. The term autism spectrum disorder (ASD) is widely accepted though more recently autistic spectrum condition is used. A triad of impairments – social interaction, social communication and imagination – is used to describe the difficulties that people with autism experience to varying degrees (National Autistic Society, 2011). The prevalence is 5 in 1000 births (Baird *et al.*, 2003), with boys four times more likely to be affected than girls. In the majority of cases causation is unknown. Characteristics include obsessive desire for order, rigid thinking, inflexibility, reliance on routines, ritualistic behaviour, poor social skills, and visual and sensory perception difficulties. Common comorbidities include attention deficit hyperactivity disorder (ADHD), food compulsions, food restrictions and gastrointestinal problems. A structured environment, clear boundaries, and rules and routines are essential components to minimise stress. Changes that can be made occur slowly and over a lengthy period.

Nutritional management

Many children with ASD show selective eating and therefore self limiting diets as a direct result of their disorder (Schreck *et al.*, 2004; Williams *et al.*, 2005). This established eating pattern continues into adulthood and may compromise nutritional status, as the individual may be extremely obsessive, selective and restrictive in food choices. Any alterations in the environment or routine may result in behavioural outbursts or food refusal. Gastrointestinal problems may also affect appetite (Williams *et al.*, 2000; Levy *et al.*, 2007a). This is a complex condition that often requires a coordinated multidisciplinary team/agency approach. The following professionals may be involved in the community team:

- Behavioural therapist.
- Clinical psychologist.
- Community nurse.
- Consultant psychiatrist.
- Dietitian.
- Occupational therapist.
- Physiotherapist.
- Social worker/care manager.
- Speech and language therapist – communication.
- Speech and language therapist – dysphagia.

Detailed nutritional assessment by a specialist dietitian should take place for clients who eat fewer than 20 different foods (Isherwood *et al.*, 2011). The dietitian will work closely with the team, advising on any nutritional deficiencies, providing the evidence base for any dietary modifications and offering practical advice as to how any deficiencies can be treated or how dietary modifications can be implemented. Common feeding concerns include:

- Difficulty with transition to textures (especially during infancy).
- Increased sensory sensitivity (including oral).
- Difficulty accepting new foods.
- Restricted intake due to colour, texture, packaging and food temperature.
- Decreased selection of food over time.
- Difficulty with changes in meal time environment, e.g. school versus home.
- Difficulty with meal time presentation, e.g. specific plate and cutlery, positioning of food on a plate.
- Continually eating rather than having set meal times.

A large number of therapeutic approaches have been developed, such as introducing gluten and/or casein free diets (Elder *et al.*, 2006; Wong & Smith, 2006). Anecdotal reports suggest that these may be beneficial in some cases and many parents and carers strongly believe in their effectiveness. There is limited robust evidence to support gluten or casein free diets (Knivsberg *et al.*, 2002). A Cochrane systematic review highlighted the need for robust studies, suitably powered to ascertain the success or otherwise of any dietary modifications (Millward *et al.*, 2008). The British Dietetic Association (BDA) has produced a professional consensus statement on dietary management of ASD (Isherwood *et al.*, 2011).

Cerebral palsy

Cerebral palsy (CP) is the most common physical disability in children and affects 2–2.5 in 1000 births in the UK (Roebroek & Stam, 2006) and 3.6 in 1000 births in the USA (Yeargin-Allsop *et al.*, 2008). Known possible causes include oxygen starvation, cerebral bleeding and abnormal brain development. Impairment to the immature brain, which can occur before, during or after birth, affects movement, posture and coordination. Depending upon the severity of the underlying condition, CP may not become obvious until early childhood. It is a wide ranging condition and can affect people in many different ways; it is not a LD, though many people with CP also have a LD.

Cerebral palsy is not progressive though some of the effects on the body may become more noticeable and function may deteriorate with age. There are three types of cerebral palsy; spastic, dyskinetic (also known as athetoid or dystonic) and ataxic, and these generally relate to which part of the brain has been affected. The effects vary enormously from one person to another and it is common for an individual to have a combination of two or more types. Some may have this condition so mildly that its effects are barely noticeable, whilst others

Table 3.7.2 Nutritional consequences of other clinical syndromes associated with a learning disability [adapted from Burton *et al.* (2009)]

Syndrome	Symptoms affecting nutritional status	Nutritional consequences	Issues
Cornelia de Lange syndrome Chromosome 5 abnormality X chromosome and chromosome 10 responsible for milder form	Low birth weight, delayed growth and stature, developmental delay, cleft palate, gaseous distension May exhibit autistic-like behaviours including self injury	Intermittent poor appetite, vomiting, constipation. GORD Nutrition intake may be variable as many behaviours are cyclical	MDT approach required May require a set of nutrition care plans depending on behaviour and ability to eat and drink
Fragile X syndrome Inhibited mental development, moderate to severe learning disability Autistic-like behaviour with physical and behavioural features and delayed speech	Need very structured environment, obsessive desire for order and familiarity, poor social skills, rigid thinking, inflexible, cannot cope with change, easily distracted from eating, changed visual perceptions	Nutrition intake may be poor and is dependent on degree of food related obsessive behaviour Need a stable macro- (competent staff, pleasant, calm surroundings – no TV or music to detract from meal times) and micro-environment (correct seating, utensils, adherence to eating and drinking guidelines, time)	MDT approach required May require a set of nutrition care plans depending on behaviour and ability to eat and drink
Klinefelter's syndrome Affects males with extra X chromosome Incidence 1 in 1000 males, 1 in 500 have the extra X syndrome without symptoms of the syndrome	Reduced muscle power and stamina NB: most will have a specific learning difficulty though some may have a degree of learning disability	Prone to depression, thyroid disease, diabetes, osteoporosis, asthma and heart disease	Difficult to feed, get tired easily Carers need to be patient and persevere with feeding
Rett syndrome Neurodevelopmental disorder characterised by microcephaly, developmental delay, scoliosis, loss of purposeful use of hands, hand flapping, poor muscle tone, gastric abnormalities, seizures and a degree of learning disability Occurs almost exclusively in girls	Problems with the mechanics of eating Breathing issues, e.g. hyperventilation and breath holding Biting, chewing, swallowing and self feeding are all affected by very poor muscle tone	Babies have a poor suck reflex and difficulty meeting their requirements, leading to faltering growth Breathing irregularities interrupt feeding Nutritional intake is an issue from birth	Hypotonia with poor food intakes necessitate texture modification of food and thickened drinks Difficulties in independent eating as a result of poor hand movements – need to be fed Constipation is very common due to a low intake of fibre and difficulty meeting fluid requirements; may be reduced gut motility
Smith Magenis syndrome Genetic condition characterised by delayed speech, distinctive facial features, sleep disturbances and behavioural problems, especially self injurious behaviour Individuals tend to be of short stature and may have scoliosis.	Dental agenesis and protruding lower jaw can lead to problems with chewing and ability to manage textures Feeding difficulties in infancy due to hypotonia causing poor suck reflex and faltering growth There is also evidence of oral sensory motor dysfunction and GORD Many become overweight in teens through to adulthood	Poor oral intake, faltering growth, reluctance to progress to more solid textures Dental problems can necessitate need for a texture modified diet Obesity can impact on mobility Behaviour problems can manifest themselves in limited food choices and reluctance to try new foods	Psychological support for challenging behaviours/self injurious behaviour A healthy balanced diet and good variety of foods should be encouraged but may need texture modification depending on degree of dental abnormality
Tourette's syndrome Neurological disease of unknown origin characterised by chronic muscular tics and vocal tics, and is socially stigmatising Often combined with obsessive compulsive behaviour and attention deficit disorder	Need very structured environment Obsessive desire for order and familiarity, rigid thinking, inflexible, inability to cope with change, easily distracted from eating, changed visual perceptions Poor social skills If not treated early leads to severe intellectual disabilities Challenging behaviours include self harm and harm to others, food aversions Weight disturbances	Nutritional intakes are likely to be poor Many clients will have feeding issues	Psychological aspects affecting food intake Physical problems affecting eating and feeding
Untreated phenylketonuria (PKU) Autosomal recessive genetic condition resulting from a deficiency in the hepatic enzyme phenylalanine hydroxylase Hyperphenylalaemia is neurotoxic and the damage is irreversible		Challenging behaviours affect food intake Can present as under- or over-weight	A low phenylalanine diet can improve nutritional status and cognitive abilities in some clients Acceptability may inhibit continuance and QOL issues need to be addressed before considering implementation of diet Dietetic management depends on symptoms

GORD, gastro-oesophageal reflux disease; MDT, multidisciplinary team; QOL, quality of life.

may be profoundly affected and require help with many or all aspects of daily life. Many children with CP frequently grow poorly due to the underlying disability, malnutrition, endocrinopathy or poor bone growth (Kuperminc & Stevenson, 2008). Other difficulties and medical conditions that can occur more commonly include:

- Chronic constipation.
- Difficulties in chewing and swallowing, especially with advancing age.
- Epilepsy.
- Gastro-oesophageal reflux disease.
- Learning disability – mild, moderate or severe.
- Oral dysfunction.
- Vomiting due to gut dysmotility and activated emetic reflex.

See Chapter 3.8.7 for further details.

Other nutritional considerations in people with learning disabilities

Key nutritional considerations include obesity, underweight, dysphagia, gastro-oesophageal reflux disease (GORD) and *Helicobacter pylori* infection.

Obesity

People with mild LD are more likely to become obese than people with more severe LD (RCN, 2006; Melville *et al.*, 2008). Evidence indicates that people with a LD tend to become overweight at an earlier age and stay overweight, whereas the general population tends to become more overweight with age (Bhaumik *et al.*, 2008; Gale *et al.*, 2009). There are many factors that predispose people with a LD to developing obesity (Jeffreys, 2000; Beart *et al.*, 2001; Draheim *et al.*, 2002; Illingworth *et al.*, 2003; Frey, 2004; Chapman *et al.*, 2005; Frey *et al.*, 2005; Hawkins & Look, 2006; Henderson *et al.*, 2007; Peterson *et al.*, 2008), including:

- Attitudes of carers.
- Boredom.
- Communication difficulties.
- Hypothyroidism.
- Lack of knowledge.
- Lack of skills including literacy.
- Lack of power/control over own life.
- Limited access to exercise.
- Low income.
- Medication (see Table 3.7.3).
- Thyroid disease in Down's syndrome.
- Mental illness.
- Misuse of food as rewards or motivators to engage in activities.
- Provision of poor diet.
- Poor self esteem.
- Sedentary lifestyle.
- Altered body composition leading to lower BMR.

Table 3.7.3 Weight gain associated with commonly prescribed drugs in learning disabilities (adapted from Leslie *et al.* 2007. Reproduced with permission of Oxford University Press)

Drug	Indicative condition	Weight change (kg)
Sodium valproate	Bipolar/epilepsy	+1.2–5.8
Lithium	Bipolar/depression	+4.0
Clozapine	Schizophrenia	+4.2–9.9
Olanzapine	Schizophrenia	+2.8–7.1
Risperidone	Psychoses	+2.1–2.3
Ziprasidone	Schizophrenia	–2.7–3.2
Prednisolone	Muscle relaxant	+2
Nortriptyline	Depression	+3.7
Doxepin	Depression	+2.7
Amitriptyline	Depression	+1.7

Levels of obesity are less prevalent in adults with PMLDs but can occur. Sometimes weight maintenance may be the best outcome, ensuring that the intake is nutritionally sound, which in itself confers positive benefits such as relief from constipation, better mood and generally feeling better. The impact of medications should not be overlooked as antipsychotic and antidepressant medications may induce undesired and rapid weight gain (Birt, 2003; Khazaal, *et al.*, 2006; Burton *et al.*, 2009), as shown in Table 3.7.3. Weight gains of 14kg in 1 year have been reported (Leslie *et al.*, 2007).

Abdominal obesity can occur if energy requirements are overestimated during gastrostomy feeding. It is important to note that energy requirements for these individuals are often lower than for the general population of comparable weight and height (Fairclough *et al.*, 2008). People with a LD are often dependent on others for menu planning, shopping and cooking. Frequently, carers have little knowledge about healthy eating themselves, and many myths about nutrition get passed on and become part of custom and practice in the care setting. The role of the carers in the prevention of obesity and other lifestyle conditions as well as in any intervention strategies should not be overlooked. Their own food beliefs, eating experiences and behaviours are imparted to the client, which places an interesting perspective on client choice (Smyth & Bell, 2006).

There is little evidence describing effective weight loss interventions, whether designed for general use and adapted for people with a LD, or targeted specifically for people with a LD. Evidence that people with a LD who are more independent are more likely to be obese (Levy *et al.*, 2006) is contradicted by other studies that suggest those living in supported accommodation are more likely to be overweight or obese (Moore *et al.*, 2004). Also, another study by Levy *et al.* (2007b) found that those living with their family are more likely to be obese. It would seem reasonable therefore that in all settings any weight loss intervention must include support and motivation from carers (Hamilton *et al.*, 2007).

In addition, as a means of preventing obesity, or limiting any further increases in weight, all paid carers should have mandatory induction training regarding implementing healthy lifestyle choices as a routine duty of care (Melville *et al.*, 2009). Training programmes on nutrition under the umbrella of health and social care are becoming more available throughout the UK. Though conventional weight maintenance regimens emphasise a high fibre and high fluid intake, this is of critical importance in this client group as some clients have difficulties consuming sufficient fluid. Therefore encouraging higher intakes of fruit and vegetables, with their naturally high fluid content, may be the preferred option rather than promoting too much insoluble fibre in the form of wholegrain foods.

In a clinic session standard preappointment processes may need to be adapted; it may be more effective and efficient to telephone the client and/or carer to make the appointment. Also, it should be considered if the appointment needs to be at the beginning or end of a clinic session, to help reduce the client's anxiety levels. Partial booking and similar procedures can be confusing, but if contact by telephone is not feasible, a minimum of (straightforward) words should be used in the appointment letter. To aid attendance, the client/carer should be telephoned and reminded on the working day before the appointment. When consulting in a one to one setting it is essential to consider the points shown in Box 3.7.1.

There is some consensus that group sessions for clients and carers are effective (Marshall *et al.*, 2003), as are those that incorporate increased physical activity (Chapman *et al.*, 2008). Mainstream weight loss group interventions can be accessed with support from carers. It is important that the carers reiterate the key messages and make sure the client feels part of the group. The information will also need to be in an accessible format to aid understanding and compliance. Box 3.7.2 gives recommendations when consulting in a group setting.

Monitoring

Regular monitoring is essential for clients with a LD to sustain motivation. Carers should follow the monitoring protocol as advised by the dietitian, which may include weight checks, food and fluid charts, and menu structure. Ongoing dietetic review is not necessary, though some adjustments to the timeline in any local pathways should be considered, as the first appointment may be introductory. Once the key messages have been understood by the client and carer, and actions and targets agreed, further dietetic reviews may be undertaken at the dietitian's discretion but with discharge, not ongoing care, in mind.

Practical monitoring issues

It is more practical to check weight using stand-on scales, but for those with poor mobility or balance problems, seated or hoist scales may be necessary. Wheelchair beam or platform scales are available. Changes to the wheelchair will mean that the chair will have to be reweighed. In cases where it is not feasible to weigh a client, global assessment taking into account fit of clothes and jewellery

can be used as indicators of weight change (Burton *et al.*, 2009).

It will be more difficult to measure an accurate height for clients with physical anomalies such as kyphosis or scoliosis. Alternative or surrogate markers of height, e.g. ulna length, knee height and supine length, have been found to be inferior to self or carer reported height if available (BAPEN, 2003).

Body mass index (BMI) must be treated with caution where an individual has altered body composition as it does not assess fat distribution (SIGN, 2010). Clients with PMLDs are more likely to have muscle wasting of their extremities and greater visceral adiposity, and thus a greater risk of coronary heart disease (CHD) and respiratory problems (Draheim, 2006). Mid upper arm circumference (MUAC) and triceps skin fold (TSF) measurements may be inappropriate (Fairclough *et al.*, 2008) for similar reasons. Targets for BMI in clients with PMLDs should be set at the lower end of the normal range. Achieving a weight loss of between 5% and 10% would be a more appropriate, realistic and achievable goal, irrespective of the degree of obesity, and would confer positive health gains for the individual (SIGN, 2010; DOM UK, 2007; NICE, 2006) (see Chapter 7.13.2). The BDA professional consensus statement on weight management for adults with a LD living in the community gives more detailed advice on managing this client group (Burton *et al.*, 2011).

Underweight

Polarisation of weight is common within the LD, with the incidence of underweight ranging from 14% to 75% depending on the severity of the LD (Gravestock, 2000; Emerson, 2005). It is not uncommon for severe undernutrition to go unrecognised by support staff and family members, particularly when it has been longstanding (Crawley, 2007). Underweight is more common in people who are immobile, and unable to feed themselves or tolerate solid foods, or exhibit regurgitation, rumination or chronic vomiting.

For more detailed information, refer to the BDA Professional Consensus Statements on the nutritional care of adults with a LD in care settings (DiMascio *et al.*, 2012) and home enteral tube feeding for adults with a LD (Fairclough *et al.*, 2008) (see Chapter 6.2).

Dysphagia

Despite dysphagia being a significant problem in people with a LD, few robust studies have been published. Reported prevalence rates vary from 36% (Hickman, 1997) to 73% (Rogers *et al.*, 1994) in inpatient populations and 5% (Hickman & Jenner, 1997) to 8% in the community (Chadwick & Jolliffe, 2009). The range of signs and symptoms of dysphagia in people with a LD include:

- Coughing during, and for up to an hour after, eating and drinking;

Box 3.7.1 Recommendations for consultations in a one to one setting

- Expect first appointment to focus on getting to know the client and gaining trust
- Collect information on the client's social and family network so you know the key people with whom to liaise, i.e. care manager, social worker, day service, college, respite, sitters, family, other healthcare workers currently involved
- Allow at least 30 minutes per consultation
- Keep distractions to a minimum
- Discourage accompanying person (if any) from answering for the client and where possible encourage them to sit behind the client
- Use straightforward language
- Pace delivery
- Ask open questions using no more than two information carrying words at a time*
- Count to 10 after each question (if needed) to give the client time to reply
- Rephrase questions to make sure the client is not just repeating your last word
- Use visual aids to reinforce the spoken word, such as food models, photographs and symbols
- Limit any areas for change to a maximum of three
- Use symbols or photographs and font 14, Arial, Comic Sans, Univers, Tahoma or Verdana in written communication
- Obtain the client's consent to send copies of recommendations and any supporting information to the care manager for distribution to day services and respite as appropriate
- Wherever possible review with same accompanying person for consistency

- Accumulation of saliva.
- Drooling.
- Choking.
- Food aversion.
- Behaviour changes.
- Rushing food.
- Difficulty taking medications.

These signs are often attributed to the learning disability itself and in many cases are not investigated; such diagnostic overshadowing is unfortunately a common occurrence within this population (Leslie *et al.*, 2009). During a routine nutritional assessment the dietitian is in an ideal situation to observe potential signs and symptoms of dysphagia. Insidious onset of symptoms, such as unexpected weight loss, taking longer to eat and drink, becoming increasingly selective with food choices and hypersalivation, can be missed or not seen as important by carers or the clients themselves (Burton *et al.*, 2012).

Amylase resistant thickeners based on guar gum/guar gum starch combinations have been suggested as beneficial for individuals who hypersalivate, although recent

Box 3.7.2 Recommendations when consulting in a group setting

- Plan first session solely for getting to know the clients and gaining trust
- Limit membership to no more than 10 clients
- Encourage carers to attend, although it is not necessary to exclude any clients who attend without support
- Two people are needed to facilitate each session
- Allow a maximum of 2 hours per session with a break midway
- Keep to one theme per session
- Plan a maximum of six sessions with no more than three key themes for the whole programme
- Keep distractions to a minimum
- Discourage accompanying people from answering for the clients
- Use straightforward language
- Pace the delivery
- Ask open questions using no more than two information carrying words at a time*
- Count to ten after each question to give clients time to reply
- Rephrase questions to make sure the clients are not just repeating the last word
- Ask clients to repeat tasks given to them
- Use visual aids and activities such as food models, photographs and symbols to reinforce points
- Limit any areas for change in individual action plans to a maximum of three
- Use symbols or photographs and font 14, Arial, Comic Sans, Univers, Tahoma or Verdana in written communication
- Make sure that copies of activities, work completed and any supporting information are available in individual take home files or folders for clients to share with carers
- Review

*An information carrying word is any word in a sentence that must be understood in order to follow an instruction, e.g. 'Give me the ball'. The person asking holds out their hand, with only a ball in front of them. The addressee does not have to understand any words, because the person has shown them what they want. This statement has no information carrying words. If there were to be a ball and a book and the same question was repeated, the addressee needs to know the difference between ball and book. This has one information carrying word level. Messages can have varying numbers of information carrying words depending on how they are said and what clues are provided. Close liaison with a SLT is recommended.

research questions this evidence (Hanson *et al.*, 2012). From a pragmatic point of view, the best thickener to use will be that preferred by the consumer. The addition of thickener to fluids may lead to an increase in energy intake, resulting in weight gain, which may or may not be

advantageous. The dietitian should consider the implications of the additional energy component that impacts on weight when choosing the type of thickener to use as the energy content of thickeners varies (see Chapter 7.3).

Oral hygiene is of particular importance in those who eat and drink very little or are nil by mouth. Reduced stimulation of the oral environment leads to dry mouth (reduced saliva production), increased risk of infection, ulceration and increased build-up of plaque or calculus (tartar). The build-up of plaque and calculus can lead to dental decay due to the presence of plaque acids, periodontal disease due to plaque toxins and bacteria, and increased risk of aspiration pneumonia (Wales, 2010). Plaque organisms such as *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* are common causal organisms of chest infections (Langmore *et al.*, 1998). Each client will require specific guidelines for oral care based on the vulnerability of their airway, underlying condition and tolerance of routine interventions such as tooth brushing, dental reviews and required treatments. Following risk assessment, oral care plans may include specific proactive and reactive strategies such as positioning for oral care, suitable equipment (e.g. using a small headed multitufted manual toothbrush or small headed powered toothbrush), low foaming toothpaste, need for suction and use of any oral hygiene adjuncts (e.g. prescribed mouthwash). People with a LD who are dependent on others for oral hygiene are at high risk of having poor oral health.

Gastro-oesophageal reflux disease

Gastroesophageal reflux disease (GORD) is a common problem in people with a LD, with there being a higher incidence in those with PMLDs. More than 50% of institutionalised people with a moderate to severe LD in the Netherlands were shown to have GORD (Böhmer *et al.*, 1999). Higher incidences have been noted in specific syndromes such as fragile X and Rett syndrome and in conditions such as CP. People taking antiepileptic medication and those with a history of rumination also display a high incidence of the disease. It is caused by acid from the stomach entering the oesophagus, resulting in heartburn, painful swallowing, vomiting and haematemesis (Crawley, 2007). The pain can be intense and individuals may not be able to describe what is wrong. This may also contribute to sleep disturbance or challenging behaviour. Many cases are missed with a single oesophagoscopy and diagnosis requires 24-hour oesophageal pHmetry, which is difficult in this client group. There is justification, therefore, to treat with proton pump inhibitors without prior endoscopy. Recommendations for the management of GORD in clients with a LD include:

- Small frequent meals.
- Feed client in an upright position – this may be difficult in those with PMLDs and advice should be sought from the physiotherapist about positioning.
- Feed slowly and encourage chewing if possible.
- Maintain the client in an upright position for at least 30 minutes after meals.

These recommendations can also be used to assist in the treatment of regurgitation and rumination, which are more common in people with PMLDs and those with behavioural problems. Carers and other key professionals require education and training to understand the rationale for careful feeding and the consequences of not adhering to guidelines.

Helicobacter pylori infection

Helicobacter pylori infection is endemic among the LD population due to communal living situations, including group homes or shared tenancies, respite homes and attending adult day centres, where individuals are in close social contact (De Schryver *et al.*, 2007; Clarke *et al.*, 2008). Diagnosis is confirmed by a breath test, which detects the presence of urea; however, people with a LD find this procedure difficult so other methods such as serological testing or stool sampling to check for antigens are recommended (Scheepers *et al.*, 2000). Infection is associated with peptic ulceration and pain, and in people with a LD can present as nausea, vomiting, general malaise and challenging behaviours when the individual cannot describe the nature of the problem. In extreme circumstances the first indication of the severity of the problem can be perforation of a gastric ulcer. It has been postulated that the high prevalence of infection with *H. pylori* in people with a LD leads to a higher prevalence of gastric carcinoma. Treatment includes antibiotics and proton pump inhibitors. Following eradication therapy reinfection can occur and the incidence of this happening is much higher in people with a LD (Wallace *et al.*, 2002).

Other factors to consider when working with clients with learning disabilities

Medication

The impact of medication is often overlooked despite clients with a LD being prescribed a large number of medications to control mood, behaviour and epilepsy on a daily basis as well as required (*pro nata*; also known as rescue medication). Some medications, e.g. anticonvulsants and osmotic laxatives, have a direct impact on nutrient absorption. Neuroleptics (antipsychotics) cause pharyngeal weakness and dystonia, whilst some of the tricyclic antidepressants, e.g. amitriptyline, reduce saliva production resulting in xerostomia (dry mouth). Medication reviews are important to discuss the impact of new drugs as well as the continued combination of current medications. Medication side effects also include chronic constipation, a frequent problem for people with a LD, which increases the risk of seizure activity. Other medications frequently prescribed for clients with a LD that can impact on nutritional status are shown in Table 3.7.4.

Carers

Many carers will have the skills and knowledge to promote good eating habits and should be encouraged to share good practices with their care teams. In some circum-

Table 3.7.4 Medications prescribed for clients with learning disabilities that impact on nutritional status [adapted from Burton *et al.* (2009)]

Medication	Nutrition related side effects
Antipsychotics , e.g. risperidone, aripiprazole	Drowsiness, apathy, confusion, depression Gastrointestinal disturbances, dry mouth, weight gain
Anticonvulsants/antiepileptics , e.g. topiramate, phenytoin	Nausea, vomiting, constipation, diarrhoea, abdominal pain, oedema, appetite changes, confusion, weight gain, dry mouth, weight loss
Antidepressants: Tricyclics, amitriptyline	Loss of appetite, constipation, weight gain, dry mouth
Monoamine oxidase inhibitors (MAOIs)	As above plus strict adherence to special diet as certain foods need to be avoided
Selective serotonin reuptake inhibitors (SSRIs), e.g. fluoxetine	Taste disturbance, increased salivation, rhinitis, changes in blood sugars
Anxiolytics , e.g. diazepam	Salivation changes, constipation, diarrhoea, vomiting
Hypnotics , e.g. temazepam	Drowsiness, confusion, gastric irritation
Antimuscarinics , e.g. hyoscine	Constipation, dry mouth, nausea, vomiting
Mood stabilisers , e.g. lithium	Weight gain, excessive thirst, oedema
Laxatives: Bulk forming, e.g. methyl cellulose	Flatulence, abdominal distension, gastrointestinal obstruction or impaction
Stimulant, e.g. senna	Diarrhoea, hypokalaemia
Osmotic, e.g. Movicol, lactulose	Long term use can interfere with the absorption of fat soluble vitamins, flatulence, abdominal discomfort
Thickeners – starch and gum based	Diarrhoea, constipation, weight gain

stances there may be a need to address specific issues pertaining to carers including:

- Varying levels of interest in food and exercise.
- Little or no experience in planning healthy menus or adapting menus to accommodate texture modification.
- Understanding that their clients do not require the same amount of food as they do and so providing smaller portions is acceptable.
- Bringing their own theories and idiosyncrasies to the meal provision process.
- Perceiving clients as not having fulfilled lives and seeking to redress this in some way using food.
- Using '*it's the client's choice*' as an excuse to provide or allow access to less healthy food from either a nutrient or texture aspect.

Paid carers often struggle to define their role, especially when the issue of choice is so far reaching. Some see their role as protecting the client's long term health, and so work hard to ensure healthier choices are made. Others see their role as promoting choice, and as long as they enable their client to make a choice, or their client can be seen to be making choices (healthy or unhealthy), they have fulfilled their role. The issue of human rights is also cited and interpreted as people with capacity having the right to make unhealthy choices. Staff need to remember that they have a duty of care to ensure their client's health needs are met and should endeavour to facilitate informed choices as much as possible. It is important to have an appreciation and understanding of the skills base, values

and belief systems of carers and to use this state of reality for training and support. Empowering carers is as important as empowering their clients.

Information

Information needs to be provided in a format that is easily understood, i.e. in an accessible format incorporating a range of techniques, e.g. symbols, photographs, audio-visual and Talking Mats™ (see useful resources). With regard to verbal communication it is important to remember how information is interpreted. Advice may be taken literally or choice may be limited to a suggestion given, e.g. '*you can have an occasional treat like chocolate*', could be interpreted as chocolate is only a treat. The term occasional is abstract and subjective, and the same could be said for daily or weekly, or even hourly depending on the client's understanding of time. Clients should be asked to say in their own words what they understand from the information they have been given. There should be no temptation to use the fact that the client can repeat what has just been said to them as a measure of understanding, as many people with a LD are quite adept at recalling the words most recently spoken to them; this is known as the recency effect (Kroese *et al.*, 1998).

Bowel function

A standardised way of describing bowel function using the Bristol stool chart is recommended (Lewis & Heaton, 1997). Constipation in particular is a frequent problem

and increases the risk of epileptic seizure activity, but it often goes unrecognised by carers because it is normal for the client (Fairclough *et al.*, 2008). Contributing factors are poor gut motility, chronic inadequate fluid and fibre intake, chronic laxative usage, lack of physical activity and medication side effects. When enteral tube feeding is commenced, there is a risk of faecal impaction and vomiting despite adequate nutrition and fluid. In dysphagia, thickeners have been reported to alter client's bowel function (diarrhoea or constipation or both). Bowel function therefore needs to be monitored to prevent complications and colonisation by *H. pylori* should be considered.

Quality of life

Any intervention should consider the four principles of medical ethics, i.e. respect for autonomy, beneficence, non-maleficence and justice (Beauchamp & Childress, 2004), as well as the issue of consent, which always needs to be obtained for dietetic interventions. When dealing with the general population, consent is customarily obtained verbally. In clients with cognitive impairment, however, the issue about capacity to consent needs to be investigated thoroughly. In determining capacity to consent, it is essential to involve both the individual and carers in the process and ensure frequent and transparent communication (Burton *et al.*, 2011).

It is important to highlight that people with a LD want to be (and should be) seen as equal citizens in their communities and wherever possible would prefer to access the same health services as everyone else (Mencap, 2010). The label 'learning disability' encompasses a wide range of disabilities from mild to profound and it is important to ensure that choice is available for all. Where it is not possible to meet the specific needs of people with a LD through adapting mainstream services, referral to a local specialist community learning disability team (CLDT) can be considered. Whilst it is important to appreciate the limitations and expectations of this client group, standard outcome measures used in dietetic practice may not be appropriate. Realistic outcome measures based on thorough assessment of need, ability and quality of life are essential in order to work effectively with, and for, this client group. If clinical expectations expressed by the professional are not harmonious with the fundamental processes operating within specific genetic syndromes, failure will ensue. It is incumbent on the practitioner to work within the parameters of a specific syndrome such as PWS or conditions associated with the LD such as autism, working towards outcomes that are practicable, achievable and most importantly, meaningful to the client.

It has been recognised for some time that people with a LD can be informative, critical and reliable service users, provided that effective interview methods are employed (Kroese *et al.*, 1998). Closer working partnerships with primary, secondary, tertiary and specialist teams, together with local advocacy groups could make inclusion a realistic objective for safeguarding health improvements for people with a LD.

3.8

Paediatric clinical dietetics and childhood nutrition

3.8.1 Introduction

Lisa Cooke and Jacqueline Lowden

Key points

- Paediatric dietetics is a medical speciality and dietitians require postgraduate training.
- Children are not small adults; their physical and medical needs are different from those of an adult.
- The nutritional needs for growth must always be considered in addition to any disease related considerations.

Paediatric dietetics is a medical speciality and dietitians require postgraduate training to become a specialist paediatric dietitian. Many medical experts view children as small adults but this a fallacy. Continuous good nutrition during childhood is imperative and lays down the genetic building blocks for a child's future health. Emerging evidence suggests that the child's diet and growth pattern in the first 2 years of life extrapolate to long term health outcomes (Lanigan & Singhal, 2009; Singhal & Lucas, 2004).

There are 22 children's hospitals in the UK with many more paediatric tertiary referral centres (RCPCH, 2011). These specialist centres often manage patient groups on a shared care basis with the local dietitian within the patient's geographical area.

This chapter gives a brief overview of childhood nutrition and paediatric dietetics; the importance of how a child grows and develops, growth monitoring, nutritional assessment, nutritional needs during childhood and the management of clinical diseases and conditions. *Clinical Paediatric Dietetics* (Shaw & Lawson, 2007) should be consulted for more detailed information and dietetic management. Many of the topics also apply to adults and further information can be found in the relevant chapters.

Dietetic care must always be supported by specialist paediatric supervision in clinical practice until dietetic competence has been achieved.

Paediatric dietetics has a clear career pathway and the British Dietetic Association (BDA) (www.bda.uk.com) has an active and supportive paediatric group. This group provides a student manual toolkit so that departments can actively expose student dietitians to the paediatric speciality. As a newly qualified dietitian, or one embarking on a role that involves paediatric medicine, there is a self directed learning pack that needs to be managed by a paediatric dietetic supervisor with relevant experience. The group produces diet sheets through Nutrition and Diet Resources UK (www.ndr-uk.org), position statements and supports guideline production. It is also actively involved with a Masters degree in paediatric dietetics as a distance learning course jointly hosted by Plymouth University and the BDA.

3.8.2 Growth, nutritional assessment and nutritional requirements

Sarah Cawtherley and Claire Conway

The growth of an infant or child is very important, as poor growth can be an indicator of underlying disease, poor nutrition, emotional neglect or a combination of these factors. Growth must be regularly and accurately monitored throughout infancy and childhood. In infancy growth is closely related to nutritional adequacy and consequently the measurement of growth relates to nutritional status. Nutritional requirements during infancy, childhood and adolescence are subject to large changes and can be affected by age, weight, activity levels and illness or disease process. Normal human growth can be divided into two distinctive sections; prenatal growth and postnatal growth.

Abnormal growth and development in childhood is associated with morbidity and mortality. Therefore, regular monitoring and plotting of weight, length and head circumference on growth charts can help identify whether a child is growing normally or abnormally when compared with other children of similar age and gender. Anyone who weighs and measures a child or infant and plots these on a growth chart in the infant's *Personal Child Health Record (PCHR)* (colloquially known as the red book) should be suitably trained.

Prenatal growth

The growth of an infant begins at conception, with the fastest growth period being between conception and birth; this accounts for approximately 30% of eventual height (Tasker *et al.*, 2008). Factors that determine growth during this period include maternal size, maternal nutrition and intrauterine environment. Hormonal factors such as insulin, insulin-like growth factor 2 (IGF-2) and human placental lactogen are important regulators of growth during this period (Tasker *et al.*, 2008) (see Chapter 3.2).

Postnatal growth

Postnatal growth can be subdivided into infancy, childhood and puberty.

Infancy

Weight

From birth to 24 months growth is rapid; an infant doubles their birth weight in the first 5–6 months and trebles it in the first year of life. The rate of growth is largely determined by the nutritional adequacy of the diet. The expected weight gain for a healthy term infant is (Shaw & Lawson, 2007):

- 200 g/week for the first 3 months.
- 150 g/week between 4 and 6 months.

- 100 g/week between 6 and 9 months.
- 50–75 g/week between 9 and 12 months.
- 2.5 kg during the second year.

Linear growth

The length of an infant reflects bone growth and therefore is a better indicator of long term growth and nutritional adequacy than weight. Expected linear growth is 25 cm during the first year and 12 cm during the second year of life (Thompson, 1998).

Head circumference

Expected rate of growth in head circumference is 1 cm/month in the first year and 2 cm in total for the second year (Thompson, 1998). This reflects the rapid brain growth and development.

Growth velocity

Growth velocity varies depending on how an infant is being fed. A breastfed infant initially grows at a slower rate than a formula fed infant.

Childhood

From 2 years until the onset of puberty the rate of growth is slower and steadier than during infancy. Children gain approximately 2 kg in weight and 10 cm in height/year, declining to 6 cm/year until puberty when a further growth spurt occurs. During this period growth is primarily dependent upon growth hormone (GH), providing that there is adequate nutrition (Tasker *et al.*, 2008).

Puberty

Puberty is defined as the changes associated with the maturation of the gonads; testes in boys and ovaries in girls. During this period growth is dependent upon the action of GH and the sex hormones testosterone and oestrogen, which induce the characteristic growth spurt of puberty. Puberty starts earlier in females; therefore, they are taller than males between the ages of 10 and 13 years. In males, puberty generally occurs later and at a greater magnitude, resulting in a larger final adult height. On average puberty usually starts at 10.5 years and 12 years in girls and boys, respectively (Tasker *et al.*, 2008). Normal puberty usually occurs gradually over a period of 18 months to 5 years. Once a child's growth spurt has occurred their nutritional requirements become those of an adult (Webster-Gandy *et al.*, 2006).

General development

Children develop at different rates and stages. In the UK the infant's development is recorded in the PCHR. For

premature infants developmental age is calculated from the original due date rather than date of delivery (Department of Health, 2009). Physical and verbal developmental milestones are also monitored. Those relating to food are:

- 11–12 months – enjoys finger foods.
- 13–15 months – begins to feed themselves very messily.
- 3–5 years – can use a knife and fork.

Weaning

The European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) recommends that weaning onto solids should begin by 6 months but not before 4 months (17 weeks) of age. Exclusive breastfeeding for about 6 months is desirable and should be continued throughout weaning, particularly in the early stages (Agostoni *et al.*, 2008). The Department of Health (1994) recommends that weaning should not be delayed beyond 6 months due to the increased risk of nutrient and energy deficiencies. The Scientific Advisory Committee on Nutrition (SACN) is currently reviewing the advice

regarding weaning and UK practices and this should be published by 2014 (www.sacn.gov.uk).

Developmental signs that an infant is ready for solids include:

- Putting objects and toys in the mouth.
- Chewing fists.
- Showing interest when others are eating.
- Being hungry between milk feeds or demanding more feeds and taking larger volumes.
- Able to sit up and support their head.

At around 6 months infants are generally more accepting of new tastes and textures, and learn to accept them quite quickly (Harris, 2000). The process of weaning is a learning process; therefore, infants should be given the opportunity to learn to accept new tastes and textures, which can take up to ten attempts with the same food (Birch & Marlin, 1982). Infants who are given puréed foods for too long and not offered lumps and finger foods by 9 months are more likely to become fussy eaters. Table 3.8.1 shows the developmental stages of weaning and Table 3.8.2 shows the key stages in the

Table 3.8.1 Developmental stages of weaning [adapted from Shaw & Lawson (2007, Table 27.3, p526)]

Stage	Age guide	Skills to learn	New food textures to introduce
1	6 months, but not before 4 months (17 weeks) if parents choose to begin earlier	Taking food from a spoon Moving food from the front of the mouth to the back for swallowing Managing thicker purées and mashed food	Smooth purées Mashed foods
2	6–9 months	Moving lumps around the mouth Chewing lumps Self feeding using hands and fingers Sipping from a cup	Mashed food with soft lumps Soft finger foods Liquids in a lidded beaker or cup
3	9–12 months	Chewing minced and chopped food Self feeding attempts with a spoon	Hard finger foods Minced and chopped family foods

Table 3.8.2 Key stages in the normal development of eating and drinking skills (Winstock, 2005)

Age	Oral motor skills	Food related play
Birth–3 months	Rhythmical suckle with up and down jaw movements Sensitive gag reflex	Sucks well, calm, watches mother
4–6 months	Touch of spoon elicits suck Spits out food with forward–back tongue movements	Takes things to mouth Blows bubbles with saliva Pats bottle
6–9 months	Jaw begins to stabilise Bites on cup Tongue tip up, munching, gag reduces	Holds food and toys Desire for some control, messy, plays with food
9–12 months	Tongues moves food from side to side Stabilisation of jaw Chewing, closes lips on spoon, spills drink	Enjoys playing with food Can hold a spoon, poor control Squeezes toys and food
12–18 months	Uses a controlled bite on a biscuit Chews efficiently with rotary tongue and jaw movement	Pretends to feed self, large teddy or person Demands food
18–24 months	Chews with lips closed Up and down sucking pattern on cup	Lifts cup to mouth Pretends to feed dolls Self feeds, still messy

normal development of eating and drinking skills (Coulthard *et al.*, 2009; Northstone *et al.*, 2001; Winstock, 2005).

Infants should be offered a variety of foods from the four main food groups on a daily basis to provide the required nutrients. The National Diet and Nutrition Survey (NDNS) (Bates *et al.*, 2011) demonstrates that diet alone now provides close to, or above, the recommended nutrient intake (RNI) for all vitamins except vitamin D. Foods high in fat and sugar should not be included in the early weaning diet.

Food neophobia

By 12 months infants should be eating family foods and be offered a wide range of foods. Food neophobia, when infants become wary of trying new foods, usually peaks at around 18 months. Infants who have a wide variety of family foods by 12 months are usually happy to continue to accept these foods. Between 3 and 5 years children can develop disgust fears and consequently may stop eating foods that they previously enjoyed. They often refuse a food that looks like something they find disgusting. Children can also develop contamination fears; this often occurs at the same time and if a disliked food is put next to a liked food, then the infant may refuse both foods (Shaw & Lawson, 2007).

Nutritional assessment

A nutritional assessment can determine if a child suffers from malnutrition, which has been defined as a state of deficiency, excess or imbalance of nutrition that has an adverse effect on body function (Elia, 2003). In developed countries malnutrition is usually associated with excess weight and inappropriate dietary habits rather than undernutrition. Information required for nutritional assessment should include dietary intake, anthropometric measurements, including height and weight, biochemistry and a clinical assessment that includes a physical examination and medical history (see Chapter 2.2 and Chapter 2.3).

Dietary intake

Methods for assessing dietary intake for children and young people are the same as for adults: 24-hour recall, food frequency questionnaire, dietary history, food diary or weighed food intake. In most cases it is possible to obtain sufficient information from discussing the child's diet with their parent or carer, and the child themselves, if appropriate. Differences between adults and children include meals and snacks at nursery or school, after school clubs, bedtime food and drinks, staying with friends and relatives, and for older children eating out with friends. Assessing dietary intakes for babies and very young children can be difficult, particularly if the infant is breastfed. It is possible to calculate how much milk a breastfed baby consumes by weighing them before and after each feed over 24 hours. In practice, this is rarely

done as it can cause anxiety in the mother and baby. Questions about the length of time the infant feeds for, sleepiness during feeds, frequency of feeds, whether or not the breast is drained and frequency of wet and dirty nappies are more appropriate and, combined with information about weight gain, can provide information about likely milk intake. If mothers express breast milk and bottle feed this to their baby, ingested volumes can be easily determined. This would only be appropriate if the mother is returning to work, the baby is ill and unable to breastfeed or the mother is leaving the baby for any length of time. For infants of weaning age, it can be difficult to assess the contribution from food to their overall intake due to the amount that is spat out or smeared around with their hands. Information on the nutrient content of ready made weaning foods is readily available.

Anthropometry

The most widely used measures are weight, height and head circumference in infants, which are measured up to 2 years. Anthropometric measurements are compared with standards specific for gender and age. An individual measurement is almost meaningless in isolation as it is impossible to determine whether or not a child is following a satisfactory growth pattern [Michaelsen *et al.*, 2000; Royal College of Nursing (RCN), 2010]. Weight and length or height measurements should be taken whenever there are concerns about a child's weight gain, growth or general health, in addition to routine checks (RCPCH, 2009). Sick infants and children who are hospital inpatients should be weighed at least once a week (RCN, 2006). Anthropometric measurements can be expressed as Z scores. A Z score is the standard deviation (SD) score; the deviation of the value for an individual from the median value of the reference population divided by the SD for the reference population:

$$\text{Z score} = (\text{observed value} - \text{median reference value}) / \text{SD reference population}$$

Growth charts

Growth charts are mathematically created reference curves based on population data to represent the normal genetic growth of healthy children living in a specific environment. There are several growth charts available for use in the UK. The World Health Organization (WHO, 2006) has published Child Growth Standards for infants and children up to the age of 5 years, using data from the Multicentre Growth Reference Study (MGRS). Healthy, full term infants exclusively breastfed for the first 4 months and partially for a year and weaned at 6 months (De Onis *et al.*, 2004) were included. These growth charts set breastfeeding as the norm. The WHO growth standards are available in centiles and as Z scores for weight for age, length/height for age, weight/height for age and body mass index (BMI) for age, for children aged 0–5 years in addition to 5–19 years.

In 2007 SACN adopted the WHO growth charts in the UK (Department of Health, 2007) up to 4 years of age, after which the UK1990 charts are used. The Department of Health recommends that the UK–WHO growth charts should be used for all new births after the 11 May 2009 and the UK 1990 charts for all children over the age of 4 years up to 18 years (Cole, 1997; Cole *et al.*, 1998; RCPCH, 2009).

UK–WHO charts

Three versions are available, 0–4-year and 2–18-year growth charts and the Neonatal and Infant Close Monitoring Chart (NICMC), previously known as the Low Birth Weight Chart. The latter is used for births before 32 weeks' gestation, ill neonates born after 32 weeks' gestation and term infants with significant growth and weight faltering (RCPCH, 2009).

UK1990 charts

These growth charts were constructed using data from a large number of different aged children in the UK during the late 1980s and describe typical but not necessarily healthy growing children. They are based on formula fed infants and should be used for children born before 11 May 2009.

Other charts

Charts are available for specific conditions; Down's syndrome, Turner's syndrome, sickle cell disease and Noonan's syndrome. Thrive lines are available for assessing faltering growth; separate charts are also available for plotting BMI and waist circumference. All charts are gender specific and can be obtained from Harlow Printing (Maxwell Street, South Shields NE33 4PU) or downloaded from www.growthcharts.rcpch.ac.uk.

Interpretation of centile lines

The UK–WHO growth charts consist of nine centile lines. The 50th centile represents the median for the population and the 2nd and 98th centiles are two standard deviations (Z scores) above and below the median. The 0.4th centile identifies extremely low measurements and only $1/250$ (0.4%) optimally growing children will fall on this centile (Wright *et al.*, 2004).

Plotting on a growth chart

Growth monitoring requires accurate measurements that are plotted accurately on the growth chart to see patterns of growth over time. This accuracy ensures the pattern of growth can be assessed correctly. The most common error when plotting growth charts is calculating an infant's age incorrectly. Age should be calculated in weeks for at least the first 6 months of life and thereafter in calendar months. If the point marked is within one-quarter of a space of the centile line, the infant is described as being on the centile. However, if they are further away than this, they should be described as being between the two centile lines, e.g. between the 4th and the 9th centile

Plotting and assessing newborn infants

A baby born between 37 and 42 weeks' gestation is considered full term and should be plotted at age 0. All preterm infants (before 37 weeks' gestation) should be plotted in the preterm section of the growth charts. The birth centiles are average values for weight, length and head circumference for full term babies (Cole, 1997). All infants tend to lose weight initially and then begin to regain their birth weight between 3 and 5 days, and 80% will have regained their birth weight by 2 weeks of age (Wright & Parkinson, 2004).

Calculating percentage weight loss

Percentage weight loss is the difference between the actual weight and the birth weight expressed as a percentage of the birth weight. If a baby has a weight loss of 10% or more at or before 2 weeks, they need careful assessment as this may indicate a possible feeding problem or illness (RCPCH, 2009).

Preterm infants

The WHO standard does not include data for preterm infants; therefore, preterm charts have been produced using the UK1990 reference data (Cole, 1997). A preterm infant born after 32 weeks' gestation should be plotted on the preterm section of the 0–1-year growth chart until they have reached their expected date of delivery (EDD) plus 2 weeks, and then be plotted on the 0–1-year chart using gestational correction. Preterm infants born at <32 weeks' gestation should be plotted on the specially designed neonatal and infant close monitoring chart.

Plotting with gestational correction

Gestational correction adjusts the plot for the number of weeks an infant is born premature. Gestational correction should continue for a year for infants born between 32 and 36 weeks' gestation and for 2 years for infants born before 32 weeks' gestation. For example, an infant born at 34 weeks' gestation is 6 weeks' premature and their growth should be corrected by 6 weeks. Once gestational correction has been calculated, it is important to calculate the actual (calendar) age of the infant and plot this on the growth chart with a clear dot. A line is drawn back from this dot by the number of weeks the infant is premature and this point is marked with an arrow. The point of the arrow shows the infant's centile with gestational correction.

Neonatal and infant close monitoring chart

The NICMC has been specifically designed for monitoring the growth of infants born before 32 weeks' gestation and low birth weight infants. It can be used from 23 weeks' gestation to the corrected age of 2 years. It can also be used for term neonates who are small for gestational age and require close monitoring of their growth pattern. A new feature of these charts is the date box system, which helps to calculate gestational age. This avoids errors in calculating the infant's age.

Adult height prediction

The adult height prediction on the UK-WHO growth charts differs from the target height calculation on the UK1990 height chart. Target height compares the child's height with those of their birth parents, and identifies children who are unusually tall or short compared with their parents. The adult height prediction tool provides a good prediction of adult height for most children, including those who are unusually tall or short, but it does not compare them with their parents (RCPCH, 2009). There it is more useful for families where one or both parents are not the biological parent. The adult height prediction is accurate for 80% of children (RCPCH, 2009).

Further information on plotting growth charts and their use can be found at www.growthcharts.rcpch.ac.uk.

Growth assessment recommendations

As part of the Healthy Child Programme children should be routinely assessed to identify the early signs of obesity and offer interventions from an early stage. The Child Growth Foundation (2012) recommends that infants and children should be routinely measured, as shown in Table 3.8.3. If there are concerns, infants and children may be weighed more often, but weighing at intervals too close

together is misleading and can cause parental anxiety. Therefore, the recommended frequency of weighing (RCPCH, 2009) is:

- No more than once a month between 2 weeks and 6 months of age.
- Once every 2 months in infants between 6 and 12 months.
- Once every 3 months in children over the age of 1 year.

This frequency of weighing should reflect the progressive slowing of weight gain in the first year (Wright *et al.*, 2010). However, in practice it is common for babies under 6 months to be weighed fortnightly, and those over 6 months monthly if there are concerns about their weight.

Anthropometric measurement techniques

A narrow plastic or disposable paper, non-stretch tape measure should be used where applicable. Three measurements should be made and the average recorded.

Head circumference

A number of genetic and acquired conditions will affect head growth and measurement of head circumference is not a useful indicator of nutritional status in these conditions (RCPCH, 2009). Measurements should be made at

Table 3.8.3 Recommended measurements for infants and children (source: Child Growth Foundation 2012. Reproduced with permission of the Child Growth Foundation (www.childgrowthfoundation.org))

Age	Weight	OFC	Length	BMI	Notes
Birth	X		X or 10 days		Weight: assess malnutrition using 5%/95% thrive line acetates or if weight/length centiles differ by over 2 centile bands. To resolve any concern: if infant is <6 months, weigh fortnightly; if >6 months, weigh monthly OFC: refer ASAP if OFC curve climbs significantly upwards through centile bands. To resolve concern, measure fortnightly Length: use length predominantly to confirm malnutrition and consider referral (for either slow/excess growth) after three measurements. To resolve concern, measure 3-monthly
24/30 hours		X			
5 days	X				
10 days	X		X		
14 days		X			
6–8 weeks	X	X			
12 weeks	X				
16 weeks	X				
6–8 months	X		X		
12–15 months	X		X	X	
2 years	X		X	X	BMI: Having monitored weight gain/length during infancy, measure both height and weight from approx 1 year, calculate BMI and refer if indicated. To resolve any concern, calculate BMI 6-monthly and similarly refer
3 years	X		X	X	
4 years	X		X	X	
Primary school	X		X	X	
Year 1					BMI HMG has still not accepted the House of Commons Health Committee's 2004 recommendation that the BMI of every primary school child be assessed annually. Payments for the BMI assessment of all secondary school age children of 16 years or over are available under the quality and outcomes framework (QoF).
Year 2	X		X	X

the widest part of the infant's head; hats or bonnets should be removed.

Weight

Only Class III or above clinical electronic scales with a metric setting should be used. These should be maintained and calibrated annually, in line with medical devices standards (Department of Health, 2010; NICE, 2008). Infants and children under 2 years should be weighed naked without a nappy on baby scales, to the nearest 10 g (RCN, 2010). Children over 2 years should be weighed in minimal clothing (ideally vest and pants, without shoes) to the nearest 100 g. Older children and adolescents should be weighed without shoes, wearing indoor clothing and with empty pockets. A child who is unable to sit or stand should be weighed on a hoist scale (RCN, 2010). If it is not possible to weigh a child, tare weighing should be used: an adult is weighed with and without the child and weight calculated by subtraction (RCN, 2010). The method should be recorded.

Length or height

Length is measured in infants and toddlers up to 2 years; height is measured thereafter. Length and height reflect bone growth and are a better indicator of long term growth and nutritional adequacy than weight. Infants under 2 years should be measured without a nappy or footwear while lying on a length board or mat (RCPCH, 2009). A child's height is usually slightly less than their length due to spinal compression; therefore, the centile lines on the UK-WHO chart shift down slightly at age 2 years to allow for this (RCPCH, 2009). Height is measured using a rigid upright measure with a T piece or a stadiometer, without shoes (RCPCH, 2009). The head should be positioned in the Frankfurt plane and the ear hole should be lined up with the bottom of the eye socket (see Chapter 2.2). Alternative methods for estimating height include lower leg length or knee to heel height.

Weight/height indices

Body mass index

Body mass index can be calculated and interpreted by plotting it on a BMI reference chart. Percentage weight for height and percentage height for age are used to identify the degree of malnutrition, although children with anorexia nervosa and chronic diseases, e.g. cystic fibrosis, often have the former calculated.

Body mass index is a useful indicator of fatness and thinness in children from the age of 2 years, when height can be measured with relative accuracy. However, unlike for adults, BMI is age dependent and therefore plotted on centile charts, rather than being read as an absolute number. A child whose weight is average for their height will have a BMI between the 25th and 75th centiles whatever their height centile. The Scottish Intercollegiate Guidelines Network (SIGN, 2010) and NICE (2007) recommend that in the clinical setting a BMI greater than the 91st centile be used to define overweight and a BMI greater than the 98th centile obese (see Chapter 7.13.4).

Waist circumference

Waist circumference is measured at the natural waistline, which is midway between the tenth rib and iliac crest. Waist circumference charts are available for children over 5 years (McCarthy *et al.*, 2001).

Mid upper arm circumference

Mid upper arm circumference (MUAC) indicates body fat distribution and can be used to determine malnutrition in children. It is useful in children younger than 5 years as until then MUAC increases rapidly; standards are available for children aged 1–5 years (Gibson, 2005). It may be used during research or for children with renal or liver disease where the presence of fluid overload or ascites makes weight inaccurate. When combined with the triceps skinfold measurement, upper arm muscle and fat stores can be estimated, and these measures correlate well with total body measures of fat mass and fat free mass (Zemel *et al.*, 1997).

Skinfold thickness

Measurement of skinfold thickness can be used to assess nutrition in young infants and older children, but it can be difficult to do this well. The process is the same as that for adults and prediction equations for skinfold thickness are available for children's triceps skinfold. These measurements are not performed routinely due to the distress it can cause children; however, it is used in research, HIV and renal and liver diseases.

Height age

Height age is the age at which the measured height of the child falls on the 50th centile. Calculation of height age is necessary when determining nutrient requirements for children who are much smaller or taller than their chronological age (Shaw & Lawson, 2007).

Percentage height for age

Height for age is a measure of linear growth and a faltering of linear growth is called stunting. A low height for age results from slowing of skeletal growth. In general, it reflects a chronic process and is used as an index of chronic undernutrition (WHO, 2003).

Percentage weight for height

Weight for height assesses the appropriateness of the child's weight compared with their height. It is sensitive to acute nutritional disturbances, and a low weight for height is described as wasting, resulting from a failure to gain weight or weight loss. It can develop rapidly and be reversed rapidly, and is an index of acute undernutrition reflecting severe weight loss, which is often associated with acute starvation and/or severe illness (Michaelsen *et al.*, 2000). Calculation of percentage weight for height is often used with cystic fibrosis patients, although it has been found to be an unreliable measure of nutritional status (Poustie *et al.*, 2000).

Both percentage weight for height and percentage height for age are used to classify malnutrition, as shown in Table 3.8.4.

National Child Measurement Programme

Since 2006/07, all children in the UK in the reception school year (4–5 years) and year 6 (10–11 years) have been invited to have their height and weight measured and BMI calculated. Results are sent to parents, which can be of particular benefit as often parents cannot tell if a child is overweight or obese (Carnell *et al.*, 2005; Jeffery *et al.*, 2005). Anonymous results are collated by the Department of Health to establish trends in children's heights and weights.

Clinical assessment

The two major components of clinical assessment are the medical history and the physical examination. The medical

history is similar to that of an adult (see Chapter 2.2). In addition, it is usual to obtain information about gestational age and birth weight, infant feeding history (breast or formula fed, age when weaned) and weight trend.

Visible signs and symptoms that suggest nutritional deficiencies are the same as in adults. In addition, bone changes in vitamin D or calcium deficiency (rickets) in children will include craniotabes, parietal and frontal bossing, epiphyseal enlargement and beading of the ribs. A suspected deficiency should be confirmed by biochemical or haematological tests.

Biochemistry and haematology

Laboratory assessment is used primarily to detect sub-clinical deficiency states, but also to confirm a clinical diagnosis. Age specific normal ranges for biochemical and haematological tests need to be established and used. Table 3.8.5 provides a summary of some biochemical and haematological measurements. Although urine is used for adult investigations, it is not commonly used for infants and children. Many tests require the collection of a 24-hour urine sample, which is difficult in babies and children, and the usefulness of a single urine sample for nutritional tests is limited (Shaw & Lawson, 2007).

Malnutrition screening tools

Malnutrition screening tools specifically for children admitted to hospital have been developed. However, there are currently no validated screening tools for use with infants aged 0–2 years. The British Association for

Table 3.8.4 Classification of malnutrition using weight for height and height for age (Waterlow, 1972)

Grade of malnutrition	Acute malnutrition (wasting)	Chronic malnutrition (stunting + wasting)
	Weight for height	Height for age
Normal	>90%	>95%
Grade 1 (mild)	80–90%	90–95%
Grade 2 (moderate)	70–80%	85–90%
Grade 3 (severe)	<70%	<80%

Table 3.8.5 Biochemical and haematological tests relating to nutritional status in children (source: Shaw 2007, table 1.7, p. 11. Reproduced with permission of Blackwell Publishing)

Nutrient	Test	Normal values in children	Comments
Biochemical tests			
Protein	Total plasma protein Albumin	55–80 g/L 30–45 g/L	Low levels reflect long term, not acute, depletion
Vitamin B ₁₂	Plasma B ₁₂ value	263–1336 pmol/L	Low levels indicate deficiency
Vitamin C	Plasma ascorbate level	8.8–124 µmol/L	Low levels indicate deficiency
Vitamin A	Plasma retinol level	0.54–1.56 µmol/L	Low levels indicate deficiency
Vitamin D	Plasma 25-hydroxy cholecalciferol level	30–110 nmol/L	Low levels indicate deficiency
Vitamin E	Plasma tocopherol level	α-tocopherol 10.9–28.1 µmol/L	Low levels indicate deficiency
Copper	Plasma level	70–140 µmol/L	Low levels indicate deficiency
Selenium	Plasma level Glutathione peroxidase activity	0.76–1.07 µmol/L >1.77 µmol/L	Low levels indicate deficiency
Zinc	Plasma level	10–18 µmol/L	Low levels indicate deficiency
Haematology tests			
Folic acid	Plasma folate Red cell folate	7–48 nmol/L 429–1749 nmol/L	Low levels indicate deficiency Low levels indicate deficiency
Haemoglobin	Whole blood	104–140 g/L	Levels <110 g/L indicate iron deficiency
Ferritin	Plasma level	5–70 µg/L	Low levels indicate depletion of iron stores. Ferritin is an acute phase protein and increases during infection

Parenteral and Enteral Nutrition (BAPEN) (Brotherton *et al.*, 2011) and the Care Quality Commission (CQC, 2010) recommend the use of paediatric malnutrition screening tools, including:

- **STAMP** – the Screening Tool for the Assessment of Malnutrition in Paediatrics, which is a validated nutritional screening tool for use in hospitalised children aged 2–16 years (McCarthy *et al.*, 2012).
- **PYMS** – the Paediatric Yorkhill Malnutrition Score (PYMS) rates BMI, weight loss, changes in nutritional intake and the predicted effect of the current condition on nutritional status to give a score that reflects the degree of the nutritional risk. It can be used in children aged 1–16 years (Gerasimidis *et al.*, 2009).
- **STRONGkids** – this screening tool consists of a subjective clinical assessment of disease risk, nutritional intake and weight loss for children aged 0–18 years (Hulst *et al.*, 2010).
- **SGNA** – the Subjective Global Nutrition Assessment is an adapted version of the Subjective Global Assessment (SGA) tool used in adults, and is for children aged 0–18 years (Secker & Jeejeebhoy, 2007).

Although PYMS, STAMP and SGNA have been compared against each other (Gerasimidis *et al.*, 2010), it is recommended that each tool be compared against dietetic assessment to identify which has better diagnostic validity in a particular setting.

Nutritional requirements in childhood

Infants and children must not be viewed as small adults as they require different nutrients at different levels and a different nutritional balance from adults. The Committee on Medical Aspects of Nutrition (Department of Health, 1991), as shown in Appendix A3, established nutritional recommendations (dietary reference values (DRVs) for infants, children and adolescents in the UK. Values have been set for infants fed on formula milks, whose nutrient intakes are dependent upon the composition of the feed being offered, but not for breastfed infants as breast milk is the best form of nutrition for an infant. As for adults, DRVs are set for normal healthy individuals. Individual requirements will vary due to age, gender, weight, height, stage of development, body stores, activity levels and genetic factors. Disease process is a further consideration in sick infants and children. It is important to remember to calculate energy requirements and nutrient intakes based upon actual weight.

Fluid

Fluid requirements for infants and children are shown in Table 3.8.6. Breastfed babies will regulate fluid intake and demand feeding will ensure that the infant gets the correct volume of milk and therefore nutrients (Shaw & Lawson, 2007). Ideally, formula fed infants should be fed

Table 3.8.6 Recommended intakes of fluid and electrolytes for infants and children

Age	Weight (kg)	Fluid (mL/kg)	RNI			
			Sodium		Potassium	
			(mmol/day)	(mmol/kg/day)	(mmol/day)	(mmol/kg/day)

15–18 years	55.5	40	70	–	90	–

RNI, reference nutrient intake. (Source: Department of Health, 1991)

Table 3.8.7 Estimation of fluid requirements in children over 10 kg

Body weight (kg)	Estimated fluid requirement
11–20	100 mL/kg for the first 10 kg + 50 mL/kg for the next 10 kg
20 and above	100 mL/kg for the first 10 kg + 50 mL/kg for the next 10 kg + 25 mL/kg thereafter

Table 3.8.8 Energy requirements for low physical activity levels in children (FAO/WHO, 1973)

Age	Energy for maintenance and growth as % of total energy expenditure (per kg actual body weight)
<3 months	90
9–12 months	85
2–3 years	77
4–5 years	71
9–10 years	74

on demand, and for those under 6 months a fluid intake of 150 mL/kg is required. After 6 months, once an infant has been weaned, fluid requirement drops to 120 mL/kg as water is also obtained from food. After 1 year, thirst will determine how much fluid is taken (Shaw & Lawson, 2007). In clinical practice, fluid requirements for children over 10 kg are estimated using the equations shown in Table 3.8.7. However, overweight children will require less than the calculated volume per kilogram. For underweight children, fluid requirements should be calculated for the child's actual weight, but they may require increased energy and protein density for catch-up growth (Great Ormond Street Hospital, 2009).

Energy

Feeding infants younger than 6 months old with 150 mL/kg, either with breast milk or formula, will meet their nutritional needs if they do not have raised requirements. Young children continue to have high energy needs, but have a small stomach capacity and often variable appetites (Thompson, 1998). They therefore require a nutrient dense diet to meet needs, although from 2 years the fat content of their diet can be reduced and lower fat dairy products can be used, as long as they are thriving, have a good appetite and consume a well balanced diet. At 5 years, children can use fully skimmed milk if they also meet the above criteria. Energy requirements peak during the adolescent years when the individual is going through their growth spurt. Children with low physical activity levels require less energy. Table 3.8.8 gives an approximate guide to levels of energy intake for maintenance and

growth alone, with no allowance for energy for activity. For older children energy requirements can be estimated by using prediction equations as used in adults (see Chapter 2.1).

In 2011 SACN published a report on DRVs for energy and, following careful consideration of the evidence, recommended a revision to the estimated average requirements (EARs) for food energy for infants, children, adolescents and adults. However, the DRVs are intended only for use in healthy populations, not individuals or groups who require clinical management. Although exclusive breastfeeding is recommended for about the first 6 months of life, it is recognised that infants are fed in a variety of ways. Therefore, separate recommendations have been made for exclusively breastfed infants, breast milk substitute fed infants and those where the method of feeding is mixed or unknown (SACN, 2011; particularly Tables 14 and 15 within this report).

Protein

Protein should provide 7.5–12% of the energy of an infant feed (Koletzko *et al.*, 2005), and 5–15% of the energy intake for older children (Jackson & Wooton, 1990). An adequate energy intake is essential at all ages, otherwise protein is metabolised as energy.

Vitamins and minerals

Vitamin and mineral requirements for normal children are provided by the DRVs. In disease states, requirements for certain vitamins and minerals will be different for each clinical condition. From 6 months infants who are breastfed, or taking <500 mL/day of formula or follow-on formula, should be given Healthy Start vitamins, providing vitamins A, C and D, and these should be continued until the child reaches 5 years of age. Other widely prescribed vitamin and mineral supplements are Abidec, Dalivit and Ketovite liquid and tablets.

3.8.3 Growth faltering

Luise Marino and Rosan Meyer

Many terms are used interchangeably for growth failure, including malnutrition, faltering growth and undernutrition, but they do not necessarily describe the same level of undernutrition. Olsen *et al.* (2007) defined protein energy malnutrition (PEM) as nutritional deprivation amongst children in developing countries, whereas faltering growth is a term more commonly used for affluent societies. A variety of different methods with varying cut-offs exist to define these terms (Olsen *et al.*, 2007; Joosten & Hulst, 2011):

- Inadequate growth or weight gain for >1 month in a child under 2 years.
- Weight crossing more than two centiles for >1 month in child under 2 years.
- Weight loss or no weight gain for >3 months in a child older than 2 years.
- Changes in weight/age of >–1 standard deviation (SD) in 3 months for children under 1 year of age on growth charts.
- Change in weight for height of >–1 SD in 3 months for children aged 1 year or older on growth charts.
- Decrease in height velocity of 0.5–1 SD year at under 4 years and 0.25 SD/year at older than 4 years of age.
- Decrease in height velocity of >2cm from preceding year during early/mid puberty.

The most common definition of growth faltering in the UK is weight crossing more than two centiles downwards over a period of 1 month. This would be equal to –0.68 of a Z score, indicating that a child may have weight faltering, but is not yet malnourished according to the WHO definition, e.g. moderate malnutrition using the WHO definition is ≤ -2 Z scores.

Prevalence

The prevalence of growth faltering amongst healthy infants in the UK at 6–8 weeks has been reported as 6.1% (McDougall *et al.*, 2009) and it is believed that in the general infant and toddler population between 5% and 9% (McDougall *et al.*, 2009; Grimberg *et al.*, 2009) develop growth faltering. The prevalence of short stature in the general UK population is reported as being 2.3%. Being short in stature as a result of growth faltering has a more detrimental long term effect on health than being acutely undernourished. Acute undernutrition has little impact on cognitive development compared with severe and prolonged malnutrition (Victora *et al.*, 2010; Rudolf & Logan, 2005). Growth faltering in weight is more commonly seen in children under 2 years in developed countries (Panter-Brick *et al.*, 2004).

Chronically ill children have a higher prevalence of growth faltering, with a reported prevalence in hospitalised children in European countries (including the UK) ranging from 14% to 24% (Joosten & Hulst, 2011; Pawellek *et al.*, 2008). In middle income countries such as South Africa and Turkey, it is between 34% and 40% (Joosten & Hulst, 2011; Marino *et al.*, 2006). The prevalence of undernutrition within a hospital setting has remained unchanged for 20 years (Sullivan, 2010). It is therefore important that dietitians recognise growth faltering early and know how to nutritionally manage the condition.

Children considered to be at a greater nutritional risk include:

- Poorer socioeconomic groups (Panter-Brick *et al.*, 2004).
- Ethnic minorities (Panter-Brick *et al.*, 2004).

- An underlying medical condition (Levy *et al.*, 2009; Staiano, 2003).
- Extreme food fussiness (Haas, 2010; Haas & Maune, 2009).

Growth monitoring

Growth monitoring is an essential part of childhood. There are numerous growth charts, as discussed in Chapter 3.8.2, and it is important that the correct ones are used and that a child's measurements are plotted on them.

Normal growth

Optimal growth is one of the most important hallmarks of childhood, as poor growth has consequences impacting on school performance and cognitive development, and in adulthood has been associated with decreased ability to be socioeconomically active (Goulet, 2010). Intrauterine growth is the most rapid of all growth; the average birth weight in the UK is 3.3–3.5 kg. Birth weight loss occurs in the first few days of life (up to 10% is physiologically acceptable) and this is more common in those who are exclusively breastfed (Cole *et al.*, 2011; DeOnis & Onyango, 2003). It can take up to 2 weeks for an infant to regain this weight loss, which is reflected in the UK–WHO growth charts (Cole *et al.*, 2012; Shaw & Lawson, 2007).

Plotting faltering growth on a growth chart

To identify a child at risk of growth faltering it is important to review their growth trend. Figure 3.8.1 shows examples of growth curves (which can be applied to length or height and weight); children with the growth curves b or c would be considered to have malnutrition, with Z scores of <2.

Frequency of monitoring, catch-up growth and follow-up

As would be expected weight gain is one of the dietary goals; all children with growth faltering should be followed up, initially monthly (UNICEF, 2005), and when the child has caught up one to two centiles or has a weight for height of greater than 90% or 1 SD increase has been reached, supplementation should be reviewed.

At this stage the child is considered to be nutritionally rehabilitated (Patel *et al.*, 2005).

Acute and chronic growth faltering

It is important to establish if growth faltering is acute or chronic, as this impacts on the nutritional management. This can be established by the following:

- *Acute growth faltering* – normal length/height but low weight for height or for age. This normally represents an acute event of short duration, e.g. following a short episode of illness.
- *Chronic growth faltering* – short length for age but normal weight for height/length even though underweight for age, e.g. chronic illness such as end stage renal failure.
- *Acute on chronic growth faltering* – short length/height for age but low weight for height/length and underweight for age, e.g. chronic illness such as end stage renal failure with a recent lower respiratory tract infection.

Organic versus non-organic growth faltering

The terms organic and non-organic growth faltering have been used to describe poor growth related to medical disease (i.e. organic) versus non-medical causes (non-organic), including maternal deprivation, maternal depression and a dysfunctional mother–child relationship (Ramsay *et al.*, 2002). There is significant overlap between organic and non-organic faltering growth (Levy *et al.*, 2009). Ramsay *et al.* (2002) found that a significant number of the children who were classified with non-organic growth faltering had subtle neurodevelopmental disorders and pathophysiology (i.e. delayed sucking ability), but were otherwise medically well. It is therefore important to ensure good history taking when establishing the origin of growth faltering and not to exclude subtle organic disease.

Organic growth faltering

The reasons for poor growth in children with chronic disease is multifactorial and linked to increased requirements, reduced intake and disordered feeding. Children with chronic diseases such as chronic lung disease, gastrointestinal disorders and neuromuscular disorders

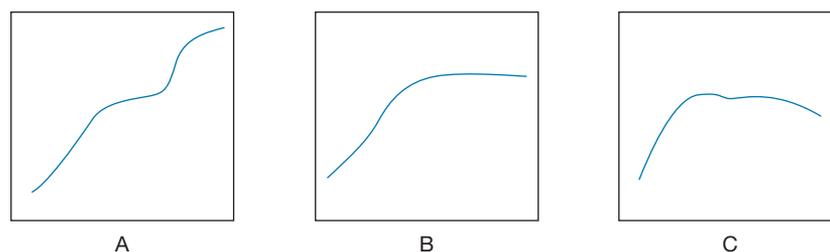

Figure 3.8.1 Examples of growth curves. (A) Growing well; (B) growth faltering; (C) malnutrition (source: WHO 2009. Reproduced with permission of WHO)

often have laboured breathing (Levy *et al.*, 2009; Haas & Maune, 2009), increasing nutrient requirements and/or increased nutrient losses through vomiting.

Non-organic growth faltering

The most common reason for non-organic growth faltering is a disrupted maternal–child relationship, which may occur due to various reasons, including neglect. In addition, toddlers are fussy eaters, as reported by 25–50% of parents (Jacobi *et al.*, 2003). Pickiness narrows the variety of foods consumed by young children (Harding *et al.*, 2010), increasing the risk of being underweight and having nutrient deficiencies, especially in those under 3 years (Ekstein *et al.*, 2010; Bowley *et al.*, 2007; Dovey *et al.*, 2008). A degree of neophobia and pickiness is considered to be developmentally appropriate and usually has no impact on growth (Richman *et al.*, 1975; Wright *et al.*, 2007).

Nutritional assessment

Nutritional assessment should include anthropometry, dietary, biochemical and clinical assessment. In addition, it is important to examine a child for signs of acute weight loss by looking at fat distribution. Some children are thin with no signs of wasting and it is important to distinguish between a well thin child, who is genetically slender, and a child who is growth faltering (UNICEF, 2005). In a child under 5 years, there should be a good layer of subcutaneous fat; therefore it is important to consider the following (Figure 3.8.2):

- What do the arms, shoulder, legs, buttocks look like?
- Is there evidence of temporal or facial wasting?
- Are there bracelets of fat around the wrist?
- Are there rolls of fat on the thighs?
- Looking from the side – are there buttocks or are they flat and sagging?
- Protruding ribs?
- Protruding hips?
- Does the stomach look out of proportion, e.g. is it distended?

Iron deficiency anaemia should be considered. In addition to inadequate iron intake, excessive intake of milk

(≥ 600 mL/day) is also associated with low ferritin and haemoglobin levels (Cowin *et al.*, 2001). Pallor is a sign of anaemia and is easiest to see by looking at a child's palm. Compare the colour of skin on your palm to that of the child, grasping the child's hand gently on either side using one hand, but not bending the child's fingers backwards as this restricts blood flow. If the palm is pale, then there is some evidence of palmar pallor; however, if the child's palm is white, there is severe palmar pallor and iron treatment should be initiated.

Diet history

A complete, detailed dietary history is invaluable, especially questions relating to feeding and dietary intake. Some useful questions to establish dietary and feeding patterns include:

- What type of milk is usually given to the child? How much and how often?
- Are they still breastfed?
- What is the quantity of the main meal eaten? Is it appropriate?
- Did the child eat fish, meat or eggs in the last week and/or any foods excluded for religious or dietary reasons?
- Does the family have good access to food?
- If the child's food intake is poor, it is important to assess whether the child has anticipatory gagging, vomiting, difficulty swallowing or chewing at meal times, has a poor appetite or frequent loose stools (WHO, 2009; Levine *et al.*, 2011).

Dietary management

Nutrition requirements for catch-up growth

Energy and protein requirements

Disease specific recommended energy requirements should be used if available. These generally vary between 120% and 150% energy and protein requirements and the calculations are based on actual body weight (Shaw & Lawson, 2007). The focus should be weight gain and attaining growth with optimal balance between lean and fat mass (73% lean and 27% fat mass) in the new accrued

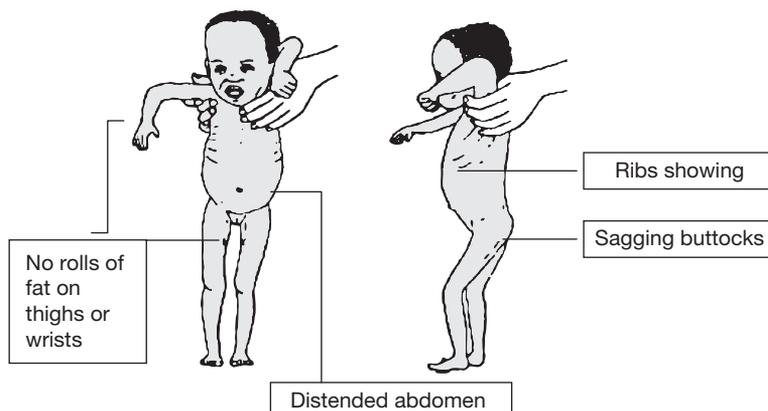

Figure 3.8.2 Appearance of an infant with severe wasting and growth faltering (source: WHO 2009. Reproduced with permission of WHO)

Table 3.8.9 Theoretical energy and protein intake for 5, 10 and 20 g/kg/day catch-up growth

Catch-up growth (g/kg/day)	Protein (g/kg/day)	Energy (kcal/kg/day)	Protein/energy (%)
5	1.82	105	6.9
10	2.82	126	8.9
20	4.82	167	11.5

tissue. Optimal catch-up growth is not only dependent on sufficient energy delivery, but also adequate protein (see Table 3.8.9). An ideal protein energy (PE) ratio for catch-up growth resulting in lean body mass accretion, rather than deposition of adipose tissue, has been shown to be 8.9–12% (Pencharz, 2010; Golden, 2009). Enriching products with modular additions of fat and carbohydrate alone often results in a PE of 4.5–6%, which does not favour optimal catch-up growth in growth faltering infants (Pencharz, 2010; Clarke *et al.*, 2007).

In younger children (<5 years) with moderate growth faltering, e.g. Z-score >−1, a weight gain of 10 g/kg/day is considered good. In these children for whom weight gain averages 5–10 g/kg/day, it is important to review whether intake targets are being met and/or whether an infection is being overlooked. Poor weight gain is <5 g/kg/day and in these children a review of biochemistry and intake should be considered. In older children (>5 years) weight gain may be slower, but 5–10 g/kg/day should still be achievable (WHO, 1999).

Vitamins and minerals

It is important to ensure that children with growth faltering also receive sufficient vitamins and minerals that aid catch-up growth. Insufficient micronutrients, in particular zinc and vitamin A, can lead to suboptimal catch-up growth. Multiple micronutrient supplementation, including vitamins A and D, zinc and iron, are effective in promoting catch-up growth in children under 5 years and should be considered a routine supplement in growth faltering children (Golden, 2009; Ramakrishnan *et al.*, 2009; Bhaskaram, 2002).

Iron

Even mild iron deficiency anaemia (IDA) can have a long term detrimental influence on mental and psychomotor development (Freeman *et al.*, 1998), although there are many confounders, including poverty, maternal education and prematurity (Aggett *et al.*, 2002). The management of IDA through iron fortified foods or supplementation results in improved growth, although improvements in cognitive outcomes have been harder to define (Domellof, 2009). At risk children should be encouraged to consume iron rich foods as part of their daily diet.

Zinc

Zinc supplementation of 10 mg/day in infants under 6 months and 20 mg/day in infants older than 6 months has

been shown to significantly reduce morbidity in those with diarrhoeal disease and pneumonia (Bajait & Tawani, 2011; Baqui *et al.*, 2003, Aggarwal *et al.*, 2007). Zinc supplementation has also been shown to be effective in promoting linear growth (Ramakrishnan *et al.*, 2009; Allen, 1994). Zinc and iron supplementation should be given separately as zinc absorption is affected by iron (Anon, 1982), although this is seen more strongly with non-haem iron foods, e.g. fruit, vegetables, grains and nuts (Solomons & Jacob, 1981).

Nutritional management of infants and children with faltering growth

Nutritional management depends on the severity and type of growth faltering (organic versus non-organic). It is important to have good communication skills and start by exploring the circumstances at home, including the child's early feeding history (UNICEF, 2005). Enriched home foods can initially be tried in those children where growth faltering is not severe; however, if this approach fails, nutritional supplements should be tried. Energy dense ready to feed infant formulae that deliver energy and protein at an appropriate energy to protein ratio have been shown to significantly improve growth and nitrogen status (Clarke *et al.*, 2007). Although it is common practice to increase the nutrient density of standard powdered formulae, attention must be paid to the osmolality and renal solute load (Kin, 2007, Ziegler & Fomon, 1989). The older child may also require nutritionally complete sip feeds if initial nutritional treatment with enriched home foods fails. If this strategy fails, enteral tube feeding should be commenced (King & Davis, 2010). Where weight or length gain is not achieved, the nutrition care plan should include next steps, e.g. moving from home enriched foods to sip feeds and then to enteral tube feeding.

Psychological aspects of growth faltering

A child's intake can be influenced by parental interactions (Harris, 2010). The factors associated with poor intake may relate to poor appetite regulation (Drewett *et al.*, 2003) (early satiety), sensory hypersensitivity, late introduction of complementary foods and/or oral motor dysfunction. They may also have inherited parental traits of food fussiness, making them more likely to be neophobic and picky, which may impact on weight gain (Harris, 2010).

Behavioural management

Fussy eating can have a severe impact on growth, development and behaviour, resulting in significant parental anxiety. For many there may be no apparent medical cause for the child's extreme fussiness; however, parents will often describe early life feeding difficulties relative to reflux (Rommel *et al.*, 2003), food allergies (Haas, 2010), autism (Volkert & Vaz, 2010) and prematurity (especially gestational age <34 weeks' gestation) (Rommel *et al.*, 2003). Feeding skills develop through practise and keen

observance, along with developmentally appropriate complementary feeding choices within a responsive feeding environment. Any disruption during this period, e.g. through illness, adverse reaction to food, acute or chronic pain, e.g. gastro-oesophageal disease or psychosocial stress, can be disruptive due to reinforcement that avoidance of food means pain or discomfort, etc. is avoided. This can lead to regression of feeding skills, non-acceptance of new foods and/or textures, altered motivation and feeding practices, leading to parental frustration and anxiety, which is mirrored back to the child (Haas, 2010; Rommel *et al.*, 2003).

In children who have been unable to acquire age appropriate feeding skills, meal time avoidance strategies are commonly apparent, e.g. tantrums, volume limiting eating patterns to avoid pain, discomfort or anxiety, habitual gagging or vomiting, mouth sealing and food refusal, or limited variety of foods consumed (Haas, 2010; Kessler *et al.*, 2010). Feeding difficulties, especially those severe enough to result in growth faltering, are usually managed within a multidisciplinary team (MDT) involving a physician, dietitian, speech and language therapist, psychologist, nurse, social worker and others (Rommel *et al.*, 2003; Davis *et al.*, 2010; Harding *et al.*, 2009). The management strategy applied is individualised and dependent on the severity of the type of feeding difficulty and the level of involvement the family is able to make. Treatment may take the form of individual counselling sessions, group feeding programmes and/or a monitored home programme (Haas, 2010).

Behavioural management aspects in this programme aim to address hypersensitivity issues to texture, smell and taste of food through imaginative and messy play, with the aim of promoting sensory integration and building the child's confidence around new food experiences in addition to practising chewing skills. When trying to address issues related to texture and taste, changes should be implemented slowly and independently of each other, e.g. change one aspect of a meal at a time. It is also imperative to provide support to the parents. Video diaries of meal times provide insight into behavioural patterns of the child and caregiver (Harding *et al.*, 2010). Useful techniques for parents at meal times include; limiting the length of meal times to 30 minutes or less, and reduction in reprimands, coercion and/or coaxing; the approach should be less directive or reprimanding in nature (Davis *et al.*, 2010; Harding, 2009).

Severe to moderate malnutrition

Undernutrition in low and middle income countries affects a significant proportion of the paediatric population, resulting in an estimated 2.2 million deaths each year. The WHO has management plans for both severe and moderate malnutrition, describing the use of products such as F75 and F100 in addition to ready to use therapeutic food (RTUF). These are pastes made from peanut butter to which oil, sugar, milk or soya powder, and a micronutrient mix is added. The benefit of RTUF over liquid feeds such as F75 and F100, which are recon-

stituted from powdered milk, is that the high fat content of the paste retards microbial growth (WHO, 1999; WHO/UNICEF, 2009). Bacterial contamination of powdered milk feeds is a significant problem and increases the risk of morbidity and mortality (Andresen *et al.*, 2007; Marino *et al.*, 2007; FAO/WHO, 2007).

Where possible, severely malnourished children are managed within a community environment with the aim of reducing the incidence of hospital acquired infections (Phuka *et al.*, 2009; Manary *et al.*, 2004; Linneman *et al.*, 2007). Many studies during the last decade have considered the benefits of RTUF at preventing growth faltering in high risk communities, in addition to their use in severe acute malnutrition and famine relief settings (Golden, 2010; Isanaka *et al.*, 2009). The benefit of RTUF is high community acceptance, good taste, better catch-up growth, decreased bacterial contamination and no requirement for water (Phuka *et al.*, 2009; Manary *et al.*, 2004; Linneman *et al.*, 2007, Matilsky *et al.*, 2009).

3.8.4 Nutritional care of the preterm infant

Kelly Larmour

In 2009 the Department of Health published a toolkit detailing how neonatal services should be delivered in England (Department of Health, 2009). It supported the existing principle that neonatal services should be organised into managed clinical networks with hospitals working as teams to ensure that babies are cared for in appropriate settings. The 23 networks in England are comprised of three types of unit:

- Special care units (SCU).
- Local neonatal units (LNU).
- Neonatal intensive care units (NICU).

Currently not all units have access to a dietitian. It is hoped that recent recommendations may drive change in staffing levels [British Association of Perinatal Medicine Standards (BAPM), 2010].

The UNICEF/WHO definition of prematurity is given in Table 3.8.10. In England and Wales 9% of live births are preterm (Office for National Statistics, 2007). Preterm infants have missed some, or all, of the third trimester of

pregnancy, which is a period of rapid growth when nutrient stores are laid down. Consequently, these infants have higher nutritional requirements compared with term infants. Preterm infants are born with immature organ systems and so establishing enteral feed tolerance can take some time.

Aims of dietetic intervention

The aims of the dietetic intervention are:

- To meet preterm nutritional requirements.
- To promote a postnatal growth rate equivalent to utero-foetal nutrient accretion (~15 g/kg/day).
- To establish enteral feeds as early and as safely as possible.
- To ensure that human milk is used wherever possible.

Methods of feeding preterm infants

Preterm infants are usually fed enterally or parenterally initially and transferred to oral feeding when appropriate.

Parenteral nutrition

Most babies weighing <1500g will require parenteral nutrition (PN). The purpose of PN is to support growth while enteral feeds are being established. The Tsang *et al.* (2005) and ESPGHAN (Koletzko *et al.*, 2005) guidelines give details of the nutritional requirements for preterm PN.

Table 3.8.10 Definition of prematurity (UNICEF/WHO, 2004)

Preterm infant	Born before 37 weeks' gestation
Low birth weight	<2500 g
Very low birth weight	<1500 g
Extremely low birth weight	<1000 g

Enteral nutrition

One of the biggest challenges in neonatal dietetics is establishing enteral nutrition while minimising feed associated risks for developing necrotising enterocolitis (NEC).

Necrotising enterocolitis

This is a potentially life threatening gastrointestinal disease in which the bowel becomes inflamed and damaged to varying extents. Treatment varies from conservative management to extensive bowel resection. No single aetiological factor has been identified, but up to 95% of cases of NEC occur after enteral feeding has been introduced; osmolality, rate of feed advancement and choice of milk have been implicated. Neonatal units with enteral feeding guidelines have a lower incidence of NEC compared with units without them (Patole *et al.*, 2005).

Starting and advancing enteral feeds

Feeding guidelines will often categorise babies according to the risk of NEC. It is increasingly accepted that enteral feeds should be started on day 1 of life in stable preterm infants, but a more cautious approach is taken with babies considered to be high risk. The latter group are more likely to receive a period of minimal enteral feeding before feeds are advanced, while bigger, healthier babies start at larger volumes and progress to full feed volumes more quickly. Enteral feeds are given via orogastric or nasogastric (NG) tubes, with most units preferring bolus to continuous administration as this is more physiological and does not appear to affect the length of time it takes to achieve full enteral feeds (Premji & Chessell 2011).

Oral feeding

Babies must be able to coordinate their suck, swallow, breathe pattern before oral feeds are considered (usually ~33–36 weeks' gestational age). Early involvement of a neonatal speech and language therapist is essential in promoting appropriate oral feeding behaviour. Maternal expressed breast milk (MEBM) is the feed of choice for preterm infants; it confers advantages in terms of neurodevelopmental outcome and immune protection. In addition, preterm infants given MEBM are up to ten times less likely to develop NEC than those fed exclusively with formula milk (Guy *et al.*, 1997). The high nutritional requirements of preterm infants are not met by MEBM unless fed with large volumes and even then, it may not be adequate depending on the composition. In this case, breast milk fortifier can be added to breast milk. Some units routinely add fortifier when babies reach a certain intake, while others prefer to consider each baby individually.

If MEBM is not available, or contraindicated, donor milk is the second choice, as it has been shown to reduce the risk of NEC and is better tolerated compared with feeding formula milk. Due to heat treatment donor milk has slightly reduced immunological components and heat labile nutrients. In addition, fat is not so well absorbed; therefore, it is used in the short term as a tool

for establishing enteral feed tolerance and babies are then weaned onto preterm formula in order to meet their requirements.

Preterm formula milks are designed to meet the needs of preterm infants if fed at 150 mL/kg/day. Term formula milks are not suitable to meet the needs of preterm infants and should be avoided. However in practice, some specialist term formula milks are used, as there is no preterm equivalent, e.g. hydrolysed formula and amino acid formula. Care should be taken to check nutritional composition against preterm requirements and manipulations such as supplementation or increasing feed concentration should be undertaken where necessary. NB: The composition of formula milk and breast milk fortifier may change; therefore, it is important to use up to date company information.

Preterm enteral nutritional requirements

Full details of enteral nutritional requirements are given by ESPGHAN (Agostoni *et al.*, 2010) and Tsang (2005). A summary of selected preterm enteral feeding requirements is shown in Table 3.8.11.

Growth

The most common reason for referral to a dietitian is poor growth. The causes are multifactorial and do not always relate solely to nutrition. Points to consider include:

- Check fluid allowance and consider increasing volume before making feed additions or changing feeds.
- Avoid use of energy supplements such as fat emulsions and glucose polymers as these add extra energy without increasing protein.
- Only make single changes at a time, e.g. increase feed volume before making feed additions such as breast milk fortifier.

Table 3.8.11 Preterm enteral nutritional requirements (Agostoni *et al.*, 2010)

Nutrient	Recommended intake	
	Infant <1 kg	Infant 1–1.8 kg
Fluid (mL/kg/day)	135–200	
Energy (kcal/kg/day)	110–135	
Protein (g/kg/day)	4–4.5	3.5–4
Sodium (mmol/kg/day)	3–5	
Calcium (mmol/kg/day)	3–3.5	
Phosphate (mmol/kg/day)	1.9–2.9	
Vitamin A (µg retinol equivalents/kg/day)	400–1000	
Vitamin D (µg/day)	20–25	
Folic acid (µg/kg/day)	35–100	
Iron (mg/kg/day)	2–3	

Vitamin and mineral supplementation

There are no national guidelines on vitamin and mineral supplementation for preterm infants and local policy should be adhered to. The nutrients that are most commonly given in this patient group are sodium, phosphate, fat soluble vitamins, folic acid and iron; zinc and selenium are also required by some infants.

Monitoring

Preterm infants should have their weight and head circumference measured weekly and their length fortnightly. The measurements should be plotted on the UK–WHO low birth weight growth charts as described in Chapter 3.8.2.

Post discharge formula

The Advisory Committee on Borderline Substances (ACBS) approves prescription of post discharge formula milks for catch-up growth in preterm infants (<35 weeks' gestation at birth) and small for gestational age infants up to 6 months corrected age. However, there is debate about indications for their use (Greer, 2007).

Weaning

The first evidence based weaning guideline for preterm infants was published in 2009 (King, 2009). Weaning should be considered in preterm infants between 5 and 8 months uncorrected age to ensure that sensitive periods for the acceptance of solids are not missed and to allow development of appropriate feeding skills. A practical guide for parents can be downloaded from the Bliss website (www.bliss.org.uk).

Neonatal dietitians' interest group

This is a sub group of the Paediatric Group of the British Dietetic Association providing an informal network for neonatal dietitians from the UK and Ireland. Further details can be found on the British Dietetic Association (BDA) web site.

3.8.5 Community paediatrics

Clare Ewan

Paediatric community dietetics can be entirely based in the community or can cover both acute and community

work. For example, in a district general hospital the paediatric dietitian may cover both acute and community

work for general paediatrics. Some posts may cover a particular speciality and be responsible for its caseload both in and out of hospital. Community paediatrics covers a wide range of work, and paediatric dietitians can be involved in many different activities. These can broadly be divided into clinical and health promotion work.

Clinical community dietetics

Clinical community work in paediatrics includes:

- *General dietetic outpatient clinics* – including one to one assessments, treatment and education around diet and nutrition specific to the particular child. They can be held in hospital outpatient departments, GP surgeries or health centres.
- *Multidisciplinary clinics* – these are held in a number of places, and can cover a variety of disciplines and conditions, e.g. diabetes clinics (jointly with diabetes specialist nurse and consultant), coeliac clinics (jointly with consultant) and feeding clinics held in hospital or special schools (jointly with speech and language therapist, community consultant, and other healthcare professionals).
- *Working with staff in child development services*, e.g. involvement in child centred assessments for children with special needs, in association with consultants and other healthcare professionals; ongoing involvement in multidisciplinary review meetings for children with special needs.
- *Home visiting* – this provides a service for children at home and school.
- *Training for mainstream and special schools* around particular nutritional issues for a child.
- *Home enteral tube feeding services* – services vary; some have a dedicated paediatric dietitian and some have access to a paediatric dietitian.

A smooth transition between acute and community dietetic care of the child is important; therefore, any dietetic plans must be practical and appropriate for the

home and school environments. It requires good communication between all members of what can be a very large team of involved carers and healthcare professionals.

Health promotion community dietetics

Health promotion community work includes:

- Involvement in the development of local nutrition guidelines, e.g. development of weaning guidelines.
- Involvement in wellness programmes, e.g. community food initiatives such as food cafés and cooking skills classes.
- Working with community staff in children's centres and Sure Start facilities to provide information and support around promoting healthy eating for families (see Chapter 3.2).
- Working with schools in their delivery of the National Healthy Schools programme, e.g. school meals and packed lunch advice.
- Working with public health nursing teams (health visitors and school nurses) to provide education and training.
- Involvement in the development of local care pathways, e.g. for care of allergy patients and management of medical issues such as constipation.
- Working with public health agencies on the development and delivery of weight management programmes (see Chapter 7.13.4).
- Working at a strategic level to develop national programmes.

These areas rely on good communication and working between the different teams and agencies, to deliver services to benefit their communities (see Chapter 4.2).

3.8.6 Autism

Emma Mills

Autism, or autistic spectrum disorder (ASD), is a neurodevelopmental disorder affecting social skills and communication, and is often characterised by stereotypic behaviours, including strict routines and desire for sameness. The spectrum ranges from individuals who are high functioning (Asperger's) to children with very severe disability. The prevalence is estimated at 5 per 1000 with four times more boys affected than girls. The incidence is increasing partly due to better diagnosis but mostly due to unknown environmental factors that trigger autism in those with a particular genetic susceptibility. It can occur in infancy, or later in life (>18 months), which is termed

regressive autism. There is growing evidence that there are significant metabolic and nutritional differences between autistic and neurotypical (NT) children and this knowledge should improve management (Adams *et al.*, 2011). The key features of autism in children are shown in Table 3.8.12.

Dietetic evaluation and treatment

Children who have difficult feeding behaviours, significant GI symptoms and are under- or over-weight are likely to be referred to a hospital or community clinic. It is

useful to request parents to complete a 7-day food diary of their child's current intake.

Gastrointestinal disturbance

Assuming tests for gastrointestinal disorders, e.g. coeliac disease, are negative, the full extent of gastrointestinal disturbance should be evaluated by taking a full and detailed history, including questions about constipation, diarrhoea, abdominal bloating and abdominal pain. Children with significant gastrointestinal disturbance may respond positively to a gluten and casein free diet (Knivsberg, 2001; Knivsberg *et al.*, 2002; Millward *et al.*, 2004). It is very important to explain to parents the commitment involved in following such a restrictive diet and that an improvement in symptoms may not occur. A trial period (minimum 3 months) should be started with a full evaluation of symptoms pre and post trial to assess effectiveness. A symptom score chart can be used to assess each symptom, i.e. 0 = symptom free and 5 = most severe. Telephone consultations can be done every 2–4 weeks, depending on how much support the family require, until the diet is established.

Table 3.8.12 Key features in autistic spectrum disorder

Key feature	Example
Major impairment in social skills/relationships	No cuddles or signs of affection with parents Difficulty making friends
Major impairment in communication	Avoidance of eye contact Limited verbalisation
Stereotypic behaviours	Insistence on certain daily rituals Repetitive behaviours
Gastrointestinal disturbance	Diarrhoea Constipation Abdominal bloating* Abdominal pain*
Selective eating	Limited range of acceptable foods Hypersensitivity to bitter and sour tastes Hyposensitivity to sweet and salty Pica
Growth and weight issues	Failure to thrive Overweight/obesity

*Non-verbal clues to look for are walking on tip toes, lying on stomach, leaning stomach against a hard surface, e.g. arm of a chair.

Selective eating

This will often be the biggest concern for parents and their attitude will influence future progress. Parents should be encouraged to keep meal times relaxed and enjoyable, and explain the need for different strategies with autistic children than those for regular fussy eaters. It is important to assess the diet for possible deficiencies and to supplement appropriately. Long term restrictive eating patterns in autistic children can have serious consequences, including permanent blindness (McAbee *et al.*, 2009), optic neuropathy (Pineles *et al.*, 2010) and reduced bone thickness (Hediger *et al.*, 2008), especially for those following a restricted dairy diet.

Food exchanges

Food exchanges, which match new foods to accepted foods in terms of their sensory characteristics, may increase variety into the diet. Table 3.8.13 illustrates the food exchange system.

Growth and weight

Faltering growth is frequently a problem in young autistic children, often due to selective eating and or gastrointestinal disturbance. Many older children become overweight due to a chronically unbalanced diet rich in processed carbohydrates, salty and sweet foods, with a significant lack of fruit, vegetables, fish and wholegrain foods. The challenge is to stabilise gastrointestinal symptoms and increase the range of acceptable, healthier food choices (see Chapter 7.13.4).

Nutritional supplements

Autistic children with inadequate nutrient intakes on a restricted diet, either because of self selection or a casein and gluten free therapeutic diet, will require nutritional supplementation. Many supplements may be rejected because of their taste or smell so unflavoured supplements, e.g. paediatric Seravit (SHS) is often used, although this does not contain essential or long chain fatty acids. This should be combined with a liquid fish oil supplement, e.g. Ideal Omega Swirl (Barlean's) or Lem-0-3 (Cytoplan), or capsules, e.g. MorEPA and MorDHA (Nutritional Intelligence) according to individual tolerance.

3.8.7 Special needs

Clare Ewan

The term special needs covers a wide range of conditions, which can be related to a congenital problem or to an acquired injury. A paediatric dietitian has a role to play in many areas of the care of these children in both hospital and in the community. The impact on nutrition will vary depending on the condition:

- Lack of, or problems with, the physical aspects of feeding.
- Neurodevelopmental delay with a consequent delay in feeding abilities.
- Nutritional requirements that differ from the general paediatric population.
- Diet that needs to be manipulated for treatment and control of the condition.

These children have different nutritional requirements and there is a wide variation between children with the same condition, e.g. a child with Down's syndrome may be able to eat normally, whilst another may have significant difficulties managing foods within their mouth because of tongue thrust (involuntary pushing forward of the tongue). Dietetic needs can change over time, e.g. children with Prader–Willi syndrome frequently have faltering growth and may need tube feeding in their first year of life, whilst in later life their unrestricted eating means they are at greater risk of becoming obese.

Cerebral palsy

Cerebral palsy (CP) is a relatively common disorder that often requires paediatric dietetic input. It is a condition in which impairment to the immature brain affects movement, posture and coordination. (see Chapter 3.7). Problems in children with CP that affect their feeding and require dietetic support include:

- *Sucking and swallowing problems* leading to poor intake, with consequent faltering growth:

- Energy supplementation may be needed.
- Aspiration, with a risk of chest infections, can occur and therefore food textures may need to be modified or the child may need to be tube fed.
- *Gastro-oesophageal reflux*:
 - Feeds may need to be thickened.
 - Antireflux medication may be prescribed.
 - In severe cases fundoplication may be performed (see Chapter 3.8.27).
- *Faltering growth* – this may be due to a combination of poor intake, and increased requirements because of the involuntary movements.
- *Constipation* is common; advice around fluid and food intake may be needed in addition to medication.

Dietetic management

The paediatric dietitian will provide support to families and other carers, nursery and school staff, and respite carers. They work with other healthcare professionals in relation to the child's feeding, sometimes in multidisciplinary feeding clinics. These include:

- *Speech and language therapists* – advise on which types of fluids and foods should be offered to the child, e.g. thickening fluids and/or solids; using special teats (Habermann) or cups (Doidy); and on specific textures of foods to offer.
- *Physiotherapists* – advise on seating and posture that benefit feeding and improve muscle tone.
- *Occupational therapists* – advise on adaptations to the child's environment, e.g. seating and cutlery.

Children with special needs are usually measured and plotted on standard or condition specific growth charts. For many children with special needs, there are challenges around weighing and measuring height. Sitting scales or hoist scales may be used. For children who

cannot stand, a supine stadiometer suitable for older children can be used (Stewart *et al.*, 2006). Lengths can be difficult to obtain in children with scoliosis or contractures, so alternative estimates of linear growth are sometimes used (Spender *et al.*, 1989). Down's syndrome specific growth charts are available in the UK (see Chapter 3.8.2). Clinical growth charts for children with CP have recently been developed in the US (Brooks *et al.*, 2011).

Other conditions that are classified as special needs and in which paediatric dietitians can be involved include autism, epilepsy, neurological problems, e.g. Parkinson's disease and multiple sclerosis, and inherited metabolic diseases. If a child presents with a rare condition, the charity Contact a Family (www.cafamily.org.uk) may be helpful for parents and healthcare professionals.

3.8.8 Paediatric general medicine

Katie Harriman

Paediatric general medicine is the initial point of contact for a child's medical care after consultation with a GP. Children are assessed in outpatients or if an emergency, on a paediatric emergency assessment unit or general ward within a hospital setting. Children can be admitted for a number of reasons but the main ones are bronchiolitis, faltering growth and general assessment. Most district general hospitals (DGHs) have a paediatric ward and this is where most dietitians will have their first experience of working with children. Referrals to the dietitian are made by the consultant, a member of the acute medical team or by the ward nursing staff after nutritional screening to assess the nutritional risk of the patient.

Care Quality Commission (2010) standards ensure that patients are nutritionally screened within 24 hours of admission and that all patients are provided with adequate hydration and nutritious foods to meet their needs. It is imperative to support those who may require extra help with eating and drinking by providing adapted cutlery and closed lidded cups at ward level. This enables children's hospitals to reduce the risk of poor nutrition and dehydration by encouraging and supporting children to receive adequate nutrition and hydration.

The range of patients seen will differ depending on whether the paediatric dietitian is working in a DGH or a tertiary children's hospital (TCH). The paediatric dietitian working within a DGH will encounter a wide range of medical conditions, including food behavioural problems, constipation, breastfeeding advice, weaning

advice, toddler diarrhoea, food allergy and intolerances, feeding problems in newborn babies and infants, gastro-oesophageal reflux, growth faltering, type 1 diabetes, obesity, neurological conditions, respiratory diseases and enteral tube feeding. The paediatric dietitian will see other specialities often with shared care with a TCH. Conditions including metabolic diseases and cystic fibrosis may be managed at these centres. These children may still be admitted to their local medical ward and therefore a good working relationship with the tertiary specialist dietetic team is essential in supporting the care of these children and families. The paediatric dietitian working within a TCH will assess acute general patients, including those with all the above conditions, through to patients with complex syndromes with feeding difficulties.

A nutritional assessment will be carried out following a trigger from the nutritional screening process or medical referral. This involves translating individual nutritional requirements into practical dietary and feeding practices or regimens, to optimise health, growth and development within the parameters of the child's particular condition. It is essential to design a practical plan tailored to the individual, so that families and carers can achieve the desired dietary changes.

Paediatric dietitians will be required to work closely with the MDT to provide advice regarding nutritional assessment and an appropriate working plan for the patient to be implemented with the help of nursing staff. Other professionals that may be involved in an acute

setting include speech and language therapists, play specialists, food provision staff and specialist nurses. Upon discharge, it is vital to liaise with health visitors, pharmacists, community children's nurses, social workers, GPs, school and home enteral tube feeding (HETF) services to provide a safe discharge and continuity of care in the community.

Complex discharges are common on a general medical or paediatric ward. Some patients have multiagency care and it is therefore critical to attend multidisciplinary meetings to work effectively with these professionals to provide a safe discharge. The general medical dietitian will also promote education and training at ward level to promote awareness on topics such as effectiveness of nutritional screening, policies around bringing food from home into hospital, accurate use of growth charts, accurate measuring and recording of anthropometric measurements, discharging a patient home on HETF, the range

of nutritional supplements and enteral feeds available and their uses, and improving awareness of standard operating procedures.

General medical paediatric dietetics also means seeing patients in regular outpatient clinics both in hospital and the community. Patients should be seen within 18 weeks of the initial referral date (Department of Health, 2012).

3.8.9 Paediatric oral nutritional support

Sara Mancell

A focus on oral nutrition is particularly important in young children as this is when oral motor skills and appropriate feeding behaviours are developed (Chailey Heritage, 1998). When planning oral nutritional support, it is important to be aware of the different settings where children eat. It is often useful to involve extended family members, schools or nurseries in planning.

Methods for supporting oral nutrition

These include:

- Regular meals and snacks.
- Food fortification.
- Energy dense foods.
- Supplements.
- Concentrating formula or feed (used primarily for infants on formula milk or older children on specialist powder based feeds).

Regular meals and snacks

Children should be offered regular meals and snacks to avoid grazing on snacks throughout the day. It may help to have set meal and snack times with at least 2 hours between each. It is important to persist with offering snacks at set times even if they are often refused as children may agree to eat these on some of the days if the opportunity is presented to them. The timing of drinks offered should be considered as many young children find it easier to drink than to eat; it may be better to have drinks after eating.

Food fortification

The nutrient density of a child's usual dietary intake can be increased by adding in foods such as butter, margarine,

oil, double cream, jam, syrup, honey, sugar, skimmed milk powder or cheese (see Chapter 6.3).

Energy dense foods

High energy snacks may improve the nutritional status of children with faltering growth (Kasese-Hara *et al.*, 2002). It is, however, important that children continue to have a nutritious, balanced diet, especially those who require long term nutritional support. Examples of high energy snacks are shown in Table 3.8.14. High energy snacks can be an inexpensive method of boosting energy intake.

Supplementation

Children's diets can be supplemented with ready made sip feeds or modules based on fat, carbohydrate or protein. Sip feeds are easy to use, time saving and avoid the risk of reconstitution errors. In contrast, recipes using feed modules must be followed very carefully to maintain the correct balance of nutrients. However, they can be used to achieve precise, tailor made macronutrient profiles.

High energy formulae and sip feeds

High energy formulae and sip feeds are shown in Appendix A10.

Supplement modules based on protein, energy and carbohydrate

Appendix A10 lists protein and energy modules that can be added to foods and drinks. The protein to energy ratio (PER) must be preserved when using these products, particularly in preweaned infants relying solely on formula. The PER should be approximately 7–12% in infants (Koletzko *et al.*, 2005) and 5–15% in older children (Jackson & Wooton, 1990).

Table 3.8.14 Examples of energy dense snacks for children

Name	Individual portion size (g)	Energy (kcal/portion)	Protein (g/portion)	Average cost [per 100 kcal (418 kJ)]
Sesame Snack Bar	30	158	5.0	0.09
Shortbread biscuit	12	65	0.9	0.04
Flapjacks	33	150	1.9	0.11
Oatcakes	8	35	0.8	0.06
Mars bar	58	259	2.4	0.11
Alpen strawberry with yoghurt cereal bar	29	121	1.7	0.30
Dairylea Strip cheese	21	73	4.4	0.39
Babybel cheese	20	63	4.5	0.47
Houmous	50	160	3.7	0.15
Sunmaid Raisin pack	42.5	129	1.3	0.31
Nestle Rolo Dessert	70	172	2.2	0.29
Cadbury Flake Twinpot	90	216	4.0	0.36
Avocado wedges	80	155	1.5	0.22
Yeo Valley Greek Yoghurt with honey	100	152	4	0.22

Concentrating feeds or formulae

Another method of increasing the nutrient density is to concentrate infant formulae or specialist powder based feeds. Adjusting the concentration by adding more powder per 100 mL and maintaining the total fluid volume, increases the nutrient density of the feed. It is important that care is taken when adjusting the concentration of a feed and must only be done by an experienced paediatric dietitian.

Cost of oral nutritional support

Oral nutritional support products are expensive and compliance can be poor; therefore, energy dense snacks may be more suitable. The aim should always be to tailor nutritional support individually to maximise compliance and, therefore, effectiveness of treatment.

3.8.10 Paediatric enteral tube nutrition

Kate Harris and Sue Williams

The main principles of enteral nutrition are similar for children and adults (see Chapter 6.4). Enteral nutrition is suitable for infants and children who have a partially functional gastrointestinal tract but who are unable to meet their nutritional requirements orally. Table 3.8.15 outlines indications for enteral tube nutrition. Enteral support can be short or long term and it can provide complete or partial nutrition, or used for fluid or medica-

tion provision only. Enteral nutrition must always be tailored to meet the child's individual needs.

Enteral formulae

The type of enteral formulation or feed chosen will depend on age, weight, gut function, (e.g. absorption capacity) and dietary restrictions (e.g. allergy or metabolic

Table 3.8.15 Indications for enteral feeding in children (adapted from Braegger *et al.* 2010, table 2, p. 112. Reproduced with permission of the *Journal of Pediatric Gastroenterology and Nutrition*)

Indication	Examples
Inadequate oral intake due to unsafe swallow or poor suck	Prematurity, neurological disorders, e.g. cerebral palsy, congenital disorders such as tracheo-oesophageal fistula, oncology tumours, trauma and burns
Malabsorption and digestive disorders	Cystic fibrosis, short bowel syndrome, food allergy
Gastrointestinal motility disorders	Gastro-oesophageal reflux, chronic pseudo-obstruction
Increased nutritional requirements and losses	Extensive burns, liver disease, heart disease
Growth failure or chronic malnutrition	Anorexia nervosa, non-organic growth faltering
Disease treatment	Crohn's disease
Metabolic diseases	Type 1 glycogen storage disease

conditions). Assessing the requirements for each individual child is important when choosing which feed to use. A generic guide to feeds is summarised in Table 3.8.16 and further details are available in Appendix A10. NB: Age and weight parameters will vary between feed suppliers. Due to a European Union Commission Directive (1999/2006) most feeds for children over 1 year are nutritionally complete.

Routes of enteral feeding

As in adults tubes can be placed in the stomach (gastric) or the jejunum for feeding. The choice of access is determined by gastrointestinal function, feeding duration and aspiration risk. The advantages, disadvantages and contraindications for nasogastric (NG), gastrostomy and jejunostomy feeding routes are summarised in Table 3.8.17.

Gastric feeding

Orogastric feeding

This route is primarily used in neonatal units.

Nasogastric feeding

This type of tube is often used when feeding is likely to be short term (<6–8 weeks). These tubes are considered non-invasive and relatively quick to place. However, they can be traumatic to place and are associated with impaired body image in older children. Younger children may experience oral food aversion secondary to NG tube use (Mason *et al.*, 2005, Byron, 2007). Aspiration due to misplacement or tube dislodgement is a safety risk. See Chapter 6.4 for details on placement checking.

Gastrostomy

This tube is used for longer term feeding, but is indicated in the short term when NG tube placement is not feasible. The most common is percutaneous endoscopic gastrostomy (PEG), but radiologically inserted gastrostomy (RIG) or surgical placements are also available. They may be replaced for a low profile skin level device once the stoma tract is formed, normally after 3 months. They are associated with exacerbating gastro-oesophageal reflux disease (GORD) and so a fundoplication may be created at the

same time as placement (Vernon-Roberts & Sullivan, 2007) (see Chapter 3.8.27).

Jejunal feeding

Jejunal feeding is indicated when gastric feeding is not viable, e.g. in gastroparesis, severe GORD, gastric outlet obstruction.

Nasojejunal feeding

These tubes are difficult to place and can migrate into the stomach or higher in the gastrointestinal tract. They are very vulnerable to blocking and are not replaceable at home.

Jejunostomy

Surgical percutaneous endoscopic jejunostomy (PEJ) or jejunal extensions through a PEG (PEG-J) may be indicated longer term. Traditionally, feeding has used continuous provision of a hydrolysed feed. However, polymeric formulae are increasingly being used due to good tolerance (ESPHGAN, 2010). The main complications for this type of feeding are dumping syndrome, abdominal pain and diarrhoea, especially if a hyperosmolar feed is used (see Table 3.8.17).

Regardless of feeding routine, time needs to be taken with the child and family to explain the planned procedure and aftercare. Communication aids can be used, e.g. cartoons, toys, videos, play therapist and specialist literature, as available (GOSH, 2009).

Feed initiation

Feed initiation will depend on the child's clinical status. Infants may start feeding with 1 mL/hour whilst adolescents may tolerate 100 mL/hour or higher. Refeeding risk must be assessed prior to initiation (ESPHGAN, 2010). Careful monitoring of anthropometry, biochemistry and tolerance is vital.

Feeding methods

There are two main methods of feed delivery; continuous and intermittent (bolus). Intermittent feeding has been

Table 3.8.16 Generic guide to paediatric enteral feeds**

Age	Weight (kg)	Comments	Type of feed	High energy	Low energy	Fibre	Impaired gut function or allergy
<12 months	Up to 8		Standard	Specialist formula, e.g. Infatrini (Nutricia), Similac (Abbott), SMA High Energy			Hydrolysed or amino acid feeds
1–12 years	8–45	Milk based Premixed, sterile, ready to use packs Lactose free Gluten free Nutritionally complete	Expressed breast milk Pasteurised donor breast milk Standard infant formula* 1 kcal/mL Suitable for most children, promoting adequate fluid intake [†]	1.5 kcal/mL Useful when fluid is restricted	0.75 kcal/mL May be used for children with low energy requirements, e.g. neurological conditions ^{††} 8–10 years: alternatively low volumes of adult feeds can be used but use with caution due to increased protein and micronutrient content ^{†††}	Available ± fibre Fibre may promote improved bowel function [®]	Hydrolysed or amino acid feeds
>12 years	>45	Use feeds designed for 7–12 years if small stature Normal stature – adult feeds <i>NB: Caution needed to avoid excessive amounts of protein and micronutrients</i>					Adult elemental feeds introduced gradually due to high osmolality <i>NB:</i> Adult partially hydrolysed feeds are not suitable for allergies

†††ESPHGAN (2010)

©NICE, (2010)

NB: Weight and age parameters will vary depending on the feed company.

Table 3.8.17 Advantages, disadvantages and contraindications of different feeding routes

	Nasogastric feeds	Gastrostomy feeds	Jejunostomy
Advantages	Non-invasive Relatively cheap Placement taught to carer/older child	No need to reinsert Devices can be discrete Less associated oral aversion	Reduced aspiration risk No frequent tube reinsertion
Disadvantages	Nasal and throat irritation/ulceration Irritation to cheek Misplacement on passing tube Easy displacement, need to replace frequently Need to check position frequently Gastric pH affected by milk, medications, etc. Can be difficult to aspirate Aspiration risk Visible Traumatic to place Difficult to unblock Oral aversion and difficulty reinstating oral intake Nausea and vomiting Change in bowel habits – short term only	Can exacerbate GORD May pull at tube Local infection risk Leakage can damage surrounding skin Over granulation Buried bumper Aspiration risk Can block Nausea and vomiting Change in bowel habits – constipation/diarrhoea Difficulty reinstating oral intake and tube dependency	Tube blockage Easily dislodged Placed with general anaesthetic Nausea and vomiting Bloating Dumping syndrome Continuous feeds only Change in bowel habits – constipation or diarrhoea Difficulty reinstating oral intake
Contraindications	Severe vomiting Intestinal/ gastric obstruction Uncontrolled GORD	Gross ascites Severe obesity Clotting abnormalities Ventriculo-peritoneal shunt GI obstruction Severe GORD	Complete intestinal obstruction Clotting abnormalities Gross ascites Severe obesity

shown to be more physiologically normal and allows greater mobility. However, continuous feeding is often better tolerated in those with GORD and can be less labour intensive. Flexibility is key to ensure that the feed plan suits the patient's lifestyle. A combinations of both methods is also possible.

Overnight feeding

Caution must be used to reduce risks of aspiration, especially in children with neurological impairment (Health Improvement Scotland, 2007). Many community teams no longer use NG night feeds, unless clinically indicated and risk assessed.

Complications

Common complications are the same as those seen in adults and include gastrointestinal disturbances, refeeding risk and potential drug–feed interactions (BAPEN, 2004) (see Chapter 6.4).

Equipment

Pumps, giving sets, pH strips, reservoirs and syringes may be needed. All equipment should be National Patient Safety Agency (NPSA) compliant to avoid confusion between intravenous and enteral equipment.

Home enteral nutrition

Moving from hospital to home is a very chaotic time for families and a smooth discharge to the community team for ongoing support is vital. Delivery services from feed manufacturers provide feed, plastics and service pumps, and are used by most home fed children (BAPEN, 2010). These services should be set up before the patient leaves hospital. Liaison with and training of family members as well as nursery and school staff is vital to ensure the feeding plan is safe and achievable. Training should cover reasons for enteral nutrition, goals and outcomes, safety issues, infection control, feeding equipment, social and practical issues, emergency procedures and contact details, oral guidelines and information on equipment deliveries (Vernon-Roberts, 2009). Contact with charities such as PINNT (Patients on Intravenous and Nasogastric Nutrition Therapy; www.pinnt.com/Half-PINNT.aspx) may provide support for families.

3.8.11 Paediatric parenteral nutrition

Kim Novell

Parenteral nutrition (PN) is an expensive form of nutrition and incurs a number of risks; therefore, it is only indicated when adequate nutrition cannot be provided by enteral nutrition alone. Demand for paediatric PN varies between institutions and is likely to be highest in the tertiary setting, particularly in clinical areas of neonatology, gastrointestinal surgery, oncology and intensive care. To expedite hospital discharge, home PN is on the rise; however, this is dependent on the availability of community services (see Chapter 6.5).

The decision to commence PN should be made as part of an experienced multidisciplinary nutrition support team (NST), and depends on the child's age, weight and clinical diagnosis. Members of the NST should include, as a minimum, a senior paediatrician, pharmacist, nutrition nurse and a dietitian (Agostoni *et al.*, 2005). The dietitian's role is to ensure the child is receiving adequate nutrition to achieve appropriate growth, and to recommend changes to feeding regimens to optimise feed tolerance. Some paediatric indications for PN are listed in Table 3.8.18.

Early initiation of PN should therefore be considered if the enteral route has been exhausted, to minimise the

risk of malnutrition and prevent permanent adverse effects on growth and development.

Nutritional requirements

Parenteral nutritional requirements vary widely within the paediatric population. Guidelines based on the most

Table 3.8.18 Indications for parenteral nutrition in children

Absolute indications	Potential indications
Premature infants	High stoma output
Congenital defects, e.g. gastroschisis, a condition in which a baby has a small hole in the front of the abdomen, through which part of the intestine protrudes	Active inflammatory bowel disease
Short bowel syndrome	Pseudo-obstruction
Necrotising enterocolitis	Intractable vomiting
Malabsorption syndromes	Protracted diarrhoea
Intestinal failure secondary to radiation/cytotoxic therapy	Hypercatabolism
	Postoperative gastrointestinal surgery
	Long periods of nil by mouth

current evidence available have been developed however; nutritional requirements need to be adapted according to the clinical situation, enteral intake and whether catch-up growth, which relates to rapid growth following a period of growth failure, is required.

Energy

Energy supply should meet the total needs of the child, whilst avoiding excessive energy intake. Average daily parenteral energy intakes per kilogram body weight considered adequate for the majority of children are shown in Table 3.8.19.

Amino acids

The amino acid preparations available for children are Primene, based on the amino acid profile of cord blood, and Vaminolact, based on the profile of breast milk (Grogan, 2007). A minimum of 1.0–1.5 g/kg/day is necessary to prevent a negative nitrogen balance; however higher intakes are required to achieve protein deposition (Koletzko *et al.*, 2005). Average amino acid requirements are detailed in Table 3.8.20.

Lipids

A range of 10%, 20% and 30% lipid emulsions are used in paediatric PN and contain soyabean oil (Intralipid), soyabean oil and coconut oil (Lipofundin), soyabean oil and olive oil (ClinOleic), and soyabean oil, medium chain triglycerides, olive oil and fish oil (SMOFlipid). Lipid intake should provide 25–40% of non-protein calories in fully parenterally fed patients (Grogan, 2007). A minimum of 0.25 g/kg/day for preterm infants and 0.1 g/kg/day for term infants and older children is required to prevent essential fatty acid deficiency. Parenteral lipid intake

should be limited to a maximum of 3–4 g/kg/day in infants and 2–3 g/kg/day in older children (Koletzko *et al.*, 2005).

Carbohydrates

Dextrose provides 60–75% of total non-protein energy intake (Koletzko *et al.*, 2005). The type of intravenous (IV) access limits maximum dextrose concentrations of solution. Central lines, inserted into large veins in the neck, chest or groin, can accommodate a dextrose concentration of up to 20%, compared with a maximum of 12% with peripheral lines, which are inserted into smaller veins (Koletzko *et al.*, 2005). Maximum carbohydrate requirements are detailed in Table 3.8.21.

Micronutrients and electrolytes

The optimal parenteral micronutrient requirements for infants and children have yet to be determined. Requirements for vitamins and trace elements are based upon standard recommendations, whereas electrolytes are typically based on individual patient requirements adjusted according to serum levels. A detailed review of parenteral vitamin, trace element and electrolyte requirements can be found in Koletzko *et al.* (2005).

Standard and individually compounded bags

Standardisation of PN formulas reduces prescribing and compounding time, and can limit the risk of errors. However, due to the wide variability of paediatric nutritional requirements, individualised PN is still widely used (Kochevar *et al.*, 2007). Individually compounded bags are based on weight, and combine amino acid and glucose; separate lipid components are produced. Individual bags are beneficial as concentrating the PN, within the maximum carbohydrate concentration, can vary volumes without compromising nutrition. Standardised all in one bags, usually based on adult requirements, are otherwise available. A portion of the bag should be prescribed to meet the child's nutritional and fluid requirements as closely as possible. To prevent the risk of over infusion it is recommend that the child's nutritional requirements be met in no less than three-quarters of the total bag.

Table 3.8.19 Energy requirements for parenteral nutrition in children (Koletzko *et al.*, 2005)

Age (years)	kcal/kg/day	kJ/kg/day
Preterm	110–120	460–500
0–1	90–100	380–420
1–7	75–90	315–380
7–12	60–75	275–315
12–18	30–60	125–275

Table 3.8.20 Amino acid requirements for parenteral nutrition in children (Koletzko *et al.*, 2005)

Age	g/kg/day
Preterm infants	1.5–4.0
Term infants	1.5–3.0
Second month to third year	1.0–2.5
Third to 18th year	1.0–2.5

Table 3.8.21 Maximal parenteral glucose supply for children (Koletzko *et al.*, 2005)

Weight (kg)	g/kg/day
Up to 3	18
3–10	16–18
10–15	12–14
15–20	10–12
20–30	<12
>30	<10

Complications

Two major potential complications of PN are catheter related sepsis and PN associated liver disease. The pathogenesis of PN associated liver disease is multifactorial and is thought to arise from an interaction of many factors, including prematurity, recurrent sepsis, PN duration, lack of enteral nutrition, excessive calories, lipid source or overload, and continuous or excessive glucose supply (Koletzko *et al.*, 2005; Drongowski & Corain, 1989; Bresson *et al.*, 1989; Colomb *et al.*, 2000). Administration of PN by trained staff using a sterile technique can minimise the risk of catheter related sepsis (NICE, 2007). To reduce the risk of liver dysfunction, the introduction of maximally tolerated enteral nutrition should be a priority. The lipid source should be considered, as there is emerging evidence that a change of lipid preparation to one containing fish oils can reverse liver disease over a 4–6-week period (Cheung *et al.*, 2009; Diamond *et al.*, 2008; Ekemaa *et al.*, 2008; Gura *et al.*, 2006; 2008). Cyclical PN, where the PN is administered over intermittent periods, may also be beneficial; however, it should only be used in children who are able to maintain their blood sugar levels during an infusion break (Koletzko *et al.*, 2005). To

prevent rebound hypoglycaemia the glucose containing component of the PN should be weaned to half rate for 2 hours prior to stopping. A more detailed account of PN complications can be found in Koletzko *et al.* (2005).

Monitoring

To ensure the PN regimen is suitable for the child's clinical needs and to minimise the risk of complications, it is recommended that an experienced member of the NST carries out regular clinical assessment of patients. A suggested monitoring protocol can be seen in Table 3.8.22. Further information on the rationale and interpretation of results can be found in the NICE guidelines on nutritional support (NICE, 2007).

Weaning off parenteral nutrition

It is useful to assess feed tolerance before weaning off PN, especially in infants and toddlers, in order to prevent nutritional and growth deficits. Children who have had an acute episode of intestinal failure may tolerate a rapid reintroduction of enteral and/or oral feeds. In contrast,

Table 3.8.22 Suggested protocol for monitoring paediatric patients on parenteral nutrition (adapted from National Institute for Health and Care Excellence 2007. Guidelines current as of 2013. Reproduced with permission of NICE)

Parameter	Frequency
Sodium, potassium, urea, creatinine	Baseline Daily until stable then 1–2 times/week
Blood glucose	Baseline 1–2 times/day until stable, then weekly
Magnesium, phosphate	Baseline Daily if risk of refeeding syndrome Or three times a week until stable, then weekly
Liver function tests	Baseline Twice weekly until stable, then weekly
Cholesterol/triglyceride	Baseline Daily whilst grading in lipid, then weekly
Calcium, albumin, C-reactive protein	Baseline, then weekly
Zinc, copper	Baseline, then every 2–4 weeks
Selenium	Baseline if risk of depletion, then further testing depending in result
Manganese	3–6 monthly
Vitamin D	6 monthly
Iron, ferritin	Baseline, then 3–6 monthly
Folate, vitamin B ₁₂	Baseline, then 2–4 weekly
Full blood count	Baseline 1–2 times/week until stable, then weekly
Urinary glucose, sodium, potassium	Weekly
Fluid balance charts	Daily until stable, then twice weekly
Weight	Daily if concerns regarding fluid balance, then 1–2 times per week
Length/height, head circumference, BMI	Baseline, then monthly
Signs of infection, drug interactions	Daily
Gastrointestinal function, enteral intake	Daily initially, then twice weekly

BMI, body mass index

children with a primary gut diagnosis may require a more gradual reintroduction.

3.8.12 Paediatric gastroenterology

Julia Smith

Infants and children with common gastroenterology disorders often present to the GP initially and are then referred to their local hospital. Those with more complex conditions can warrant a referral to a tertiary unit or children's hospital (see Chapter 7.4).

Infants

Reflux

Simple reflux, where gastric contents reflux back into the oesophagus, is common in infants. Severe and persistent, gastro-oesophageal reflux disease (GORD) can cause vomiting, pain, discomfort and an aversion to feeding. First line advice is to position upright during and after feeding to allow gravity to minimise the reflux. Feed volumes and frequency should be reviewed to ensure that the infant is not receiving too much feed at any one time. A prethickened formula can also be used, e.g. SMA Stay-down or Enfamil AR, or a thickener can be added to the regular formula, e.g. Instant Carobel (Cow and Gate) or Thick and Easy. These can be used alongside antireflux medications, which reduce acid production and promote

gastric motility. Thickened feeds may be more difficult for the infant to suck than standard formula and they may require a faster flowing teat. If there is faltering growth, an atopic family history, worsening of symptoms on the introduction of formula or cow's milk protein, associated diarrhoea or constipation, non-IgE mediated cow's milk protein allergy should be considered.

Transient lactose intolerance

Transient lactose intolerance can present following an episode of gastroenteritis and should not be confused with congenital lactose intolerance, which is rare. Typically, diarrhoea continues after vomiting has stopped post gastroenteritis. Stools are fermentative and often described as sweet smelling. The infant's buttocks can be excoriated and sore, but they are otherwise well and are unlikely to have faltering growth. Treatment is with a lactose free formula and diet for 6 weeks (MacDonald, 2007) to allow for the return of the lactase enzyme activity. After this time, the infant should resume a normal lactose containing diet. If the symptoms do not settle,

non-IgE mediated cow's milk protein allergy should be considered (see Chapter 7.4.6).

Toddlers

Altered stool patterns

Toddlers have stool patterns that vary according to their dietary intake, but symptoms of persistent diarrhoea or constipation can initiate a referral. Toddler diarrhoea is associated with the fast transit of food that can often be seen undigested in the stool. This diagnosis is made if the child is otherwise well and thriving. Diet histories often reveal a high fibre intake, including wholegrains, excess fruit and/or vegetables, and fruit juice. Manipulation of fruit and vegetable intake to appropriate amounts and portion sizes, and limiting fruit juice and squash intake can often help limit symptoms. Constipation is also common in toddlers. Ensuring adequate fibre and fluid intake is essential and there can often be a behavioural component with stool holding and toilet avoidance. Constipation can also be associated with non-IgE mediated cow's milk protein allergy (MacDonald, 2007).

Non-IgE mediated food allergy

Many infants and children with a non-IgE mediated food allergy present with gastrointestinal symptoms, including vomiting, GORD, constipation, enterocolitis enteropathy, eosinophilic oesophagitis, proctitis (inflammation of the rectum and anus) and proctocolitis. The presentation of non-IgE mediated allergy (T cell mediated) is often delayed (24–48 hours), and symptoms and signs typically affect the skin or gastrointestinal tract (Grimshaw, 2007). Cow's milk protein allergy is one of the most common food allergies reported in infants and children, with an estimated prevalence of 2–7.5% in the UK and Europe (Vandenplas *et al.*, 2007). Typically, it presents in early infancy soon after initial exposure to cow's milk protein formula or weaning solids. It can also present in exclusively breastfed infants, although the incidence is much lower (0.5%) (Grimshaw, 2007). The prognosis is good with a remission rate of approximately 85% by 3 years (Vandenplas *et al.*, 2007) (see Chapter 3.8.18).

Coeliac disease (see chapter 7.4.7)

Coeliac disease can present at any age following the introduction of gluten (NICE, 2009). Symptoms can be gastrointestinal: vomiting, diarrhoea and constipation, with faltering growth, abdominal distension, poor appetite and a miserable or clingy child. Dietary treatment is the same as in adult practice but in addition, some children may present with secondary lactose intolerance. It is recommended that gluten free oats are also avoided at diagnosis, although local policy may suggest introduction at a later stage and monitoring of symptoms (British Society of Paediatric Gastroenterology, Hepatology and Nutrition, 2006).

Annual review is essential for these children (Ciclitira, 2002) and should include:

- A dietary review, including micronutrient intakes – especially iron and calcium.
- Age appropriate education to allow independence, e.g. parties, eating out, school meals, cooking for themselves.
- Advice on gluten free products available on prescription (Codex Alimentarius Commission, 1983).
- Monitoring of growth and pubertal assessment.
- Assessment of compliance.

Inflammatory bowel disease

Inflammatory bowel disease (IBD) commonly presents during adolescence. Children with ulcerative colitis have fewer nutritional complications, but may require nutritional support for disease related malnutrition. However, nutrition is key in the treatment and management of Crohn's disease. Features can include raised inflammatory markers, hypoalbuminaemia, loose stools, abdominal pain, nausea, vomiting, weight loss, poor appetite, mouth ulcers, erythema nodosum, iron deficiency anaemia and delayed puberty. These have often been present for some time and children can present with significant growth failure (Wisikin *et al.*, 2007). It is also common for dietary restriction to have been tried before diagnosis and this may also impact on nutritional status (Rigaud *et al.*, 1994).

At diagnosis children with Crohn's disease should be offered exclusive enteral nutrition to induce remission (Beattie *et al.*, 1994; BSPGHAN, 2008; Wisikin *et al.*, 2007). Traditionally these were elemental feeds (E028 Extra SHS Nutricia), but there is no evidence to support that these are more effective than polymeric (whole protein feeds) (Zachos *et al.*, 2001), e.g. Modulen IBD (Nestle Nutrition) or Alicalm (SHS Nutricia). Feed is given exclusively for a period of 4–8 weeks depending on local policy (BSPGHAN, 2008; Johnson *et al.*, 2006). Most children will require 120% of estimated average requirement (EAR) for energy (BSPGHAN, 2008). The daily feed volume should be calculated according to requirements, split into around six drinks/day and introduced over 2–5 days depending on tolerance and risk of refeeding syndrome (Rigaud *et al.*, 1994). Drinks should be taken slowly over 20–30 minutes to prevent osmotic diarrhoea and abdominal cramps. Nasogastric feeding can be used if the child is unable to take sufficient volumes by mouth. Flavourings, chewing gum, mints and flavoured water may aid compliance, but use varies according to local policy. Regular contact and support during this period can also help with compliance. Adolescents can be encouraged to access appropriate support websites.

3.8.13 Cystic fibrosis

Alison Coates and Julie Crocker

The majority of infants with cystic fibrosis (CF) are identified through the national screening programme. Diagnosis is confirmed by a sweat test and/or genetic mutation analysis. Most families will be advised of the diagnosis within 3 weeks of their baby's birth; early diagnosis allows treatment to be commenced promptly. One in 10 babies with CF is born with the bowel obstruction meconium ileus (MI). Meconium is a thick, black material present in the bowels of newborns and in CF it is so thick that it can block the bowel instead of passing through. The obstruction may be managed conservatively, but some babies may require urgent surgery to relieve and bypass the blockage, which may require a gut resection (Patchell, 2007) (see Chapter 7.4.13).

Newly diagnosed infants should be seen for dietetic review every 1–2 weeks until treatment is established, malabsorption symptoms are controlled and the infant is thriving. Subsequent follow-up is usually monthly for babies up to 1 year, then every 8 weeks, although more frequent review may be required. Children will either receive full care from a specialist CF centre or shared care within an agreed designated network (Cystic Fibrosis Trust, 2011). A paediatric dietitian is most likely to see children with CF at a MDT clinic or as an inpatient, par-

ticularly during admission for respiratory exacerbations. All children with CF should have an annual assessment, which includes specialist investigations, including a full dietary report that should include a care plan for the coming year.

Pancreatic insufficiency

Up to 90% of CF patients will be pancreatic insufficient and will require pancreatic enzyme therapy. Following diagnosis, measuring faecal pancreatic elastase assesses pancreatic function. Enteric coated microspheres are most commonly used in infants. Many factors affect the efficacy of pancreatic enzymes; therefore, doses should be advised individually and reassessed regularly depending on weight gain and symptoms of fat malabsorption.

Nutritional requirements

Energy requirements

The energy requirements of children with CF are variable and generally increase with age and disease severity. Fat malabsorption and increased energy expenditure both

increase energy requirements. Therefore, an infant with good absorption control may have normal energy requirements. A teenager with poor respiratory function may have significantly higher energy requirements than expected for age. Many factors may inhibit a child with CF from meeting their increased requirements, including chronic poor appetite, infection related anorexia, gastro-oesophageal reflux, vomiting, low mood and feeding behaviour problems. Regular review by a dietitian experienced in the management of children with CF is essential. A normal to high fat diet should be encouraged (Cystic Fibrosis Trust, 2002).

Vitamins

In CF, there is usually loss of vitamins in the stools, particularly fat soluble vitamins; therefore, regular vitamin supplements are required. The daily supplement should include 4000–8000 IU of vitamin A, 400–800 IU of vitamin D and 50–200 mg of vitamin E. From 8 years a calcium intake of 1300–1500 mg/day is recommended to optimise intake during the child's growth spurt (Cystic Fibrosis Trust, 2007).

Fibre and fluid

Adequate fibre and fluid is important as part of a balanced diet to help maintain normal bowel function and prevent constipation. Salt depletion can occur in children with CF with increased sweating and in infancy when dietary intake is normally low. Salt supplementation should be considered and some centres routinely recommend salt supplementation. However, generous additions of salt to the child's food is not recommended unless advised by the CF team.

Evaluation of growth

Weight and height, and body mass index (BMI) at a later age, should be recorded at each clinic visit and plotted on the appropriate growth chart. Children with CF often show delayed puberty, which may lead to an overestimation of malnutrition. Assessment of pubertal stages is therefore important when interpreting growth data.

Feeding

Infants and toddlers

Most infants with CF will thrive on either breast milk or a standard infant formula if malabsorption is controlled; breastfeeding should be encouraged. High energy formulae can be useful in infants with poor weight gain. Infants who have had a surgical resection for MI usually require a protein hydrolysate feed. Normal weaning practices are advised with support on modifying pancreatic enzyme doses. If weight gain is poor, advice on the use of higher energy or high fat foods should be given (Cystic Fibrosis Trust, 2002). Feeding behaviour problems such as food refusal and inappropriate parental responses are more common in young children with CF. These issues should

be addressed at an early stage to prevent unhelpful behaviour patterns becoming entrenched. Joint dietetic and psychology input can be very effective.

School age children

As children get older, there is an increased likelihood of worsening chest symptoms, leading to greater energy requirements. Close monitoring of growth and nutritional status continues to be essential. The need for enzymes can highlight to a child with CF that they are different from their peers. This can result in problems of acceptance of their condition and adherence to treatment. Advice should be given to parents on how best to deal with this.

Adolescence

Adolescence is a challenging time in the dietary management of CF. The main growth spurt occurs during this period and weight gain and growth can decline dramatically. In addition, poor adherence to enzyme, vitamin and nutritional supplementation is common. It is essential to acknowledge what is important to the teenager. Motivational interviewing for goal setting, together with compromise can be helpful.

Nutrition support

Intervention for poor weight gain should start with improving food and energy intake. The use of dietary supplements, e.g. high energy sip feeds, may be required. Care needs to be taken that these are used in addition to current intake and not as a meal replacement as children's appetites can be small. They may be more useful short term during periods of acute illness rather than as a long term intervention. Tube feeding may be required if growth is failing (Cystic Fibrosis Trust, 2002). Families should be involved early in the decisionmaking process and their views and individual circumstances taken into account regarding choice of intervention and timing of feeds. An overnight continuous feed via a gastrostomy is usually the preferred option. Energy dense feeds are often used to reduce the volume required and usually provide 30–50% of energy requirements.

Complications

The progressive nature of CF means that complications increase in prevalence as children age and move into adulthood. Complications include diabetes, liver disease, bone disease and distal intestinal obstruction syndrome. Investigations to screen for these complications are carried out during the child's annual review, including a dual energy X ray absorptiometry (DEXA) scan from 10 years old to monitor bone density. From 12 years of age, children with CF are screened for CF related diabetes.

3.8.14 Paediatric liver disease

Kirsten Tremlett

Liver disease in children differs significantly from in adults. The major differences (Klein *et al.*, 1997):

- Less frequent occurrence per capita in paediatric patients.
- A much wider range of causes.
- Diseases or defects that are present at birth may prove fatal before adulthood if not diagnosed early in life.
- A greater prevalence of inborn errors of metabolism, biliary tract disease, primary infections and autoimmune disorders.
- A higher likelihood of more nutritional deficiencies; these will generally be caused by the higher anabolic needs for growth, compounded by the catabolic effects of the liver disease.

The nutritional management of infants and children with liver disease will be governed largely by whether the presenting condition is acute, chronic or has been caused by an inherited metabolic disease.

Acute presentations may be due to hepatitis, the onset of autoimmune liver disease or the ingestion of a toxic substance, e.g. paracetamol. Infants tend to present with symptoms of biliary tract disorders that can progress to a chronic condition, e.g. biliary atresia.

Specific inherited metabolic disorders within the liver may present undiagnosed as an acute liver failure, including tyrosinaemia, fatty acid oxidation disorders, urea cycle defects, glycogen storage disease, galactosaemia and fructosaemia. These disorders require specific dietary treatment as outlined in Chapter 3.8.16 and Chapter 7.8.

Chronic presentations with significant nutritional implications include Alagille's syndrome and progressive familial intrahepatic cholestasis (PFIC).

Nutritional assessment

A thorough nutritional assessment is essential, including anthropometry, biochemistry, clinical, social and dietary assessment (Smart *et al.*, 2011). The presence of organomegaly and/or ascites will often mask actual body weight and make the screening for malnutrition meaningless. Regular weights can give an indication of ascites progression. Similarly, length or height is not a sensitive short term marker, but can be useful as a long term measure of chronic malnutrition. More reliable indicators include serial measurements of mid upper arm circumference (MUAC) and triceps skinfold thickness (TSF), and

therefore arm muscle mass, which is thought to be more sensitive to the patient's nutritional state (Taylor & Dhawan, 2005; Paul *et al.*, 1998; Battler & Roberts, 2000). Percentiles published by the World Health Organization (WHO, 2006) provide a reference for plotting MUAC and TSF (Taylor & Dhawan, 2005; Frisancho, 2008). There is a strong correlation between liver disease severity, when evaluated by liver function tests, and poor nutrition status, as evaluated by anthropometry (Hurtado-Lopez *et al.*, 2007). Although this is a useful general rule, careful interpretation is needed when complications such as peripheral oedema are present, as these may mask the child's true nutritional state. The situation may be further complicated when nutrition related problems are present, e.g. nausea, vomiting, diarrhoea or anorexia (France, 2007). Anthropometry and biochemistry should be considered together with clinical features when deciding upon nutritional management of paediatric liver disease.

Acute liver failure

Acute liver failure describes a severe impairment of liver function in association with hepatocellular necrosis, where there is no underlying chronic liver disease. The term fulminant is usually used when the failure is associated with encephalopathy. Infants and children are often well nourished if they present immediately after onset. In these cases, nutritional management is aimed at maintaining the patient's nutritional status until the liver function improves. However, if the onset is dramatic, there is a possibility of the critical life threatening complication of cerebral oedema; such patients are often treated in intensive care. It is possible for an undiagnosed chronic liver disease to present acutely and all possible causes must be investigated thoroughly, in order to exclude this possibility (France, 2007).

Dietary management

Current practice is to provide maximum nutritional support. However, dietary management lacks consensus and some aspects of treatment are regarded as controversial. Nevertheless, as the cause of acute liver failure in infants could be an undiagnosed inherited metabolic disorder, the introduction of feed should be delayed until these have been excluded. This is less likely in an older

child or adolescent, so they may be given a standard enteral formula.

Chronic liver disease

There are many causes of chronic liver disease in paediatrics and it can present at any age. It is particularly important to diagnose treatable causes of liver disease that present in early infancy. These include sepsis, galactosaemia, tyrosinaemia, endocrine disorders, biliary atresia and choledochal cyst. Dietary management depends on the presenting symptoms, which can include the following:

- Cholestatic jaundice and fat malabsorption – the presence of cholestasis in infants usually indicates that a medium chain triglyceride formula should be used, with fat soluble vitamins and essential fatty acid supplements.
- Hypoglycaemia.
- Failure to thrive.
- Ascites.
- Hepatomegaly.
- Portal hypertension and malabsorption.
- Chronic encephalopathy.
- Oesophageal varices.

A detailed description of the management of these symptoms has been reviewed by Smart *et al.* (2011).

Paediatric liver transplantation

Advancements in the selection of donor organs, together with the wider availability of immunosuppressive therapy and the increased expertise of specialised paediatric transplant teams, have all contributed to the success of paediatric solid organ transplantation. Survival rates at 5 years post cadaveric transplantation are 78–88% and for living related donor grafts are slightly higher at 83–87%. Children aged 6–10 years have the best 5-year post transplant survival rate (88%) (Tolan, 2011). Patients often have to wait for extended periods before receiving a transplant, owing to the shortage of suitable donor organs. During this period, aggressive nutritional management is essential in order to achieve an optimum outcome (Tolan, 2011).

Ensuring an optimum outcome has been shown to improve the post transplantation survival rate, resulting in fewer infections and a reduction in the frequency and severity of surgical complications (McDiarmid, 2001). Post transplant feeding usually commences in the first 72

hours if the patient is stable. If enteral feeds are indicated, a normal standard age appropriate feed may be introduced. The length of time enteral feeding is required will usually depend on the patient's nutritional status prior to transplant, the underlying diagnosis and presence of postoperative complications. However, most patients should expect to require feeds for up to 2 months after transplant, with normal diet for age being achieved within 6 months.

All paediatric liver transplants and hepatobiliary surgery is carried out at one of three paediatric supraregional liver centres in the UK (King's College Hospital, London; Birmingham Children's Hospital; Leeds General Infirmary). All have specialist paediatric dietitians working as part of the MDT.

3.8.15 Paediatric nephrology

Sarah Trace

Established renal failure requiring renal replacement therapy (RRT) is a rare but significant cause of long term morbidity and mortality in children (Singa *et al.*, 2010). In the UK there are 13 specialist centres for paediatric

nephrology with 10 providing transplantation services. Many children live a significant distance from their renal centre, so may access some of their care at their local hospital. Dietetic care at a local hospital will be on a

shared care basis, led by the specialist dietitians at a specialist centre. The specialist dietitian will have an important role within the MDT; the renal team therefore will not only meet the clinical needs of the child, but will also support their social, psychological and educational needs (see Chapter 7.5.1).

Common presentations

The most common primary presentation of acute kidney injury (AKI) in children is haemolytic uraemic syndrome (HUS) associated with *Escherichia coli* infection, which has an annual incidence of 1–2 in 100 000. Acute kidney injury may also present secondary to a multifactorial illness in a severely unwell child. The annual incidence of established chronic kidney disease (CKD) requiring renal replacement therapy (RRT) is 5–10 children per million (Singa *et al.*, 2010). Congenital disorders, including congenital anomalies of the kidney and urinary tract and hereditary nephropathies, are responsible for about two-thirds of CKD in developed countries (Harambat *et al.*, 2012).

Nutritional assessment

In addition to the usual considerations made during a paediatric nutritional assessment, nutritional care planning for children with kidney disease will depend on the nature and severity of the disease, the resulting biochemical changes and medical management, including RRT methods and fluid status. In CKD a detailed assessment is complex to perform and needs to be carried out by an experienced renal paediatric dietitian (Royle, 2007). The USA National Kidney Foundation Kidney Disease Outcomes Quality Framework Initiative (KDOQI), Clinical Practice Guideline for Nutrition in Children with CKD is a useful resource (The National Kidney Foundation, 2008).

Dietary management

Acute kidney injury

These children are very unwell, usually unable to eat anything significant, are highly catabolic and usually require dialysis. Nutritional support will aim to prevent catabolism and control biochemical disturbances. The choice of support is dependent on intake and children many require tube feeding. Feed choice and regimen is dependent on the previously described factors and general clinical condition, including the presence of vomiting and or diarrhoea (Royle, 2007).

Chronic kidney disease

Most children with CKD will require specialist renal paediatric dietetic monitoring and advice when the kidney function declines to a glomerular filtration rate (GFR) of 30–60 mL/min/1.73 m² (CKD stage 3) and below.

Poor growth and weight gain is a major problem. Malnutrition and resulting hypoalbuminaemia is associated with increased mortality (Wong *et al.*, 2002). Dietary

restrictions must only be instigated when absolutely necessary. Many will require tube feeding, but this itself can be problematic due to the increased incidence of gastro-oesophageal reflux (Ruley *et al.*, 1989). Feeding problems are common in children; those who have a feeding tube placed before 1 year of age are much more likely to develop feeding difficulties (Dello Strologo *et al.*, 1997). As with any chronic disease, an infant can miss key developmental stages during repeated periods of illness. There is frequently a decline in food intake. As renal function falls, food intake decreases further, with one study demonstrating a fall of to 85% of the estimated average requirement (EAR) when the GFR was <25 mL/min/1.73 m² (Norman *et al.*, 2000). Uraemia, caused by the accumulation of waste products, leads to loss of appetite and taste changes (Bellisle *et al.*, 1995). Frequent nausea and vomiting may lead to food refusal, even when a child is well.

Dietary aims

Optimal nutritional status to promote growth and wellbeing, whilst aiding control of biochemical disturbances, is the aim of dietary management. There is no evidence that children consume more energy than their EAR, although energy dense diets and feeds may be needed due to vomiting, or poor or restricted intake. In order to achieve adequate growth, the child's reference nutrient intake (RNI) for protein is the minimum amount that needs to be achieved. In non-dialysed children with good appetites, there may be a need to reduce usual protein intake if there are symptoms of uraemia. In dialysed children, requirements are additionally determined by dialysis method and biochemical assessment (Royle, 2007).

Control of phosphate, calcium and parathyroid hormone levels will help to prevent calcification of the vessels and renal bone disease. Dietary phosphate intakes usually need to be limited to less than the RNI, which is usually achieved by phosphate binding therapy. Fluid and electrolyte requirements depend on disease, biochemical control and RRT. Fluid requirements and restriction or supplementation of sodium and potassium need to be individually tailored. Dietary restriction of electrolytes, combined with phosphate, severely limits food choice. More research is needed to determine other micronutrient requirements. Folic acid, iron and water soluble vitamins are commonly recommended (Royle, 2007; The National Kidney Foundation, 2008; Warady *et al.*, 1994). A paediatric renal specific micronutrient supplement, Paediatric Delyvit (Vitaline Pharmaceuticals), has been developed which also provides some trace elements (Dixon *et al.*, 2004).

Transplantation

Many children will receive a kidney from a live related donor, usually a parent. Immediately following transplant the child and their family will need advice on basic food safety for a short period whilst on high doses of immunosuppressant drugs, due to an increased risk of food poisoning. There can be an increase in appetite due to steroids, so weight gain should be monitored.

Long term aims are for the child to have a healthy balanced diet; however, 13% of transplanted children become obese (Hanevold *et al.*, 2005). The importance of healthy eating is stressed as the impact of CKD on cardiovascular health is high. A child with CKD has a 1000 times higher risk of cardiovascular death than the healthy age adjusted population (Foley *et al.*, 1998), so the importance of lifelong healthy living is paramount.

3.8.16 Neurology and the ketogenic diet

Camille Jankowski

One of the more common neurological disorders in childhood is epilepsy. Epilepsy is defined as a brain disorder in which normal brain function is disrupted by epileptic seizures (Fisher *et al.*, 2005). An epileptic seizure is the result of excessive and disorderly neurone activity in the brain (Fisher *et al.*, 2005). There are different types of epileptic seizures and an individual child may present with a variety of different seizures. Epilepsy is estimated to affect between 260 000 and 416 000 people in England and Wales (NICE, 2012).

Children with epilepsy will be under the care of a specialist paediatric neurology consultant and they may also have the support of a clinical epilepsy nurse. The majority of children will have their epilepsy successfully controlled through the use of antiepileptic drugs (NICE, 2012). Children whose seizures do not respond to antiepileptic drugs should be referred to a tertiary care centre for consideration of the use of the ketogenic diet under the care of a paediatric dietitian who specialises in it (NICE, 2012).

In 1921 it was reported that fasting patients with uncontrolled epilepsy could lead to an improvement in their seizure control (Freeman *et al.*, 2007). During starvation the body mobilises fat to produce ketone bodies and these can pass through the blood–brain barrier for the brain to use as an alternative energy source. As starvation is not a long term solution for patients with epilepsy, the ketogenic diet was developed to mimic the metabolic

effects of starvation (Freeman *et al.*, 2007). The aim of the high fat content and limited carbohydrate intake with this diet is to drive the process of ketogenesis so that ketone bodies will be the body's main source of energy.

The ketogenic diet can be used to treat a range of different types of epilepsy in patients of all ages. It has been noted to be more effective in certain epilepsies, such as severe myoclonic epilepsy of infancy, myoclonic atstatic epilepsy and tuberous sclerosis complex (Kossoff *et al.*, 2009). The ketogenic diet is a high fat diet, with controlled amounts of protein that meet requirements for growth and a limited amount of carbohydrate. Fat provides between 80% and 90% of the total energy (Zupec-Kania & Zupanc, 2008). Fat is mainly provided from foods, e.g. butter, cream and oil, enough protein for growth by, for example, poultry, fish and meat. The remaining energy is provided by carbohydrate from fruit and vegetables. Foods high in carbohydrate, e.g. bread, pasta and rice, are often not allowed in the diet (Zupec-Kania & Zupanc, 2008). The diet plan is usually based on three to four meals with snacks if required. There are currently four different types of the ketogenic diet.

Classical ketogenic diet

The classical ketogenic diet is based on long chain fats and a ratio system of fat to protein and carbohydrate combined. The main ratios used are 4:1 and 3:1; for every

4 or 3g of fat, there is 1g of protein and carbohydrate. The amount of protein is kept to a safe minimum for growth and development, and carbohydrate is limited to achieve the appropriate level of ketosis (Cross *et al.*, 2010). The classical ketogenic diet can be provided to patients who are enterally fed with the use of the enteral feed Ketocal (SHS Nutricia).

Medium chain triglyceride ketogenic diet

An alternative to the classical ketogenic diet is the medium chain triglyceride (MCT) ketogenic diet, where MCT is used as a fat source. MCTs are more effective at producing ketone bodies than long chain triglycerides, allowing more protein and carbohydrate to be consumed, thus improving palatability (Cross *et al.*, 2010).

Modified Atkins diet

The classical and MCT ketogenic diets are very restrictive and adherence is difficult in older children. A modified Atkins diet (MAD), which is similar to the classical ketogenic diet with a ratio of 1:1, can be successful (Hartman & Vining, 2007). The MAD enables the patient to consume more protein and carbohydrate, making it more appealing and easier to plan meals (Kossoff *et al.*, 2009).

Low glycaemic index diet

Low glycaemic index (GI) treatment was developed following the observation children on the ketogenic diet tended to have stable blood glucose levels, which may be a reason for its effectiveness (Kossoff *et al.*, 2009). It allows carbohydrate intake of up to 40–60g/day as long as the carbohydrate integrated into the diet has a GI of <50 (Kossoff *et al.*, 2009).

Monitoring

The ketogenic diet is not balanced and requires close monitoring by the specialist dietitian to ensure sufficient growth and nutritional adequacy. It is important that patients and parents are informed of the adverse effects of the diet, including constipation, vomiting, kidney stones, poor bone mineralisation and poor growth. The diet does not work for everyone and parents are asked to commit to a trial for 3 months while keeping a seizure diary. This information is used to determine diet effectiveness and the child's quality of life. Typically, a child stays on a ketogenic for 2 years. If after 2 years the family want to remain on the diet and the child is not experiencing any adverse effects, this should be supported with con-

tinued dietetic follow-up; such diets have been used for up to 12 years (Kossoff *et al.*, 2009).

Discontinuation

The child must be weaned slowly over a 2–3-month period as stopping suddenly can induce a life threatening seizure. The fat to protein and carbohydrate ratio is reduced from 4:1 to 3:1 to 2:1, and once ketosis stops, high carbohydrate foods can be reintroduced (Kossoff *et al.*, 2009).

Illness

If a child becomes unwell while on the ketogenic diet, the illness must be treated and this may mean the diet has to stop for a short period of time. If appetite is decreased and meals are not completely eaten, an emergency ketogenic milkshake can be given as a replacement.

3.8.17 Inherited metabolic disorders

Diana Webster

There are over 500 known inherited metabolic disorders (IMD) (Burton, 2005) and many are diagnosed in infancy

or early childhood. A significant proportion of those that affect carbohydrate, lipid or protein metabolism require

Table 3.8.23 Inherited metabolic disorders affecting carbohydrate, lipid and protein metabolism that require significant dietary treatment

Carbohydrate metabolism disorders	Lipid metabolism disorders	Protein metabolism disorders
Galactosaemia	Medium chain acyl-CoA dehydrogenase deficiency (MCADD)	Amino acid disorders: Phenylketonuria (PKU) Maple syrup urine disease (MSUD) Homocystinuria (HCU) Tyrosinaemia
Glycogen storage diseases (GSD)	Long chain acyl-CoA dehydrogenase deficiency (LCADD)	Urea cycle disorders: Ornithine transcarbamylase deficiency (OTC) Carbamyl phosphate synthase deficiency (CPS) Citrullinaemia Arginosuccinic aciduria (ASA) Arginase deficiency
Fructose-1,6-biphosphatase deficiency	Very long chain acyl-CoA dehydrogenase deficiency (VLCADD)	Organic acidaemias: Glutaric aciduria type 1 (GA1) Methylmalonic acidaemia (MMA) Propionic acidaemia (PA) Isovaleric acidaemia (IVA)
Hereditary fructose intolerance	Multiple acyl-CoA dehydrogenase deficiency (MADD) Carnitine transporter disorders Peroxisomal disorders Familial hypercholesterolaemia (FH)	

specialist dietetic support as a major part of their ongoing management (Table 3.8.23).

The majority of children with IMD will be seen in a tertiary level specialist children's hospital. However, some children may be seen in a district general hospital (DGH) with local shared care, based on a hub and spoke model. In tertiary care the patients will be under the care of a metabolic paediatrician as part of a specialist MDT. The IMDs that are most likely to be seen in a DGH are phenylketonuria (PKU) and medium chain acyl CoA dehydrogenase deficiency (MCADD). Both of these conditions can be identified by newborn (heel prick) blood spot screening, which is carried out on all newborn babies between days 5 and 8 of age. The aim of this screening is to diagnose these conditions early, so they can be treated quickly to prevent severe disability or, in the case of MCADD, even death. This test is performed irrespective of feeding times, gestational age and medical state. Expanded newborn screening is currently under discussion in the UK to include maple syrup urine disorder, homocystinuria, glutaric aciduria type 1, isovaleric acidaemia and long chain 3-hydroxyacyl CoA dehydrogenase deficiency.

The incidence of each inherited metabolic disorder is very low. For example, one of the commonest, PKU, has an incidence in the UK of 1 in 10000 live births. As a result, families with a child affected by an IMD can feel very isolated and often experience great difficulty in explaining the needs of their child's management to a wide range of people, including healthcare professionals, social services and educational establishments. Families are encouraged to become members of charities such as Children Living with Inherited Metabolic Disorders

(CLIMB) and the National Society for Phenylketonuria (NSPKU), which provide a wide range of resources.

The diagnosis of an IMD means some level of care will probably be needed for life, with the paediatric dietitian being a significant member of the care team for many years. The degree of disability for a particular child is extremely variable, depending on the particular condition and the severity of the individual genetic mutation. Some children will be able to lead a normal life, whereas others will be severely disabled or die at a young age.

Dietary management

At the time of diagnosis the paediatric dietitian will discuss information on the dietary management of the particular disorder, prescribe any essential dietary products, e.g. alternative infant formulae, and provide written information for the family. This will be followed by regular contact, on a daily basis at certain crisis times, to ensure the child is adhering to the diet and growing well. Contact with other members of the MDT, other health professionals and agencies, e.g. health visitor, home enteral tube feeding team, and education and social services will also be necessary. The child will be seen at all clinic visits and for an annual nutritional assessment. Biochemistry will be regularly monitored and abnormal results may indicate a need for dietary adjustments. For example, carers of a child with PKU will need to send a blood spot on the newborn blood spot card at regular intervals to the clinical biochemistry laboratory; twice weekly to monthly, dependent on the child's age and current level of control. If blood phenylalanine levels are out of the normal range

for age, it may be necessary for the dietitian to increase or decrease the phenylalanine content of the diet by adjusting the daily protein intake.

There are manufacturing companies that produce specialist dietary supplements and low protein foods used in the management of many of the IMDs. They are continually developing new products to make adherence to the diet more manageable. Protein substitutes are an essential component of the diet in the management of protein disorders for provision of adequate protein and other essential nutrients without the amino acid(s) affected by the particular disorder. Low protein prescribable foods, e.g. flour, pasta, egg replacer, milk, chocolate, biscuits, bread, dessert mixes, burger mixes, savoury snacks and cakes are an essential component of the management of a disorder of protein metabolism for the provision of energy and variety.

Emergency regimens

Children with some of the IMDs can become acutely unwell if they have an intercurrent infection. If not treated promptly, this can lead to metabolic decompensation, encephalopathy or possibly death. The treatment for any suspected intercurrent infection is usually to stop the usual diet and commence an emergency regimen for a period of 24–48 hours. The emergency regimen is based on a glucose polymer solution, which provides an exogenous supply of energy and prevents a catabolic response that could potentially become toxic. Each child requiring an emergency regimen should have written information from the dietitian and the parents are encouraged to carry this at all times. The concentration of the glucose polymer is age dependent and will be checked when the child comes to their outpatient visits to ensure it is still age appropriate and that the family still understands its importance. Preparation of emergency regimens when a

child is unwell at home can be extremely inaccurate and inappropriate volumes can be given (Gokmen-Ozel *et al.*, 2010). It is important that carers are taught how to prepare the drinks, and have relevant written information and in-date product available, which should be carried with them at all times. The children should be offered the drink when they are well so they remain familiar with the flavour. Palatability can be improved by the addition of commercial drinks to a specified recipe.

Professionals working with IMDs can gain support by becoming members of the British Inherited Metabolic Diseases Group (BIMDG) and Scientific Society for Inherited Errors of Metabolism (SSIEM). With improved screening and treatment, children with these disorders now have extended life expectancies and require dietetic management in adulthood (see Chapter 7.8).

3.8.18 Paediatric food hypersensitivity

Sarah Heath

It is estimated that 6–8% of children up to the age of 3 years are affected by food hypersensitivity, with one study showing the prevalence to be between 2.2% and 5.5% in the first year of life (Venter *et al.*, 2006). The most common hypersensitivities are to milk and egg. Children are much more likely to outgrow a food allergy than adults, with reported levels of tolerance development being 85–90% for milk by 3 years (Høst, 1994), and 66% to egg by 5 years (Boyano-Martínez *et al.*, 2002). Allergies to fish, shellfish and nut are more likely to persist into adult life, although some will still be outgrown.

Most simple paediatric food hypersensitivity will present and be managed in primary care; therefore, dietitians running general paediatric clinics are likely to be

involved in the management of some food hypersensitivity. Children with multiple food hypersensitivity or complex disease may be managed in secondary care or tertiary clinics.

Diagnosis in children is similar to that in adults and involves an allergy focused history in conjunction with tests such as skin prick or specific IgE testing, diagnostic exclusion diets or food challenges (NICE, 2011). Due to the likelihood of changes in food hypersensitivity status, children will need regular reviews. There are no specific guidelines, although in practice children under 5 years are likely to be reviewed every 6–12 months. Chapter 7.11.2 provides more information on both testing and food reintroduction.

Treatment

Currently the treatment of food hypersensitivity is avoidance of the offending food and treatment of reactions should they occur. A promising new area is oral immunotherapy. It involves giving very small doses of a food to which a child is hypersensitive and increasing this over a prolonged period of time. It should be noted that this is still in a fairly experimental stage and due to the possibility of severe reactions should only be used as part of an appropriate hospital led protocol.

Nutritional aspects

Children with food hypersensitivities do not have special nutritional requirements, but the impact of food exclusions can increase the risk of malnutrition. Diets that necessitate the avoidance of a whole food group (e.g. dairy foods), staple food items (e.g. wheat) or multiple foods will have the most impact. In addition, any child with other coexisting dietary restrictions, e.g. vegetarianism, cultural or religious restrictions, and fussy eating will be at a higher risk of deficiencies.

Where possible, replacement of nutrients lost through food exclusions should be managed by dietary manipulation initially. This is likely to include a combination of alternate normal foods as well as some specialist free from foods. Vitamin supplements should continue to be recommended as per Department of Health guidelines, see Appendix 3. This may be particularly important in cases where acceptance of hypoallergenic formula is poor. Other nutritional supplements may be necessary following dietetic assessment, e.g. calcium supplements for children with milk hypersensitivity. For cow's milk hypersensitivity, a suitable replacement will be essential where breastfeeding is not available. The following is a summary of the main points [see Chapter 7.11.2 and the World Allergy Organization DRACMA (Fiocchi *et al.*, 2010) guidelines for further details]:

- Non-breastfed infants and children under 2 years should be given a suitable infant formula as a main milk replacement:
 - An extensively hydrolysed or amino acid based formula is suitable for most infants.
 - Soya infant formula is not recommended for infants under 6 months except in a few circumstances (BDA, 2011). Care should also be taken to check for coexisting soya allergy.
 - When intake of infant formula is adequate, a ready made milk substitute could be used in cereals or cooking from 6 months.
- In children over 2 years of age a ready made milk may be suitable as a main milk replacement if the child has a good diet, this can include:
 - Alpro soya©, a product aimed at children over 1 year of age.
 - Calcium fortified versions of these milks should be encouraged (NB: organic brands are not fortified).

- Rice milk is not recommended for any child under 4.5 years due to the possible increased arsenic content (FSA, 2009).
- Most children with cow's milk allergy will also react to goat's and sheep's milk; therefore. these milks should not be recommended.

Dietary management

The main aspects of managing food exclusion are similar to those in adults. Chapter 7.11.2 provides an outline of allergen avoidance, food labelling and eating out. There are additional considerations when managing paediatric food exclusion and these include the following:

- *Other carers* – extended families, nurseries, child minders and schools may all be involved in food provision. They will require education and support to safely manage the child's diet whilst in their care, especially whilst the child is young and unable to understand their dietary restrictions.
- *Parties or playgroups* – in these situations food is often readily accessible to children who may not understand the need for restrictions. Advising parents on practical ways of managing these situations can help maintain a good quality of life for both the parent and child.
- *Specialist free from foods* can play an important role in maintaining a varied diet whilst allowing children to eat a similar diet to their peers. Advice on suitable products should be made available to parents, taking into account factors such as cost and nutritional adequacy of the foods, e.g. salt content, as well as considering other less specialist alternatives.

Weaning

The weaning period is a time of nutritional risk as infants move from formula or breast milk onto solids. Parental anxiety around managing food hypersensitivities can, in some situations, lead to delayed or restricted weaning. Dietetic advice, including written supporting information, can help to ensure that the infant meets their nutritional needs as well as developing age appropriate eating skills. Parents will need to be advised on which foods they can safely introduce to their child's diet; in some situations, testing may support this. It should be noted that whilst it is important to avoid foods a child is known or suspected to be sensitive to, there is no evidence that delaying weaning or the introduction of specific foods will prevent food hypersensitivities developing (Agostoni *et al.*, 2008).

Adolescence

Older children should be encouraged to become gradually more involved in their dietary management and use of emergency medications. As with many chronic conditions, the teenage years may be particularly challenging with regards to compliance and more input may be required from the team at this stage.

3.8.19 Paediatric human immunodeficiency virus

Lisa Cooke

There are approximately 1500 children with human immunodeficiency virus (HIV) in the UK [Collaborative HIV Paediatric Study (CHIPS), 2011]. Most children are of sub-Saharan descent and have acquired the virus from mother to child transmission. The majority of children living with HIV in the UK live in and around central London and are cared for in three major centres: Great Ormond Street Hospital for Sick Children, St Mary's, and St George's. These three hospitals form the hub centres for the hub and spoke network of care for children around the rest of the UK [the Children's HIV National Network (CHINN)]. Smaller numbers of patients are seen within the spoke areas of the network within a defined radius surrounding their locality. Each team caring for these children should consist of a paediatrician, (usually an immunology specialist), specialist nurse, dietitian, psychologist, social worker and pharmacist.

There is still much stigma attached to this condition and this brings challenges to its management. In the majority of cases family members also have HIV and the mothers of these children often carry much guilt from the fact they have infected their child. Due to an excellent antenatal screening pathway now in place, there is <1% transmission of the virus from mother to child within the UK.

Dietetic management

Since the introduction of highly active antiretroviral therapy (HAART) treatment in the late 1990s, all children, if well managed, should live a full and physically active life. Some of the medications can have gastrointestinal side effects, e.g. nausea. For long term health and wellbeing it is essential that they do not miss a dose of medica-

tion as the HIV virus can become resistant to the drugs. The main dietetic interventions centre on supporting a healthy lifestyle and diet, avoidance of being over- or under-weight and careful management of lipidaemia.

HIV affects blood cholesterol levels, which are often naturally higher in individuals with the condition. Certain antiretroviral drugs can also raise blood lipid levels. The mini DHIVA (Paediatric Dietitians working in HIV) arm of DHIVA have developed a lipid algorithm to support lipid management. This has been accepted by the Children's HIV Association (CHIVA, www.chiva.org.uk) and is available on their website. Mini DHIVA has also produced an annual assessment form that all paediatric dietitians working in HIV are encouraged to use with their patients. This can also be found at CHIVA.

Many children are from black and ethnic minority groups and due to the high latitude of the UK, vitamin D status is often poor. Levels of this vitamin should be measured and supplementation prescribed. CHIVA have developed prescribing guidelines that are available on its website (www.chiva.org.uk).

The aims of the dietetic intervention are to:

- Monitor growth and development, optimising it where necessary. Awareness of clinical condition, past medical history, parental heights and current treatment status is necessary to inform the child's predicted growth.
- Measure mid upper arm circumference (MUAC) and waist measurement.
- Assess serum lipid levels, CD₄% (cell count), renal function, vitamin D levels, blood pressure and insulin levels.
- Assess diet using dietary recall and be guided by the annual assessment form.

- Focus on a cardioprotective style diet.
- As this is a chronic condition aim for behavioural change management throughout the child's life.

It is vitally important that the dietitian is an integrated member of the MDT and is aware of the child's knowledge of their condition through close working with this team. Due to the stigma surrounding the condition, it is important that disclosure of the diagnosis is done slowly, age appropriately and fully supported by the parents, within the MDT and supported by all members.

Many children will eat a traditional diet at home. Therefore, a good knowledge of the sub-Saharan African diets is essential (see Chapter 3.5 and Chapter 7.11.3).

3.8.20 Paediatric diabetes

Shelley Easter and Natalie Mohamdee

The incidence of childhood type 1 and type 2 diabetes is increasing (Ma & Chan, 2009). The current estimate of prevalence of type 1 diabetes in children in the UK is 1 per 700–1000. Prevalence figures for children with type 2 diabetes are limited, but as many as 1400 children may have this diagnosis in the UK (Diabetes UK, 2010).

A recent Department of Health (2011/12) guidance document has outlined best practice in caring for children with diabetes. A child should be offered four multi-disciplinary clinics per year, one of which should be an annual review clinic. There should be eight additional support sessions (which can be by phone) of 15 minutes each by any team member. The annual review clinic should include a dietary assessment and other clinical investigations, including thyroid function, retinopathy screening, microalbuminaemia and blood pressure from the age of 12 years (NICE, 2004).

To ensure that the special needs of children and young people with diabetes are met, the MDT based in secondary care should include a paediatrician, diabetes specialist nurse and paediatric dietitian. Access to a psychologist and social worker should be available. Parents of young children should be actively involved, as well as other carers: school, nursery, child minders, etc. (Department of Health, 2001; Smart *et al.*, 2009; SIGN, 2001; NICE, 2004). For each clinic visit the child or young person's weight and height should be measured and plotted on the appropriate growth chart, along with calculating and plotting BMI. This will help identify normal growth and/or any significant changes in weight as these may reflect changes in glycaemic control (NICE, 2004).

The dietitian's role is to balance the necessity of strict glycaemic control with the family diet and to convert

scientific theory about food into practical and sensible advice (Couper & Donaghue, 2009). The aims of dietetic management are to:

- Provide an appropriate energy intake for optimal growth, BMI and health.
- Encourage lifelong healthy eating habits, which preserve social, cultural and psychological wellbeing.
- Achieve a balance between food intake, requirements and insulin profiles to obtain optimal control.
- Achieve lipid levels in a desirable range.
- Prevent and treat acute complications of diabetes: hypoglycaemia, illness and exercise.
- Reduce the risk of micro- and macro-vascular complications.

Type 1 diabetes mellitus

There is a preference for intensive insulin regimens, such as multiple daily injections or pump therapy, where education on matching insulin to desired carbohydrate intake is required. Such regimens allow maximum flexibility of food choices. An individual insulin to carbohydrate ratio allows the adjustment of the premeal insulin according to the estimated carbohydrate content of the meal or snack. Visual resources can be very useful when educating the family on carbohydrate counting, especially if mathematical skills are not strong or a bolus advisor or expert meter is not used. *Carbs and Cals* (Cheyette & Balolia, 2013) is a visual guide to carbohydrate and calorie counting and a useful teaching aid.

Conventional therapy may still be used, if this is the best treatment option for the family. Twice daily insulin

injections are given, which contain a mix of short and long acting insulin. This therapy requires a day to day consistency in carbohydrate intake to prevent hypoglycaemia during periods of hyperinsulinaemia. Snacks are required and particular attention should be paid to the energy profile of meals and snacks to prevent excessive weight gain.

Type 2 diabetes mellitus

Type 2 diabetes is increasingly recognised in children. It is more prevalent in the developed world where there is an increased prevalence of childhood obesity.

Features associated with the diagnosis are (Couper & Donaghue, 2009):

- Obesity.
- Age >10 years.
- Strong family history of type 2 diabetes.
- Acanthosis nigricans – a brown/black velvety hyperpigmentation of the skin.
- High risk racial or ethnic group.
- Undetectable pancreatic autoantibodies.
- Normal to high C-peptide levels.

Aims of nutritional management are to prevent acute and chronic complications by achieving normoglycaemia, and addressing the child's weight in those with a BMI greater than the 95th percentile and any comorbidities, such as dyslipidaemia. The family should be involved in lifestyle changes and encourage the parents should be encouraged to act as positive role models. Oral antidiabetic agents to reduce glucose absorption, increase insulin secretion and action, and reduce gluconeogenesis and/or insulin may be used. Regular follow-up with monitoring of weight, glycaemic control and treatment is essential.

Other nutritional considerations

Type 1 diabetes is an autoimmune condition; therefore, there is an increased risk of other autoimmune conditions. Coeliac disease occurs in 1–10% of children with diabetes (Smart *et al.*, 2009). All newly diagnosed children should be screened for coeliac disease. Further screening is no longer included in guidance documents (NICE, 2004), but many centres will screen for coeliac disease in the annual review clinic. The gluten free diet is the only accepted treatment. It is common for those with diabetes who develop coeliac disease not to adhere to the gluten free diet, as they may be asymptomatic and dietary manipulation for both disease states is difficult. These children and their families will require additional dietetic support, with realistic, family centred advice.

Health professionals should be aware that children and young people with type 1 diabetes, in particular young women, have an increased risk of eating disorders. Those in whom eating disorders are identified should be offered joint management involving their diabetes care team and child mental health professionals (NICE, 2004).

Age group specific advice

Infant and toddlers

Breastfeeding to 12 months should be encouraged alongside a healthy weaning diet, which encourages a variety of tastes, colours and textures of foods. Frequent, small meals may promote better glycaemic control, depending on the insulin regimen, and may also avoid food refusal. Insulin pump therapy has been shown to be effective when difficulties arise with food refusal. Parental anxiety is common; consideration of this is a priority when deciding upon the insulin regimen.

School children

The diabetes regimen should fit into the school day. Advice should be given on food portion size, healthy food choices, low fat snacks, reduced fat dairy products and physical activity to reduce the risk of inappropriate weight gain and cardiovascular disease. Sleepovers, parties and trips away from home should be discussed. Continuing diabetes nutritional education with the child and family, including problem solving techniques, may be useful.

Adolescents

Lifestyle advice, support and education targeted towards the teenager are required as the teenager starts to take over their diabetes management. Focused surveillance of weight monitoring is also required, as excessive weight gain may be associated with attempts to obtain excellent glycaemic control; weight loss or poor weight gain may be a sign of insufficient intake, inappropriate insulin administration, disordered eating and/or poor glycaemic control. Careful review of insulin dose, food intake and activity is advisable and the association between weight loss or failure to gain weight and disordered eating needs to be recognised. Rebellion, binges and erratic eating behaviour may require psychological support and counselling. Going out with peers, parties or holidays and a healthy lifestyle need to be discussed. Advice on the safe consumption of alcohol and its prolonged glycaemic effect should be discussed, along with advice on increased appetite with alcohol, and information given on the nutritional content of takeaways and shop bought foods. Careful planning of exercise and sport should be encouraged. Young people may wish to be seen alone or in small intervention groups that provide a forum for support and guidance, which can lead to improvement in knowledge, self care and blood glucose control. The planned transfer of care of young people from paediatric to adult services promotes diabetes self care and improves outcomes (Department of Health, 2001) (see Chapter 7.12).

3.8.21 Cardiology

Philippa Wright

Congenital heart disease (CHD) describes defects in the structure of the heart that are present at birth. It affects 1 in every 145 births (www.BHF.org.uk) and there are a number of associated genetic syndromes, e.g. Down's syndrome. Children with CHD are usually of normal weight for gestational age at birth but are particularly vulnerable to malnutrition due to a combination of severe fluid restriction, inefficient absorption of nutrients and high metabolic demands (Avitzur *et al.*, 2003) (Table 3.8.24).

Children are looked after in designated children's cardiac centres, with shared care arrangements with their local district general hospitals and community, both pre- and post-operatively.

Physiology

Congenital heart disease is defined according to its haemodynamic effects, which fall into two groups; cyanotic and acyanotic. These types of cardiac malformations can have an effect upon outcomes regarding growth and nutritional intake. Cyanosis refers to a reduced level of oxygen in the blood and cyanotic lesions have been found to cause the greatest degree of stunting (Jacobs *et al.*, 2000). The acyanotic group of lesions can be further divided into obstructive malformations and left to right shunt malformations. These lesions have been observed to affect weight rather than height, especially in the presence of pulmonary hypertension (Mehziri & Drash, 1962;

Umansky & Hauck, 1962). In this situation blood is pumped to the lungs under greater pressure, preventing effective oxygenation. As a result the heart pumps faster and the child's breathing increases in an attempt to improve oxygenation. This ultimately increases the child's energy requirements and results in weight loss.

For detailed descriptions of all cardiac lesions, see the British Heart Foundation website (www.BHF.org.uk).

Congestive heart failure

Congestive heart failure (CHF) is the main concern in children with CHD. It occurs when the heart can no longer meet the metabolic demands of the body. Signs include tachycardia, fatigue on feeding and early satiety, all resulting in growth faltering. Diuretic therapy relieves CHF but commonly used diuretics can cause sodium, potassium, chloride and calcium losses. While losses can be replaced, it is important to note that persistent hyponatraemia can result in poor growth and must be corrected.

Anaemia can also mimic the signs of CHF; cyanotic children can have higher iron requirements as they have an increased red cell mass. These infants should be screened for iron deficiency using ferritin, red cell indices and total iron binding saturation, as haemoglobin may be within normal range even though the patient is iron deficient (Premer & Georgieff, 1999).

Table 3.8.24 Factors that may influence the development of malnutrition and growth failure in infants with congenital heart disease (Nydegger & Bines, 2006)

Causative factors	Physiological impact
Type and clinical impact of cardiac disease	Cyanotic versus acyanotic defects Shunts Congestive heart failure Operative status: age at surgery, type of surgery, complications
Disturbances in energy metabolism	Increased energy expenditure: Cardiac hypertrophy Abnormalities in body composition Increased sympathetic nervous system activity Increased haematopoietic tissue Increased basal temperature Recurrent infections Pharmacological agents
Decreased nutritional intake	Anorexia, early satiety Pharmacological agents Decreased gastric volume caused by hepatomegaly
Disturbances in gastrointestinal function	Malabsorption: Oedema and chronic hypoxia of the gut Interference with drugs Compressive hepatomegaly Decreased gastric volume Increased gastro-oesophageal reflux
Prenatal factors	Chromosomal disorders Intrauterine factors Birth weight

Mechanisms of malnutrition in congenital heart disease

Malnutrition can be caused by fluid restriction, poor absorption and fatigue on feeding, causing a reduced total intake, gastro-oesophageal reflux disease, increased metabolic expenditure, early satiety, anorexia and frequent infections. Energy for growth is diverted to meet the child's increased metabolic demands. Studies give a range of energy requirements from 120 to 170 kcal/kg/day (Yahav *et al.*, 1985; Unger *et al.*, 1992; Barton *et al.*, 1994; Ackerman *et al.*, 1998; Waterlow, 1992). To facilitate weight gain it is therefore advisable to first aim for 120 kcal/kg and to increase this if weight gain is not achieved (Lawson & Shaw, 2001).

Surgery

After surgery children will be admitted to the paediatric intensive care unit (PICU). Postoperative requirements have been shown to be much lower than previously thought, especially in the immediate postoperative ventilated patient. No difference has been observed between cyanotic and acyanotic lesions; the only statistical difference was for those children requiring cardiopulmonary bypass. The non-bypass group appears to need less energy than the bypass group. This could be related to inflammatory response to bypass, but further studies are needed (De Wit *et al.*, 2010).

When calculating requirements in the immediately postoperative ventilated cardiac child, it is important to understand the amount of sedation, paralysis and ventila-

tory support they are receiving. The Schofield equation is currently used to calculate postsurgical requirements; however, the addition of a stress factor of 20% relates to calorimetry findings (Jackson, 2000).

Postoperative weight gain

After discharge from the PICU the growth faltering child may need to return to preoperative requirements until catch-up growth has been facilitated. Enhanced energy content feeds and, in some cases, nasogastric or gastrostomy feeds may be necessary to maintain the patient's growth pre- and post-operatively. If fluid is restricted, then high energy formula or fortified expressed breast milk will be required. Breast milk can be fortified using commercially available fortifiers or by adding 3–5% of standard infant powdered formula. If breast milk is not available, then the following high energy formulae are available:

- SMA High Energy: 91 kcal/100 mL (2 g/100 mL).
- Infatrini: 100 kcal/100 mL (2.6 g protein/100 mL).
- Similac High Energy: 101 kcal/100 mL (2.6 g protein/100 mL).

If weight gain is still not achieved once 150 kcal/kg is provided, then additional energy can be given through the addition of a glucose and fat polymer. The protein to energy ratio of 9–14% must be preserved (Jackson, 2000; Wharton, 1994). However, the 24-hour urinary sodium balance should be measured if weight continues to falter. As these infants are often fluid restricted, which ultimately impacts on energy intake, it is important to ask the

medical team if an increase of fluids is possible in order to increase nutritional intake.

Feed administration

The method of feed administration is important and the following steps should be employed, if required, in order to meet the child's dietary requirements for growth or catch-up:

- Offer smaller volumes and more frequent feeds orally.
- Give unfinished feeds via a NG tube if required.
- Give small frequent bolus feeds via a NG tube.
- Give overnight continuous feeds via an enteral feeding pump in addition to small frequent daytime feeds (always refer to local policies and guidelines when advising overnight tube feeding).
- Give feeds continuously over 20 hours via a feeding pump, allowing the gut time to rest and pH to return to normal.

Anthropometry

Anthropometric data is essential and accurate weights must be recorded on growth charts (syndrome specific charts should be used where appropriate) from the point of referral. Be aware that fluctuating fluid balances can mislead weight records so patients at risk may have daily weights recorded.

Expected weight gain

Expected weight gain values are difficult to achieve in children with CHD; therefore, an average gain of 10–20g/day would be more appropriate in children under 6 months and 120–210g/week in children aged 6–12 months (17–30g/day) (Forchielli *et al.*, 1994).

Complications

Complications that can occur after surgery include:

- *Chylothorax* – the accumulation of chyle in the pleural space. Conservative management involves the reduction of long chain fats (Chan *et al.*, 2005) to <1g per year of life to a maximum of 5g/day.
- *Protein losing enteropathy* – there is limited evidence regarding specific diet therapy; however, it is suggested that the diet should consist of 5–10g/day of fat and be high in protein, with additional fat replaced with a medium chain fat source to improve overall energy intake (Shaw & Lawson, 2007).
- *Necrotising enterocolitis (NEC)* – specific lesions and surgeries may increase the risk of NEC in the child with

CHD. Reduced gut perfusion can occur and the patient will require extremely slow reintroduction of feeds in conjunction with parenteral nutrition if considered at risk.

3.8.22 Paediatric cancers

Nicola Williams

Approximately 1500 children are diagnosed with cancer in the UK every year. Survival of childhood cancer has

more than doubled since the 1960s with survival now in about 70% of those affected (Children with Cancer UK,

Table 3.8.25 Relative contributions of main diagnostic groups of childhood cancer to overall incidence among children aged 0–14 years (*National Registry of Childhood Tumours*, <http://www.ccrq.ox.ac.uk/datasets/registrations.shtml>)

Type of cancer	%
Leukaemia	31
Central nervous system	25
Lymphoma	10
Soft tissue sarcoma	7
Neuroblastoma	6
Renal	6
Bone	4
Retinoblastoma	3
Germ cell	3
Liver	1
Other carcinomas and melanomas	
Other	

www.childrenwithcancer.org.uk; The Children's Cancer and Leukaemia Group, www.cclg.org.uk). Cancer in children differs from that in adults in terms of the body areas affected and how it responds to treatment. Table 3.8.25 shows the types of cancer seen in children (*National Registry of Childhood Tumours*, <http://www.ccrq.ox.ac.uk/datasets/registrations.shtml>). Depending on the type of cancer diagnosed, treatment will usually comprise of chemotherapy with or without surgery and/or radiotherapy.

Nutritional implications

Nutrition support is a key part of supportive care for children with cancer to ensure normal growth and development. Children may present malnourished or cachexic at diagnosis; in addition treatment side effects impact on nutritional status. It is recognised that good nutrition may reduce treatment complications and infection rates, and improve response to intensive anticancer treatments (NICE, 2005; RCN, 2010). Table 3.8.26 shows the types of childhood cancers associated with high or low nutritional risk (Shaw & Lawson, 2007).

Dietetic management

Nutritional assessment

There is no specific nutrition screening tool for children with cancer, although a diagnostic tool for malnutrition in these children has been designed to use alongside the Screening Tool for the Assessment of Malnutrition in Paediatrics (STAMP) (McCarthy *et al.*, 2012). For further information see the Royal College of Nursing (2010).

Nutrition support

Management is determined by nutritional risk of diagnosis, nutritional status, symptoms and anticipated gut func-

Table 3.8.26 Types of childhood cancers associated with high or low nutritional risk (source: Shaw & Lawson 2007, table 22.3, p. 466. Reproduced with permission of Blackwell Publishing)

High nutritional risk diagnoses	Low nutritional risk diagnoses
Advanced diseases during initial intense treatment	Acute lymphoblastic leukaemia (graded low risk)
Stages III and IV Wilms' tumour and unfavourable histology Wilms' tumour	Non-metastatic solid tumours
Stages III and IV neuroblastoma	Advanced diseases in remission during maintenance treatment
Ewing's sarcoma	
Pelvic rhabdomyosarcoma	
Some non-Hodgkin's lymphoma	
Multiple relapse leukaemia	
Acute lymphoblastic leukaemia (graded high risk)	
Medulloblastoma	

tion. Symptoms relating to treatment that may impact upon nutritional status include infection, diarrhoea, nausea and vomiting, mucositis, anorexia, xerostomia and constipation.

Oral nutritional support may be adequate when nutritional status is stable, but intake is reduced. If nutritional status deteriorates, enteral tube feeding should be started early to prevent a further decline in weight and health. Parenteral nutrition is reserved for when gut function is compromised for >5 days. Whole protein feeds are usually the first choice; however, during treatment causing severe gastrointestinal toxicity, a hydrolysate or elemental feed is recommended.

Monitoring and follow-up

The child's tolerance to nutritional support may change significantly depending on the type of anticancer therapy they receive. Frequent monitoring of the feeding regimen and anthropometry will ensure nutritional requirements for normal growth continue to be achieved. As treatment reduces in intensity (called maintenance chemotherapy) or is completed, nutritional support can be weaned, with the aim to progress towards a balanced diet (see Chapter 7.15).

3.8.23 Paediatric haematopoietic stem cell and bone marrow transplantation

Zoe Hull

Bone marrow transplantation (BMT) [more accurately known as haematopoietic stem cell transplantation (HSCT)] is a highly intensive, life saving therapy available to treat malignant and non-malignant diseases of the bone marrow. High doses of chemotherapy and radiotherapy are given to improve the chances of curing the malignant disease, particularly for cancers with a high risk of relapse. For non-malignant disease, the poorly functioning bone marrow is removed and replaced with stem cells of normal function (Kline, 2006). However, the resulting toxicities and complications, including severe immune suppression, predispose a child to malnutrition (see Chapter 7.15.8). Mortality rates are much improved and more children are surviving transplantation as a consequence of improved donor or recipient matching and supportive care. The role of the dietitian is to help maintain nutritional status before, during and after the transplant, and to maximise quality of life and growth (Ward, 2007).

Transplant procedure

In the UK there are 16 specialist paediatric units where transplantation is carried out (British Society of Blood and Bone Marrow Transplantation, <http://bsbmt.org/>). The main types of transplant are:

- *Autologous* – the child's own marrow or stem cells are frozen (cryopreserved) and returned after treatment with high dose chemotherapy (stem cell rescue).
- *Allogenic* – the child receives donor marrow or stem cells, ideally from a sibling or close relative to enable a close tissue type match. This is a more complicated, high toxicity procedure with a longer recovery period.
- *Syngeneic* – marrow or stem cells are donated from an identical twin, enabling a perfect genetic match and reduced toxicities.

Prior to admission, stem cells are collected from the bone marrow or peripheral blood, or umbilical cord blood donation is used (Lipkin *et al.*, 2005). After admission high dose chemotherapy with or without total body irradiation (TBI) destroys the remaining cancer cells and the marrow and immune system. The child becomes sick and profoundly immune suppressed. The stem cells are returned to the child intravenously and they are isolated

for 5–6 weeks to monitor side effects and recovery until they produce new blood cells (engraftment).

Dietetic management

The transplant process can cause severe oral and gastrointestinal toxicity. The majority of children require nutritional support (Muscaritoli *et al.*, 2002). Side effects leading to compromised nutritional status include:

- Prolonged anorexia.
- Mucositis.
- Nausea and vomiting.
- Diarrhoea and abdominal cramping.
- Malabsorption.
- Bacterial and viral infections
- Prolonged taste changes.
- Xerostomia.
- Gastroparesis.
- Acute and chronic graft versus host disease (GvHD).
- Hyperglycaemia as a result of steroid treatment.
- Fatigue.
- Depression.
- Neutropenia (low level or absent neutrophil count).
- Food aversions.

Children may have increased metabolic requirements resulting from infection, protein losing enteropathy, GvHD or veno-occlusive disease of the liver (Kline, 2006). Enteral nutrition via nasogastric, nasojejunal and gastrostomy feeding is preferred using a semi elemental or elemental feed to protect the gut and aid tolerance during periods of gastrointestinal mucositis (Ward, 2007). Temporary gastrointestinal failure is common and if enteral feeding is not successful, parenteral nutrition is (Murray & Pinderia, 2009). Advice should be given to minimise the risk of food borne illness and gastrointestinal infection while the child is immunosuppressed. A low microbial diet is recommended and all food must be prepared and cooked safely Yokoe *et al.*, 2009). The degree of dietary restriction and duration that must be followed differs between specialist centres.

3.8.24 Nutrition support in the critically ill child

Luise Marino and Rosan Meyer

During the last few decades, advances in anaesthetic and intensive care have improved outcomes in critical illness (Rittirsch *et al.*, 2008). On average 0.1% of the childhood population in England and Wales is admitted to a paediatric intensive care unit (PICU) per annum, of whom 50% are under 1 year of age. The mean stay is between 1 and 2 days (range 1–35 days) (Parslow *et al.*, 2009). Sixty per cent of admissions are a result of unplanned emergencies, including neurological injuries, cardiac disorders and respiratory distress (O'Donnell *et al.*, 2010). Although this represents only a small number of children admitted for a short period of time for a variety of diagnoses, undernutrition is common (Hulst *et al.*, 2004a,b), which impacts on morbidity, mortality and therefore length of stay in hospital (Goiburu *et al.*, 2006; Kyle *et al.*, 2005; Coss-Bu *et al.*, 2001). It is important to ensure optimal nutritional support from admission to discharge based on anthropometrical and biochemical parameters, clinical assessment and previous dietary intake.

Determining a nutrition care plan

Anthropometry

The rate of acute or chronic malnutrition within the PICU is between 24% and 55% (Delgado *et al.*, 2008). The causes of malnutrition are multifactorial and include pre-morbid disease, e.g. cystic fibrosis, congenital heart disease, acute or chronic suboptimal nutritional support in addition to increased protein breakdown and reduced protein synthesis, especially in the acute phase of an illness (Hulst *et al.*, 2006a). Every child should be weighed on admission to calculate their energy and protein requirements. The clinical condition must be considered as some children are too unstable to be weighed and weight may also be inaccurate due to oedema, ascites or tumour masses. It is usually impossible to perform an accurate length measurement (Feferbaum *et al.*, 2009). It is useful to consult the child's growth chart in their Per-

sonal Child Health Record to give an insight into how well they have been growing and whether they are at risk of malnutrition on admission (Shaw & Lawson, 2007).

Biochemistry

Biochemical abnormalities are common in critically ill children and may impact on nutritional support. The most important indices to consider include serum urea, glucose, albumin, C-reactive protein, magnesium, calcium, phosphorus, selenium, zinc, manganese and lactate acidosis. It is essential to refer to Clinical Paediatric Dietetics (Shaw & Lawson, 2007) as biochemistry, and abnormalities in children will differ from those in adults (Table 3.8.27).

Clinical factors

Critical illness can have a profound impact, resulting in increased glucose synthesis, protein breakdown, fat oxidation and the risk of metabolic derangement (Hulst *et al.*, 2006b). A nutritional assessment should take into account these factors and others, including the impact ascites or oedema may have on actual weight and/or enteral feeding tolerance, in addition to protein and energy requirements relative to wound healing.

Dietary intake

Children and infants have significantly less fat and protein stores compared with adults and are unable to tolerate prolonged periods of starvation, e.g. 3–5 days or longer. In addition, the need to support continued growth and development is important, and nutritional support should be started as soon as possible (Skillman & Wischmeyer, 2008). There are many challenges within a PICU setting that impact on the actual delivery of nutrients (Feferbaum *et al.*, 2009; Hulst *et al.*, 2006b):

Table 3.8.27 Relevance of biochemical indices in critical illness

Biochemical index	Comment
Serum urea	Indicative of catabolism and protein breakdown associated with trauma, impaired renal function, dehydration, polyuria or severe sweating impacting on fluid management (Hulst <i>et al.</i> , 2006b) Although linked with muscle mass, it is not a reliable marker to assess nutritional support
Glucose	Debatable as to whether it has a positive impact on outcome, decreasing morbidity and mortality Important to monitor, especially in children receiving IV preparations and PN (Skillman & Wischmeyer, 2008)
Albumin	Likely to be low especially if receiving intravenous saline (McClave <i>et al.</i> , 1999) Not a good nutritional index, due to long half life. A marker of inflammation, intravascular or extravascular fluid shifts and catabolism (Evans <i>et al.</i> , 2006)
C-reactive protein (CRP)	An index of the acute phase response, usually measured serially Serum prealbumin and CRP are inversely related, i.e. serum prealbumin levels decrease and CRP levels increase in proportion to the severity of illness, returning to normal once the illness has resolved, e.g. <0.5 mg/mL In infants, <0.2 mg/mL associated with a return of anabolism, with a concomitant rise in prealbumin (van Waardenburg <i>et al.</i> , 2009)
Magnesium	Hypomagnesaemia is commonly found in critically ill children (Braegger <i>et al.</i> , 2010)
Calcium	Strongly associated with hypokalaemia and hypocalcaemia (Hulst <i>et al.</i> , 2006b)
Phosphorus, selenium, zinc, manganese	Hypophosphataemia (up to 61% of critically ill children) (Santana e Meneses <i>et al.</i> , 2009) Low serum levels of selenium, zinc and manganese are also commonly found in critical illnesses (Hulst <i>et al.</i> , 2006b)
Lactate acidosis	Common in critically ill children, reflecting hypoperfusion, including diabetic ketoacidosis, septic shock and cardiogenic shock (Zamberlan <i>et al.</i> , 2011) Lactic acidosis, base excess and a strong anion gap are associated with increased risk of death (Zamberlan <i>et al.</i> , 2011) A level >2 mmol/L may be used as a crude proxy for cell function. Resolution correlates with survival (Zamberlan <i>et al.</i> , 2011)

PN, parenteral nutrition.

- **Fluid volume restriction** is the main barrier to adequate nutrition delivery (Feferbaum *et al.*, 2011).
- **Procedural interruptions** can account for 11–57% of total interruptions and affect up to 62% of patients (McClave *et al.*, 1999). Often, feeding rates are not increased to compensate for time lost during the interruption, making it challenging to achieve nutrition goals (Feferbaum *et al.*, 2011) and resulting in large energy and protein deficits which negatively impact on weight (Hulst *et al.*, 2004a).
- **Interruption due to gastrointestinal intolerance**, especially where there is vomiting, diarrhoea, large gastric residuals and abdominal distension, may occur in up to 57% of patients.
- **Mechanical problems** such as nasojejun tube dislodgement, nasogastric tube blockage and/or enteral feeding pump dysfunction can impact on the amount of feed delivered (Feferbaum *et al.*, 2009).

There is little published data on energy or protein requirements in critically ill children. Table 3.8.28 summarises some recommendations.

Type of feed

Ready to use paediatric specific enteral or infant feeds should be used to decrease the risk of bacterial contami-

nation. The use of energy and nutrient dense infant formulae have been especially useful in critically ill infants (<1 year) (Evans *et al.*, 2006) where there are fluid restrictions, thus improving energy and nitrogen balance (van Waardenburg *et al.*, 2009).

Polymeric fibre containing feeds are appropriate for the majority of critically ill children and are associated with fewer episodes of diarrhoea. A 1 kcal/mL feed will meet the requirements of most children, but where there is fluid restriction, a 1.5 kcal/mL feed may be more appropriate. A small minority of patients with malabsorption syndromes will require hydrolysed, elemental feeds and/or specialist feeds when indicated (Braegger *et al.*, 2010).

Initiation of enteral feeds

Most centres aim to start feeds within 12–24 hours of admission (Briassoulis *et al.*, 2001; Meyer *et al.*, 2009) with the aim of achieving the goal rate as soon as possible (Zamberlan *et al.*, 2011). Early enteral feeds, using a stepwise approach, i.e. feeding algorithms or protocols, is well tolerated in critically ill children and is associated with improved nutritional outcome (Skillman & Wischmeyer, 2008; Briassoulis *et al.*, 2001; Meyer *et al.*, 2009). Most children should tolerate nasogastric tube

Table 3.8.28 Recommendations for energy and protein requirements of critically ill children

	Recommendations
Energy requirements	70% EAR – no evidence (Meyer <i>et al.</i> , 2009) Schofield equation – without stress addition or activity factor, shown to deliver the closest value to measured REE (Hulst <i>et al.</i> , 2006, Briassoulis <i>et al.</i> , 2001; Mehta & Compher, 2009; Oosterveld <i>et al.</i> , 2006) In long term PICU patients (>7 days), especially where not using muscle relaxants and where there is active physiotherapy, a higher calorie intake may be required (van der Kuip <i>et al.</i> , 2007) Ventilated children can be overfed, especially if liberalising fluid volumes. Overfeeding can result in fatty liver, hyperglycaemia, increased CO ₂ production and increased length of hospital stay (Skillman & Wischmeyer, 2008)
Protein requirements	0–2 years, 2–3 g/kg/day 2–13 years, 1.5–2 g/kg/day 13–18 years, 1.5 g/kg/day (Mehta <i>et al.</i> , 2009) 4 g/kg should not be exceeded (excluding for extremely low birth weight preterm infants) as increases the risk of hypertonic dehydration and exceeds maximal protein oxidation rates (Klein <i>et al.</i> , 1998)
Glucose oxidation rate	5 mg/min/kg/day (7.2 g/kg/day) – maximal oxidation rate Excessive glucose intake will increase risk of hepatic steatosis (fatty liver) and CO ₂ production Amounts will vary for critically ill neonates and infants (Koletzko <i>et al.</i> , 2005)
Feed composition	10–15% energy from protein (Clarke <i>et al.</i> , 2007) 50–55% energy from carbohydrate 35% energy from fat (Flaring & Finkel, 2009)

REE, resting energy expenditure.

feeding, but there will be cohort of patients for whom a nasojejunal feeding tube is indicated, i.e. feed intolerances with nasogastric tube feeding, or at higher risk of aspiration (Mehta *et al.*, 2009; Braegger *et al.*, 2010). Although bolus feeding is more physiological, continuous feeds delivered via a volumetric pump may be better tolerated as they have less impact on clinical indices such as hyperglycaemia, although the research in this area is limited and not unequivocal, with some reports showing no difference between tolerance, e.g. diarrhoea and vomiting (Horn & Chaboyer, 2003).

Refeeding syndrome

As the prevalence of malnutrition within the PICU population is high, the risk for refeeding syndrome should be considered. When enteral or parenteral nutrition is commenced in children who have not received optimal nutritional support for some time, e.g. 3 days or more, it is important to ensure there is a multidisciplinary approach to determine the risk of refeeding syndrome, in addition to an appropriate management strategy regarding electrolyte replacement, vitamin supplementation, and energy and protein restriction (Braegger *et al.*, 2010; Byrnes & Stangenes, 2011; Afzal *et al.*, 2002; Solomon & Kirby, 1990; Crook *et al.*, 2001).

Critically ill children represent a nutritionally vulnerable population who may already be malnourished on admission. Nutritional support in this population group requires attention to detail to ensure the challenge of meeting nutritional requirements occurs early in their PICU stay with a focus on achieving equilibrium and not over- or under-feeding.

3.8.25 Neurosurgery

Luise Marino

Only five centres in England are able to provide access to a full time consultant paediatric neurosurgeon; the remaining centres rely on adult neurosurgeons to make a specialist assessment of the individual child's needs, including surgical intervention (Chumas *et al.*, 2008). Paediatric neurosurgical services in the UK accommodate children with hydrocephalus undergoing shunt insertion and other related procedures, central nervous system (CNS) tumours, spinal surgery (excluding scoliosis), neurovascular conditions (excluding those related to head injury) and other specialist surgical work, e.g. cerebral abscesses, craniofacial surgery, epilepsy surgery and interventions for CNS malformations, e.g. Budd–Chiari syndrome (Parslow *et al.*, 2005). The emergency management of children with intracranial problems is initiated in the

local hospital before transfer to a regional centre for intensive care and management of intracranial problems, including surgical intervention where appropriate (Tasker *et al.*, 2011)(see Chapter 7.17.2).

Severe head injury in children is the highest cause of morbidity and mortality over the age of 1 year (Malakouti *et al.*, 2012). Infants have proportionally more head injuries (Shi *et al.*, 2009; Bayreuther *et al.*, 2009) and increased risk of mortality from isolated head injuries (Bayreuther *et al.*, 2009). Early nutritional support is fundamental to recovery (Malakouti *et al.*, 2012). Neurological injury in children has significant morbid sequelae impacting on short and long term memory, in addition to difficulties with executive functioning, resulting in attention deficit disorders with long term implications for

social, behaviour and cognitive development (Prins, 2008; Kosoff *et al.*, 2009).

Scoring systems and nutritional support

The most common coma scoring system used in children is the modified child's Glasgow Coma Scale (CGCS) (Kirkham *et al.*, 2008). Children with a CGCS score of 12 or less are likely to require nutritional support via a nasogastric feeding tube, due to either increased risk of aspiration and/or dysphagia.

Secondary brain injury

Whilst the primary insult accounts for some of the early mortality, it is the secondary brain injury, occurring as a result of hypotension, hyperglycaemia and raised intracranial pressure (ICP) that leads to poor outcome. Treatment modalities including nutrition management, have been shown to significantly improve outcome (Sharma *et al.*, 2009).

Nutritional assessment

In order to determine a nutrition care plan for children with neurological injury anthropometry, biochemistry, clinical parameters and diet should be considered.

Anthropometry (see chapter 3.8.23)

It is important to consider how well the child has been growing up to the point of admission.

Biochemistry

- **Glucose** – in a recent study considering the relationship between hyperglycaemia and outcome in children with severe traumatic brain injury (TBI), any hyperglycaemia (persistent or episodic) beyond the first 48 hours was associated with poor outcome (Smith *et al.*, 2012). It is therefore important to ensure that any nutritional support being given does not exceed glucose (g/kg) recommendations.
- **Sodium** – low sodium enteral feeds should not be used in children with TBI. Medical management of TBI is aimed at maintaining sodium levels at the higher end of normal usually (145–150 mEq/L) with the aim of reducing ICP as hyponatraemia is detrimental to the brain as it results in cerebral oedema (Carpenter *et al.*, 2007). However, injudicious use of hypertonic solutions can also result in brain shrinkage, increasing the risk of intra cerebral haemorrhage (Patanwala *et al.*, 2010).

Clinical factors

To understand whether the medical management will impact on the type of nutritional support being provided, it is important to have a basic understanding of the treatment modalities and rationale for their use (Huh & Raghupathi, 2009).

Dietary management

Energy and protein

Energy and protein requirements in neurological injury are not well researched. There are some published recommendations, e.g.:

- The Brain Trauma Foundation proposes providing 130–160% of resting energy expenditure for children with neurological injury (Malakouti *et al.*, 2012).
- The American Society of Parenteral and Enteral Nutrition (ASPEN) guidelines suggest protein requirements as: 2–3 g/kg for 0–2 years; 1.5–2 g/kg for 2–13 years; and 1.5 g/kg for 13–18 years (Mehta & Compher, 2009).

However, other research suggests that energy expenditure in children with TBI is no higher compared with other critically ill children (Briassoulis *et al.*, 2006), so a similar approach to that used in critically ill children may be more appropriate. Muscle relaxants, sedation, mechanical ventilation and malnutrition lead to a reduction in energy requirements as a result of decreased muscle mass activity (Briassoulis *et al.*, 2000; Vizzini & Arando-Michel, 2011). Both over- and under-feeding in neurological injury have negative sequelae, with underfeeding resulting in muscle wasting and weight loss of up to 15%/week (Vizzini & Arando-Michel, 2011; Phillips *et al.*, 1987) and overfeeding resulting in hyperglycaemia and hepatic steatosis (Vizzini & Arando-Michel, 2011).

Initiation of enteral feeds

Children not fed within 5–7 days have a two- to four-fold increased likelihood of dying (Hartl *et al.*, 2008) in contrast to those who are fed within 72 hours (Vizzini & Arando-Michel, 2011). Enteral feeds should be commenced as soon as the child is medically stable (Mehta *et al.*, 2010). For most this is within 4–6 hours post surgery or admission with the aim of achieving the goal rate within 72 hours post admission (Mehta *et al.*, 2010). However, enteral feeding in neurological injury is not effective in preserving muscle protein content, resulting in a negative nitrogen balance and hypoglutaminaemia (Vizzini & Arando-Michel, 2011; Charrueau *et al.*, 2009). The implementation of feeding protocols may help to achieve nutrition goals (Vizzini & Arando-Michel, 2011; Mehta, 2009; Meyer *et al.*, 2009). Children with TBI do not require specialised enteral feeds, but as bowel motility is often affected by TBI, a fibre containing feed can be important, with the aim of producing a daily soft stool. Constipation and straining to defecate should be avoided as this increases the risk of raised ICP.

Complications of nasogastric feeding

Complications that are of particular relevance to children with neurological injury are increased risk of enteral feeding intolerance, which correlates with raised ICP and/or low CGCS (≤ 8), resulting in delayed gastric emptying (Marino *et al.*, 2003), higher gastric residuals and

increased risk of aspiration pneumonitis. Nasojejunal feeds should be considered (Vizzini & Arando-Michel, 2011); nasogastric and nasojejunal tubes ideally should only be placed for a maximum of 4 weeks, after which a gastrostomy or jejunostomy should be considered, especially in children who remain dysphagic or who have a CGCS of 12 or less (Vizzini & Arando-Michel, 2011).

Nutrition support of children with TBI in the future may include the use of acetyl-L-carnitine (Scafidi *et al.*, 2010), n-3 fatty acids (Mills *et al.*, 2011), vitamin E (Aiguo *et al.*, 2010) and a ketogenic diet (Prins, 2008; Prins *et al.*, 2005).

3.8.26 Burns

Jacqueline Lowdon

Every year in the UK, over 6000 children are admitted to hospital for acute burn care (National Burn Care Com-

mittee, 2001). The causes and types of burn injury in children include:

- Thermal – scalds, contact, flame, flash.
- Chemical.
- Electrical.
- Radiation.
- Cold injury.
- Diseases, e.g. vesiculobullous skin disorders, staphylococcal scalded skin syndrome (SSSS).

In the UK, children with a burn injury will be treated either at a burn unit or burn facility, with the burns centres taking the more complex cases and where PICU may be required. A network of care also exists between the units, facilities and centres, to allow for communication and sharing of expertise.

Nutritional support

All children admitted with a burn injury are at nutritional risk. A burn injury causes a hypermetabolic state, increasing nutritional requirements. Nutritional support is therefore one of the most significant aspects of burn injury care. The aims of nutritional support are to promote optimal wound healing and skin graft take, maintain normal growth and development, and maintain immunological competence.

Calculation of requirements

There is no agreed classification for the severity of burn injury. The extent of skin injury is quantified in terms of the extent of the total body surface area (TBSA) involved in the injury, expressed as a percentage. This, together with the depth of the injury, is the most commonly used method of classification. However, other factors also have to be considered when initially assessing nutritional requirements:

- Age.
- Sex.
- Weight.
- Height or length.
- Preadmission nutritional state.
- Pre-existing medical condition.
- Special dietary requirements.
- Site of injury.
- Gastrointestinal function.
- Pyrexia.
- Grafted area.
- extent of healing.

Other factors that will influence whether nutritional requirements are met include pain management, periods of nil by mouth for grafting or change of dressings, and psychological distress.

Minor burns (<10%)

Burn injury in children does not raise the resting energy expenditure (REE) proportionally as much as it does in adults. When normally active, children become inactive due to the burn injury; this partly offsets the increase in REE (Goran *et al.*, 1990; Childs 1994; 1995). Optimal

nutritional state and weight maintenance can normally be achieved by aiming for the estimated average requirement (EAR) for a non-burned child. Children with minor burns are usually encouraged to meet their nutritional requirements orally. However, it is important to remember that in some children with an injury of <10% that enteral tube feeding may be required depending on site of the burn (e.g. the face), preadmission nutritional status and surgical management (e.g. grafting).

Major burns (>10%)

In a major burn injury, nasogastric or nasojejunal feeding should be commenced within the first few hours post injury. Early enteral feeding of burns patients, within the first 6 hours, reduces the incidence of paralytic ileus. Paralytic ileus can occur in severe sepsis, where septic diarrhoea causes paralysis of the ileus muscles. Other benefits include (Herndon & Tompkins, 2004; Chiarelli *et al.*, 1990; McDonald *et al.*, 1991; Hansbrough, 1998):

- Moderation of the hypermetabolic response.
- Maintenance of gut integrity; reduction in bacterial translocation.
- Improvements in immune status and wound healing.

Continuous feeding should be commenced initially and the rate increased slowly, to reach full maintenance within the first 24 hours post injury (McDonald *et al.*, 1991). Due to the broad spectrum antibiotics used in paediatric burn patients, diarrhoea occurs frequently. This is not usually related to feed osmolality or volume (Thakkar *et al.*, 2005). Feed volume will need to be titrated when oral intake commences, as long as nutritional requirements are still being met. Bolus feeds can be considered once the child starts to eat.

Energy requirements

Energy requirements are thought to increase in burn injury by >10% and are calculated using the Hildreth formula (Hildreth & Carvajal, 1982; Hildreth *et al.*, 1989; 1990; 1993), as shown in Table 3.8.29.

Table 3.8.29 Hildreth formula for energy requirements in paediatric burn patients (Haycock *et al.*, 1978)

Age (years)	Energy requirements
<1	2100 kcal/m ² (body surface area) + 1000 kcal/m ² (burn surface area)
<12	1800 kcal/m ² (body surface area) + 1300 kcal/m ² (burn surface area)
>12	1500 kcal/m ² (body surface area) + 1500 kcal/m ² (burn surface area)

Surface area = square root of [Height (cm) × weight (kg)]/3600
or
Surface area¹⁴ = weight (kg)^{0.5378} × height (cm)^{0.3964} × 0.024265
Burn = surface area × % burn

Normographs are available for estimating burn surface area (British National Formulary for Children, 2006; McCarthy & Hunt (2001).

Protein requirements

Burn injured children have a higher protein requirement than the recommended nutrient intake (RNI). The BDA Burns Interest Group currently recommends the following as a guide:

- Infants under 1 year, use RNI.
- For children aged 1–3 years, use 2–3 g/kg/day (Cunningham *et al.*, 1990).
- For children aged over 3 years and adolescents, use 1.5–2.5 g/kg/day (Bell *et al.*, 1986).

Fluid requirements

All burns units have fluid resuscitation guidelines and the dietitian will need to work out a feed regimen within this allowance. If the child is pyrexia, an extra 10% will need to be added for every degree rise in temperature.

Micronutrients

There are very few studies that have looked at vitamin and mineral requirements for children with a burn injury. Before considering a supplement, check the nutritional composition and bioavailability of the nutritional intervention in conjunction with the biochemical markers.

Parenteral nutrition

This should only be considered where there is a prolonged paralytic ileus or poor tolerance of enteral feeds. However, trophic feeds should continue to maintain brush border integrity of the gastrointestinal tract.

Monitoring

Daily food and fluid charts need to be maintained accurately in order to monitor and evaluate intake (Vijfhuizen *et al.*, 2010). Bowel habits also need to be monitored closely as this may affect feed tolerance, e.g. analgesia and being bed bound can result in constipation. Weight should be reviewed when possible in theatre or when there is a change of dressings. It is important to remember that oedema due to the initial injury may mask a true weight. Nutritional biochemical markers should be requested and monitored as necessary.

Burn injuries are dynamic, as the percentage burn surface area changes due to wound healing or degradation due to infection; therefore, so will a child's nutritional requirements, and these require reassessment as necessary.

Post discharge

During hospitalisation the child and family will have been advised about a high energy, high protein diet. On

discharge, this needs to be reassessed on an individual basis.

3.8.27 General surgery

Shelley Easter

There are many conditions and procedures that affect a child's feeding ability. It is important for dietitians in non-specialised hospitals who receive surgical patients from larger centres to understand surgical practices and, for more complex patients, liaise with the centre's dietitian. For example, district general hospitals may receive infants who have had corrective surgery for gastroschisis or duodenal atresia.

As with any admission, a child's intake can be altered just by being away from home and not receiving their usual food choices. This can be compounded by surgery, even if there is not a specific linked nutritional condition. For example, a child who is nil by mouth prior to surgery and for the remainder of the day following their surgery is unlikely to need dietetic input. However, if a teenage boy, who will have a high energy requirement, does not eat well prior to surgery and takes several days to regain his appetite fully, he may lose weight and need brief but quickly implemented nutritional support. Therefore, nutritional screening with a prompt response to any issues raised is essential.

Common surgical procedures that require dietetic input

Fundoplication

This surgery is a treatment option in severe cases of gastro-oesophageal reflux when medication fails to control symptoms and growth is compromised. The most common type performed is a Nissen's fundoplication when the fundus is wrapped around the lower part of the oesophagus to form a valve between the oesophagus and stomach. This reduces stomach capacity, which has nutritional implications immediately postoperatively. If a child is tube fed, the feed plan will need reviewing, either during admission or after discharge, with their local home enteral feeding team as bolus feeding will now be possible and feeding times could also alter. A reduction in feed may now be indicated if the child is no longer vomiting and absorbing all their feed (Vandenplas *et al.*, 2009).

Gastroschisis and exomphalos

These are abdominal wall defects that require corrective surgery soon after birth; in some cases the bowel is returned to the abdomen in a staged return. Parenteral nutrition is commenced until enteral feeding can be fully established. If breast milk is not available and the gut has had a lot of handling or suspected trauma, a partially hydrolysed feed may be used to establish enteral feeding. On reaching full feeds, the infant should be graded over to a standard formula to check if this is tolerated and thereby avoid inappropriate use of a specialist feed.

Oesophageal atresia and tracheo-oesophageal fistula

Both are congenital defects; in oesophageal atresia the oesophagus ends in a blind pouch rather than connecting continuously to the stomach, and in a tracheo-oesophageal fistula there is a connection between the oesophagus and the trachea. Corrective surgery is done soon after birth and, following the repair, the infant will have a transanastomotic tube *in situ* to keep the area patent. Feeds (expressed breast milk or a standard infant formula) can be given via this tube until oral feeding can start. Other points to consider include:

- Corrective surgery may not be possible soon after birth.
- Feeding difficulties can occur, or become more severe, prior to an oesophageal dilation, where the oesophagus is stretched. As the oesophagus starts to narrow, feeding can be difficult and the infant may fail to meet their needs orally. In some cases, temporary nasogastric feeding is needed.
- At weaning, some foods may be more difficult to tolerate and extra advice and support for parents will be needed at this point.
- Both conditions are frequently associated with other medical conditions and syndromes, such as vertebral, anorectal, cardiac, tracheo-oesophageal, renal and limb defects (VACTERL) and coloboma, heart defects, choanal atresia, retarded development, genital hypoplasia and ear abnormalities (CHARGE).

Duodenal atresia

This congenital condition results in a bowel obstruction as there is a blind pouch or a web preventing any further passage through the intestine; therefore corrective surgery is required. Parenteral nutrition should be started after surgery and enteral nutrition is not commenced until gastric aspirates reduce to minimal levels, indicating that the bowel is functioning appropriately; the surgeons will direct this.

Short bowel syndrome

In short bowel syndrome there is a significant loss in bowel length, resulting in malabsorption. It requires intensive and careful nutritional management and is greatly affected by which part of the bowel is lost. Parenteral nutrition is often needed for a considerable time and effort should be made to ensure appropriate growth with action taken to minimise complications associated with parenteral nutrition. Once enteral nutrition is permitted, feed choice and delivery needs careful consideration, along with the use of agents to slow transit time.

SECTION 4

Specific areas of dietetic practice

4.1

Freelance dietetics

Elaine Gardner

Key points

- Freelance practice can be a rewarding career, has benefits and risks, and requires careful thought and planning.
- Self employment has legal and financial implications, and professional advice is needed.
- Constructing a business plan is essential when establishing a new business to assess its viability and monitor its success.
- Professional standards and codes of conduct must be complied with.
- Help and support will lessen feelings of isolation.

Traditional working patterns are changing and an increasing number of people now work in a freelance capacity. Freelance businesses are credited with contributing 8% of business turnover in the UK (Kitching & Smallbone, 2008). The number of freelance dietitians is increasing. The Freelance Dietitians Group (FDG), a specialist group of the British Dietetic Association (BDA), was formed in 1999 to support dietitians who are (or are planning to) work in a freelance capacity. More information can be found in the members' section at www.bda.uk.com and www.freelancedietitians.org.

The following information is intended as guidance only. Professional codes of conduct and legal requirements change and it is the responsibility of each individual to ensure that these are met. It is recommended that professional expertise be sought for individual circumstances.

Becoming a freelance dietitian

For many practitioners, the idea of becoming a self employed, freelance dietitian is an attractive option. Working freelance usually means becoming self employed and setting up a small business. However, there are financial, emotional and professional risks. Unfortunately, many new small businesses fail in their start-up period. In the UK the small business failure rate is about three in 10 in the first 4 years (Maloney, 2010). In order to become successful there are a number of important issues to address and strategies to develop, which may well fall outside the experience of a previously employed dietitian.

There can be a number of reasons for considering becoming a freelance dietitian. Dietitians need to look honestly at their reasons for considering the freelance option and to take an objective look at themselves. What sort of person are they? What are their strengths and weaknesses? Have they got what it takes, including the motivation and self discipline?

Implications of changing from employed to self employed status

When first considering a career as a freelance dietitian it is worth taking note of what may be lost, e.g. from leaving a full time post. Losses may include:

- *Financial benefits:*
 - A regular salary (which is paid irrespective of whether clients attend for appointments).
 - Annual salary increments, holiday pay, sick pay, maternity/paternity leave.
 - Automatic deductions for National Insurance (NI), tax and pension.
 - Professional indemnity insurance cover.
 - Subsidised canteen, accommodation, car loans, etc.
- *Career benefits:*
 - Recognised career path.
 - Supported continuing professional development (CPD).
 - Paid leave to attend conferences and meetings.
 - Free and ready access to journals and libraries.
 - Immediate support of colleagues.
 - Opportunities to work in a range of areas.

- **Environment:**

- Equipment, e.g. desk, chair, computer, printer, telephone, pager, etc.
- Administrative and secretarial support.
- Consulting rooms and booking in and appointment service.
- diet sheets, resources and equipment, e.g. scales.

Many of these benefits will not be automatically available to the self employed person. The freelance dietitian therefore has to be prepared to take on the uncertainties and expenses associated with working for themselves. A compromise is part time freelance and part time employment. However, this may have tax implication (see section on taxation).

A freelance dietitian seldom knows when work will be commissioned and this demands good time management, both in the quiet and the busy periods. Working freelance may result in working long hours and at weekends in order to meet deadlines and, conversely, having unwanted, unpaid free time when contracts and projects have not been won or are scarce. Making effective use of quiet periods and keeping motivated, as well as productive time management and organisation are key skills required by a freelance dietitian. The nature of freelance work means that a great deal of energy and time needs to be devoted to building and maintaining the business to provide sufficient commissions to equate to a full time job and salary. Although the number of full time, freelance dietitians is increasing, the majority is working in freelance areas part time.

Required qualifications and experience

Registration with the Health and Care Professions Council (HCPC) is essential. A minimum of 5 years' supervised, clinical experience is needed for private, clinical practice as many private medical insurance companies (PMIs) stipulate this as a requirement for registration. A varied dietetic experience after qualification and a broad background is recommended for other areas of freelance work. In addition to dietetic qualifications, it is beneficial to possess other qualifications, e.g. a teaching certificate in adult education or recognised expertise in sports nutrition. A catering qualification, membership of the Hotel and Catering International Management Association (HCIMA) or work experience in catering or food manufacture can also be useful. If the business includes writing, becoming a member of the Guild of Food Writers or the Guild of Health Writers may be valuable. If the business is to offer advice in a particular speciality, the dietitian must have the necessary additional qualifications and experience to justify this.

New skills such as marketing your business, tendering procedures, contracts and remuneration proposals will probably need to be developed for the business to succeed. The most common reason for small business failure is poor cash flow management (Experian, 2010), and advice and training in financial business skills are highly recommended.

Work opportunities

A freelance dietitian can work in the areas of dietetics and nutrition. The opportunities are wide ranging and extremely varied, covering a broad spectrum of dietetic practice. Figure 4.1.1 provides a sample range of work opportunity areas that were identified by the members of the FDG in 2009.

Specialist skills such as lecturing, giving talks and presentations, counselling and research expertise are all marketable and can be valuable skills in a number of areas including:

- Writing diet related articles and books for both the consumer and professional press.
- Media work such as journalism, broadcasting, press releases, scientific or medical briefings and seminars. resource development.
- Consulting in the field of marketing and project management.
- Specialist dietetics, e.g. allergies, child health, obesity and weight management, diabetes, renal disease, coeliac disease, women or men's health. Expertise in achieving behaviour change will be invaluable.
- Menu planning, calculations and evaluation.
- Recipe development and analysis.
- Catering, food policies and writing or advising on catering tenders.
- Health claims research for food companies.
- Sports nutrition/fitness and health consultation and advice.
- Health promotion session development.
- Workplace nutrition programmes.

Clients

Business can come from a wide variety of sources. The fees commanded are likely to vary between the different areas (see Table 4.1.1). It is appropriate to register with a number of PMIs. Each company has its own requirements and specified payment terms. This may mean that the number of consultations or payment rate may be capped and the balance of payment may need to be obtained from the clients themselves (see [www .freelancedietitians.org](http://www.freelancedietitians.org) for further details).

Planning the business

If the reason for becoming freelance is to earn easy money, then disappointment and hard work will soon become the reality. Setting up a freelance business is a venture that must be taken seriously. While the professional work may be similar to that of working as an employee, the freelance environment is quite different and demands a different set of skills and aptitudes. To be successful a business-like approach must be adopted, no matter how little or how much work is done. In the early stages it may be worthwhile asking an experienced freelance dietitian to act as a mentor. In addition to excellent dietetic skills and professionalism, the freelancer

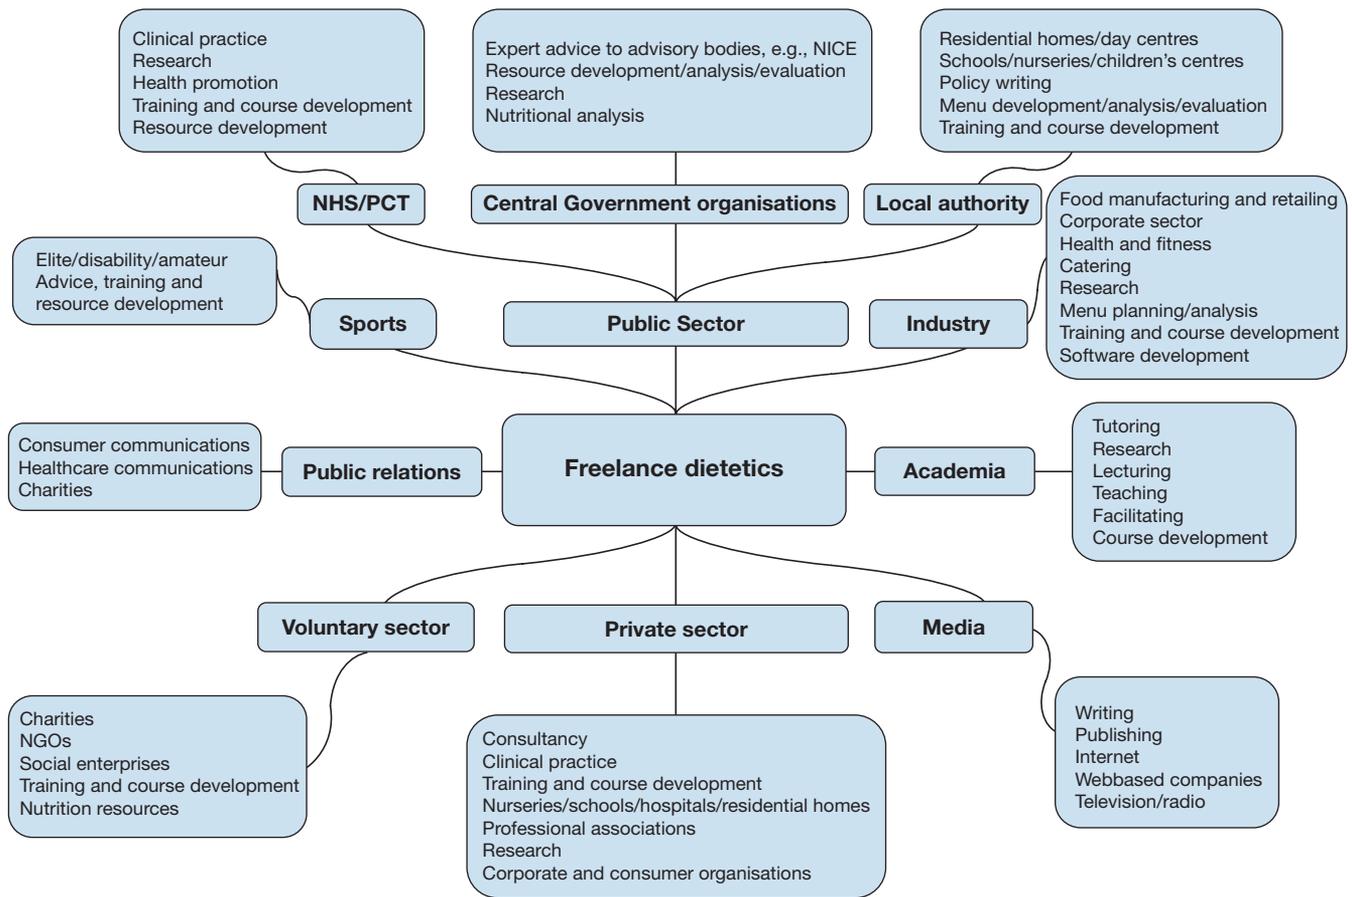

Figure 4.1.1 Work opportunity areas for freelance dietitians (from BDA Freelance Dietitians Group – Where do freelance dietitians work? <http://members.bda.uk.com/groups/fdg/files/FDGwheredietitianswork.pdf>) [source: The British Dietetic Association 2013. Reproduced with permission of the British Dietetic Association (www.bda.uk.com)]

GP, general practitioner; NHS, National Health Service; NGO, non-government organisation; NICE, National Institute for Health and Care Excellence; PCT, primary care trust

Table 4.1.1 Examples of clients in the public and private sectors

Public sector	Private sector
GP sessions	Private medical insurance companies, private patients
Hospital clinics	Public relations companies – product promotion and support, brochures, customer leaflets, press releases
Research, e.g. for government bodies	Food retailers and manufacturers – fact sheets, product development and specifications, customer support, recipe cards, magazine articles
Project management for service providers and area teams within the health services	Television, radio and other media – research and consultancy
Expert witness	Publishing companies – newspapers, magazines and books
Education providers, e.g. lecturing, development of programmes and materials	Medical and health charities – advice and creation of support material
	Catering companies
	Conference and event organisation or management
	Pharmaceutical companies

needs to set up a business and therefore needs to be able to:

- Work independently and unsupported.
- Be fully committed to the project.
- Demonstrate exceptional organisational and multitasking skills.
- Be proactive:
 - Cope under stress and pressure.
 - Have sufficient funds to set up and survive until work comes in and invoices are settled (these can take 2–4 months to be paid).
 - Live without the security of a regular salary.
 - Take responsibility for tasks previously done by an employer, such as taxation and NI payments, and pension arrangements.
 - Have sufficient experience, confidence and contacts.
 - Write a business plan.

Business plan

The first step in starting any business is to prepare a business plan that outlines the concept of the business and evaluates its strengths and weaknesses, and therefore its viability. It is essential to write a business plan before resigning from employment. A business plan should answer the following questions:

- What is it that is being sold?
 - Dietetic skills and knowledge are now the ‘products’. This requires a different mindset.
 - What particular skills and expertise does the business have to sell?
- Who will buy this product?
 - Who will the clients be?
- Where can these clients be found?
 - How will they get to know about the new business?
- How big is this client ‘market’?
 - Does it even exist?
 - Can it grow?
- How much will they pay for the services?
 - Will they pay and if so, when?
- What is the competition doing?
 - Who are the competitors?

The business plan should include a month by month plan of the coming year with a realistic estimate of income and expenditure; this can be used as an objective measure of business progress. The plan should be reviewed on a regular basis so that the business can build on its successes and remain profitable. It should set ambitious but realistic goals for the business within a reasonable time frame. A business plan can be viewed as a starting point and can (and should) be reviewed as the business develops. Help in developing a business plan and start up information can be obtained from the business departments of high street banks and the government organisation Business Link (www.gov.uk/business-support-helpline). A number of aspects need to be considered when constructing the business plan.

Type of business

Working practices vary but the majority of freelance dietitians are self employed sole traders. There are alternatives to working alone, such as setting up a formal partnership or group practice. Consideration should also be given to forming a limited company. It is recommended that professional advice be sought as to which option best suits the individual situation and needs of each business; all have different financial implications. Talk to people about the business idea, listen to criticism and negative feedback, as well as doing all the necessary research.

Income and cash flow

Establish the income target that needs to be earned to cover ongoing financial commitments (both business and personal). Factor in standing orders for NI, telephone rental, pension payments, etc. that have to be paid whether there is an income or not. Tax requirements vary (depending on the type of business) and there may be a requirement to pay tax in advance of income receipt. As a safeguard, it is a good idea to set aside contingency monies (consider 4–6 months of requirements) at the outset. Consider that you may need to tender for work, complete the work (or a reasonable proportion of it), invoice the client and then wait for it to be paid before any income is received.

Equipment, resources and paperwork

Take time to consider what hardware is needed to run the business. It is recommended that a computer is dedicated to the business, as is a phone line and broadband access. Consider whether items such as a laptop, scanner or high speed printer are essentials or luxuries at this stage. Software programmes may be needed to write lectures and presentations, to run spreadsheets, or for dietary analysis. Other resources may need to be purchased such as weighing scales, height measures (stadiometers), diet sheets, posters, leaflets, replica foods and audiovisual equipment, depending upon the business focus. Professional documentation such as business cards may need to be obtained and other paperwork such as invoice templates and contracts need to be developed for the business. While there are many examples to be found on the Internet, professional advice regarding specific content may need to be purchased. Membership of professional organisations, both dietetic and business, is an essential expense that also needs to be included.

Office accommodation

Carefully consider whether the business is going to be run from home or an office. Take advice from experts and consider the advantages and disadvantages of each option.

Working from home

It may be that the reason for becoming freelance is to be able to work from home. If this is the case, then ensure

that the family are in agreement and will provide full support. The business may need to take precedence over social activities or family events and this must be allowed for. Being at home may bring conflict between family and business, and a proper workspace needs to be allocated and office hours respected by all. Switching off from other activities in the house can be difficult and it is also easy to be consumed by work and difficult to take breaks, especially if there is an urgent deadline. Schedule adequate rest and relaxation as tiredness will slow work, lead to mistakes and reduce creativity.

If private patients are to be seen from home, it will be necessary to consider aspects such as parking facilities, disabled access, waiting areas, toilet facilities, public liability insurance, personal security and disruption to the family. Use of a domestic residence for business purposes may also have implications in terms of house insurance and council tax. If working from home, then the business (and home address) may appear on advertising materials and letterheads. Consider privacy and safety, and perhaps opt for a box number address or similar. If working from home, it is imperative that the business is still run with a professional manner and mindset.

Renting office space

Having a separate work place can be advantageous in keeping work and private life compartmentalised. It may be more professional to use rented accommodation for consultations rather than a room at home. There may also be an opportunity to share a receptionist who can take calls or make appointments. Alternatively, there are call centres that can handle your calls and pass on messages by text or email.

Suitable premises can include private hospitals, clinics and gyms. Alternatively, it may be worth considering linking up with other professionals, e.g. other dietitians, physiotherapy practices, pharmacies, or health and fitness clubs. It is important to find out what will be included in the rental. Does the room contain a telephone, computer, scales and chairs or do these need to be provided? Is there safe storage space for equipment allocated within the rental or does that need to be considered separately? Is the rental per session, week or month? These costs need to be incorporated into the business plan.

Arranging holiday cover

Events such as holidays should be anticipated and strategies developed to minimise their effects on the business, e.g. by informing regular clients that you will be unavailable between certain dates or arranging with colleagues to provide cover. In this way the goodwill of the client will be maintained, which is essential for continued business success.

Professional obligations

Registered dietitians must comply with the professional standards laid down by the HCPC and must make sure that the nature of the business, and the way it is con-

ducted and promoted, conforms with these standards (HCPC, 2007) (see Chapter 1.1). Freelance dietitians working in private practice may have self referrals from clients. In such cases, dietitians must adhere to a strict code of professional conduct designed to protect the interests of both client and professional (BDA, 2008). It is important that freelance dietitians understand the circumstances when medical confirmation, or even formal medical referral, should be obtained for a self referred patient. Further guidance is available from the FDG.

Setting up a business

A new set of rules and regulations will apply and a dietitian must think and act as the owner of a business, not as an employee. For example, a dietitian who sees private patients and keeps patient details on a database will need to register in accordance with the Data Protection Act 1988. It is recommended that independent legal and financial advice is sought to help develop and action the business plan. Some of the issues that may need to be discussed are outlined below.

Banking

At least two business accounts should be opened; a cheque or current account for day to day banking and expenses incurred in running the business, and an interest earning reserve or savings account. Money should be put into this account to pay for tax and NI when it becomes due and, given the irregular nature of freelance work, it may be wise to allocate a proportion of earned income to this account to cover quiet periods when there is little work, or during holiday periods or in the event of illness. It is essential that business and personal accounts are kept clearly separate.

Insurance

It is important to know which types of insurance policies are necessary. This will depend on the professional activities of the business, the type of clients and from where the business is being conducted, but may need to include:

- *Additional professional liability insurance* – membership of the BDA includes a certain level of cover with regards to professional liability insurance. Check the extent of the cover and consider whether circumstances dictate a higher level or whether this is adequate. NB: Some areas of freelance work, although covered by this policy, require notification to the insurance providers to ensure adequacy of coverage for the profession. Additionally, it is advised that a provision for dietetic advice that is not face to face, e.g. given via the Internet or text, is discussed with the insurance providers.
- *Public liability insurance* – this is an essential requirement of some contracts but it may also be wise depending on the nature of the business.
- *Additional household insurance* – to protect business hardware.

- *Additional car insurance* – if a car is being used for business purposes, the insurance company must be informed and the premium may need to be adjusted.
- *Income protection* – this may be needed in case of minor illness or injury that means you are unable to work for a period of time.
- *Critical illness cover* – this may be recommended in case of serious health problems. This is useful, even if working part time, as it could provide money to help with childcare or a partner's expenses during a difficult time.
- *Private medical insurance* – this may be advantageous as medical treatment can usually be carried out quickly and can be dovetailed with work commitments, thus minimising disruption to earning capacity.

Pension provision

Retirement may seem a long way away but planning for it is strongly recommended and there are tax advantages in doing so. Retirement planning is a complicated area and it is important to take proper advice from qualified professionals, such as independent financial advisors who specialise in this area.

Taxation and national insurance

An accountant should advise on these and HM Revenue and Customs (HMRC) should be informed as soon as possible after the period of self employment begins. The HMRC provides fact and advice sheets about all areas relating to taxation and NI.

Taxation

Most self employed people will complete an annual self assessment form for the assessment of their tax liabilities. The rules governing the taxation of employed and self employed people differ in some respects and HMRC may not regard regular hospital clinic and lecturing commitments as self employed work. Such details will need to be clarified on an individual basis.

National insurance

Special arrangements apply for self employed people and it is essential to get advice on exactly what is required. Currently, Schedule D Class 2 will need to be paid from the outset and is best done by a standing order from the current business account. Class 4 is liable over a certain profit level and is assessed at the annual tax return.

Corporation tax

This is paid by a limited company on overall taxable profits; it is recommended that an accountant is consulted on this type of taxation.

Setting fees for services

The rate of fees charged for freelance dietetic services is important to the profit and hence sustainability of the business. Charges need to be clearly stated at the outset and clients need to be clear about what they will be

getting for their money. Recommending a fee structure is difficult because of differences in the area of expertise, the client (public or private sector), dietetic experience, the amount of work and time involved, and the degree of difficulty. Fees can be set hourly for individual patients or per therapeutic session (perhaps one of three visits); per half day or day, per recipe, for one-off lecture or a series of lectures, for private patients or a regular clinic; or for charities or large companies, a long term project, a retainer, or according to the degree of urgency. Different fees may be necessary according to the region, e.g. fees may be higher in London and the South East of England.

Fees must take full account of the business set up and running costs. These include:

- The time required to prospect for new business and clients, follow up leads, put together bids and proposals, and attend interviews.
- Taxation, NI, pension, accountant's fees, insurance policies, professional memberships, subscriptions, etc.
- Hardware such as computer and printer, laptop and office furniture.
- Rental of office space, telephone (mobile and landline) and Internet access.
- Website development and hosting.
- Administrative and secretarial help to send out invoices and follow up those that remain unpaid.
- Cost of stationery, stamps, printer paper and ink.
- Loss of earnings during holidays or illness, or the costs of providing holiday or sick leave cover.
- Costs and travelling time.
- Continuing professional development – costs of subscribing to journals, buying textbooks and attending meetings, including travelling expenses.
- Sundry other expenses.

Approximately, 40% of a fee should be paid into a business reserve or savings account to cover tax, NI, and other expenses so that money will be available when these are due. Fees should be competitive and updated annually. It is important that a proper rate is always charged because undercutting fees devalues professional skills. It is essential that freelancers do not breach competition law by agreeing amongst themselves what they are going to charge for services and they must not discuss their fee structure with competitors.

Book keeping

It is essential that records are kept of all income and receipted expenditure. If the business is not too busy or complicated, it might be possible to run accounts on a spreadsheet or simple accounting software. Employing a bookkeeper and/or an accountant with experience of small businesses may be advantageous, particularly when dealing with HMRC. Invoices need to be sent out regularly to maintain a steady cash flow and any unpaid invoices followed up promptly. Although rare, bad (unpaid) debts can arise, so proper invoicing systems need to be in place to help prevent this. If this does

happen, there are a number of options available for dealing with non-payment: invoking the Late Payments Act, the Small Claims Court, or hiring debt collectors.

Contracts

A contract defines the relationship between the business and the client. It needs to reflect and record accurately the joint commercial intentions and visions so that when an invoice is presented there are no surprises for the client. It can be used as a point of reference to help avoid any disputes and also as a tool for discussions with regards to further work or time allowance. It should contain case specific details such as who everybody is, dates, payment basis, services to be provided, the boundaries of these services, e.g. does it include travelling expenses and time? It may also be important to detail what is not included to help define the boundaries. It should also contain legal background details, e.g. terms, responsibilities for defective work, confidentiality and termination of contract. This section may be similar for all work undertaken. A written agreement or contract needs to be signed before work is started.

Advertising and marketing

Potential clients need to know that the business is operating and what services are being provided. Advertising the products and marketing the services are an essential part of the business, but as a registered dietitian there are limitations on what can be said, where it can be said and how it is expressed. Generally, it is recommended that advertisements be accurate and restrained; they must not be false, fraudulent, misleading, deceptive, self laudatory, unfair or sensational. Increasingly new technologies are being utilised by dietitians to market their services and promote their business. Consider establishing a website and registering the business in professional directories or with healthcare providers. It is essential that the right image is communicated via the company name, website and on headed paper and compliment slips, business cards and leaflets. Ensure that these all reflect what the business is about and what is being marketed.

Many jobs are obtained by word of mouth from contacts and by reputation. Some may be advertised in professional magazines or on websites. A specialist healthcare employment agency may also be a source of potential work. Ensure that a *curriculum vitae* (CV) is up to date and relevant for each potential client.

Help and support

There is a lot of help available, much of it free. Until November 2011, the UK government had a one stop website Business Link, which provided free and easy access to information, advice, funding and training for the small business, but this was suspended in November 2011. Details of replacement services are available at www.gov.uk/business-support-helpline. Local newspapers

can be a useful source of information on courses and business networks that can provide help and support.

The FDG produces, and continually updates, a series of fact sheets for freelance dietitians on a wide range of topics, including Business Planning, Taxation and Accounting for your Business, Setting up in Private Practice, and Self Referrals. These are an invaluable resource for anyone involved in or contemplating freelance work.

Maintaining and expanding the business

Getting the business up and running may seem a challenge but keeping up the momentum is just as important and can be challenging to a dietitian working alone. It is not easy to look to the future when busy on a daily basis. It is important to maintain a professional approach:

- Keep to deadlines, deliver promptly and always deal with clients in a professional manner.
- Keep up to date.
- Pass on work to other freelance dietitians that is not within the area of expertise of the business, or where there is insufficient time to do the job properly.
- Be proactive – follow up leads and keep in touch with people. Be seen at relevant meetings or perhaps present a paper.
- Consider writing a newsletter for circulation to past and current clients.
- If working from home, dress the part. The freelancer who looks professional will feel more competent when talking to a client on the telephone in the office.

Staying motivated

Working single handed may bring feelings of isolation or even boredom, especially after working in a busy department. It is all too easy to put things off until later, e.g. go shopping rather than follow up client leads. If work does not come in as planned, then there is increased pressure, particularly financial, to succeed. Staying motivated can be one of the most difficult things to do.

Lack of work

It is inevitable as a freelancer that there will be times when there is no work. Be prepared for this, make good use of the time and consider the following:

- Enrolling on a course such as media, cookery, food hygiene, advanced computing, web design, etc. and make use of the newly acquired skills by, for example, writing an article or producing a website.
- Volunteering to be a member of a committee that might be useful and relevant to the business.
- Attending conferences and contacting former colleagues.
- Reviewing the business plan and tidying up paperwork, e.g. expense receipts.
- Updating the CV or the continuing professional development (CPD) portfolio.

Continuing professional development

Any or all of the range of activities undertaken as a freelance dietitian can be used to provide evidence of how the HCPC's CPD standards are being met. The focus of the freelance business often evolves and changes and this can be excellent material for the portfolio. The CPD activity could show professional development alongside business development and evidence could be details from specific examples. It is important to document and evaluate every piece of freelance work that is done and every meeting that is attended. This document should be regularly updated and reviewed to see what has been learned and how this can be extended. This is an intrinsic and necessary part of being a professional.

4.2

Public health nutrition

Alison Nelson

Key points

- Public health nutrition is concerned with improving the health of the population and preventing diet related illnesses across that population.
- There has been increasing recognition that nutrition is a major and modifiable determinant of many chronic diseases; diet can have positive and negative impacts on health throughout life.
- Obesity and other diet related diseases are an immense health and economic burden in the UK.
- A consistent evidence based message about good nutrition is important to give consumers confidence to change their food choices and eating behaviours.

Public health is defined as the *'the science and art of preventing disease, prolonging life and promoting health through the organised efforts and informed choices of society, organisations, public and private, communities and individuals'* (Wanless, 2004). Public health aims to improve the health of the population and reduce health inequalities by helping people live longer, healthier and more fulfilling lives, while improving the health of the poorest fastest. It considers the wellbeing of the population, including mental and physical health, while engendering a sense of control over the way people want to live. Public health focuses on the wider environment by influencing those factors that enable people to make healthier choices.

Today there are significant challenges to public health, e.g. two in three adults in the UK are overweight or obese. In addition, inequalities in health remain widespread with people in the poorest areas living on average 7 years fewer than those in the richest areas and spending up to 17 more years living with poor health (Department of Health, 2011c). The most effective way to address public health is considered to be one that addresses the wider social determinants of health (poverty, housing, education, etc.) and health inequalities so that *'no one should be disadvantaged from achieving their full health potential'* (Whitehead, 2000), whilst adopting a life course framework by addressing influences from infancy to old age.

A range of factors within and outside of the individual's control influence the health and wellbeing of individuals

and populations across all age groups. The Dahlgren & Whitehead (1991) *Policy Rainbow* is a commonly cited model, which represents the range and interrelationship of factors that influence health (Figure 4.2.1). It describes factors that are fixed (core, non-modifiable factors), e.g. age, sex and genetics, and those that can be modified and expressed as a series of layers of influence. The relative contribution of each layer to improving health, and the actions required to change each of the influencing factors, has become a framework for the development of public health policy. It recognises that behaviour change can only take place in a supportive environment. For example, families wanting to maintain a healthy weight will be able to do so more easily in a supportive environment; an environment in which food production and retail facilitate access to healthy food at an affordable price, education provides the skills and knowledge to buy and prepare healthy food, employment or benefits provide adequate money, the workplace and schools have food policies in place, and housing is adequate to maintain family life.

Public health workforce

The public health workforce is diverse in what it does and the places it works. It is categorised into three distinct groups (Department of Health, 2001):

- *Specialists* – those qualified in public health and operating at senior strategic levels. This will include dietitians who are registered on the voluntary register for

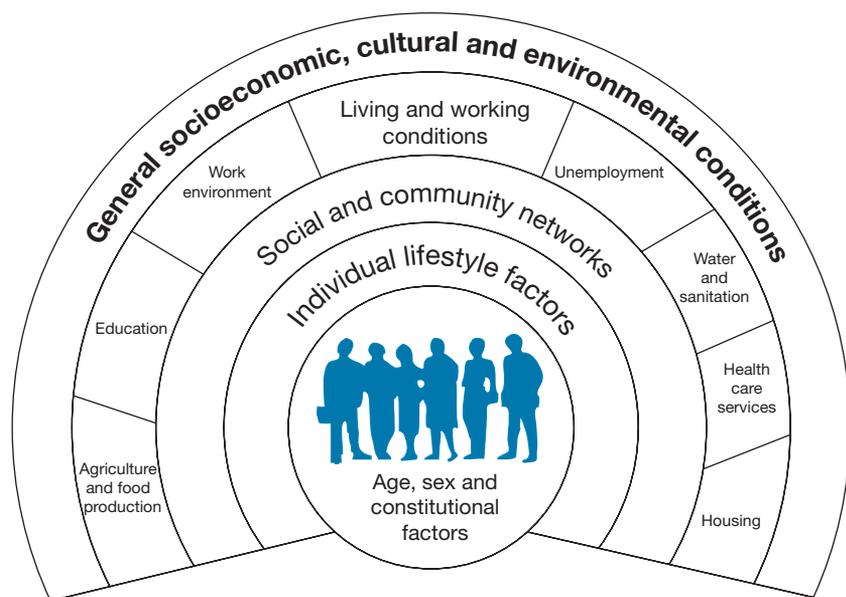

Figure 4.2.1 A social model of health (source: Dahlgren & Whitehead 1991. Reproduced with permission of the Institute for Future Studies, Sweden)

public health consultants or working at a senior strategic level.

- *Practitioners* – those working at an operational level to deliver public health programmes and services, such as public health dietitians, public health nurses, environmental health officers and public health analysts.
- *The wider workforce* – those who are able to influence the health of the population through their roles, including such disparate groups as teachers, spatial planners and directors of finance of health organisations. All dietitians working within a clinical specialty could be included in this group because of their influence on the wider family or community of patients they are working with.

Public health nutrition

Public health nutrition (PHN) is concerned with improving the health of the population by focusing on the wider environment to understand and influence the issues that help or hinder people to make healthy food and lifestyle choices. Public health nutrition aims to improve the population's health and prevent diet related illnesses across that population, rather than treating the diseases of individual patients. It recognises that the way people choose to live their lives is influenced both by individual factors and other factors that may be outside of individual choice. Hence, the work of a public health dietitian could include:

- Identifying need, e.g. using local data to illustrate pockets of increased childhood obesity.
- Planning strategy by engaging partnership groups, e.g. coordinating a group of stakeholders to develop a healthy weight strategy.
- Providing the evidence to support dietary change, e.g. literature review or research.

- Developing programmes, e.g. to increase fruit and vegetable uptake through school cookery clubs.
- Evaluating outcomes.

This chapter outlines the context for PHN and the principles behind the dietary recommendations that support public health policy work. It does not aim to outline the competences required by a public health dietitian or the theoretical models used to underpin ways of working. The history of our food supply and the social and economic influences on the way we eat are fascinating and important for a public health dietitian to understand, but are outside of the scope of this chapter.

Importance of public health nutrition

There has been increasing recognition that nutrition is a major and modifiable determinant of many chronic diseases, and that diet can have positive and negative impacts on health throughout life. The rising rates of obesity in the UK (and around the world) may have been responsible for this resurgence of interest and emphasise the importance of not just addressing micronutrient deficiencies in small groups, but also the need for policies to address whole systems to support people to make changes to the way they choose their food. The implication for health costs, as a result of this obesity and chronic diseases linked to obesity, are now recognised. Improving the population's diet becomes a necessity both for health and the economy. Modelled projections suggest that indirect costs of obesity (including direct NHS costs and loss of earnings) could be as high as £27 billion by 2015 [National Obesity Observatory (NOO), 2010a] (see Chapter 7.13.1).

It was estimated that 70 000 premature deaths in the UK could be prevented each year if diet matched nutritional guidelines (Strategy Unit, 2008). However, this has

recently been revised to 33 000 deaths (Scarborough *et al.*, 2011). A third of heart disease and a quarter of cancers are thought to be diet related. The largest number of these deaths could be avoided if fruit and vegetable intakes increased to meet the 5 A DAY target (400 g/day). Reducing average salt intake from 9 g to 6 g could prevent a further 20 000 deaths. A fall in saturated fat intake by 2.5% of total energy intake and added sugar by 1.75% would each make a further reduction of 3500 premature deaths (Strategy Unit, 2008).

There are consistent reports of differences in health in different geographical areas of the UK and diet has a significant impact on these geographical differences (Scarborough *et al.*, 2011). Populations in Scotland and Northern Ireland consume a diet of poorer quality than populations in England. For example, the people of Northern Ireland on average eat a diet that is 4% higher in saturated fat, 7% higher in salt and 20% lower in fruit and vegetables. In Wales, whilst the health risks from diet are similar to those in England, the average diet is higher in fruit and vegetables but also higher in saturated fat and salt.

Although obesity has been the focus for much food and health policy work, it is only one consequence of poor diet. Low levels of breastfeeding, dental caries and constipation in childhood have implications for quality of life. In addition, poor nutrition is common in adults, particularly in older age, with 25% of patients screened on admission to hospital, 41% of residents recently admitted to care homes and 19% of adults admitted to mental health units identified as being malnourished (BAPEN, 2012). The need for consistent and integrated strategies to detect, prevent and treat malnutrition in the community to prevent older people from being admitted to hospital with malnutrition is necessary and has been identified as a major healthcare cost with direct NHS costs higher than those for obesity (BAPEN, 2005) (see Chapter 6.2).

National public health policy and strategy

This section outlines the main policy and strategy documents that have set the direction for public health and PHN, and the key agencies responsible for their implementation in the UK. In the UK, following devolution, the responsibility for formulating and implementing public health policies are under the auspices of the each of the four countries of the UK. The structures, policies and agencies described here may be limited to one country of the UK. More detail of structures in the devolved administrations can be found at:

- NHS Health Scotland www.show.scot.nhs.uk.
- Health in Wales www.wales.nhs.uk.
- Department of Health, Social Services and Public Safety in Northern Ireland www.dhsspsni.gov.uk.

Healthy Lives; Healthy People

This White paper is the UK government's long term vision for the future of public health in England and is part of

the reform to the NHS in England introduced in 2010. [For full details of the NHS changes, see *Equity and Excellence: Liberating the NHS* (Department of Health, 2010a).] It marks a radical change by aiming to deliver a wellness service and to strengthen both national and local leadership. To achieve this vision, the responsibility for public health has moved from the NHS to local authorities that will take the lead in protecting and improving people's health and tackling health inequalities. Local government has the responsibility for commissioning public health services, largely determining local priorities supported by a specific grant. Embedding public health in local authorities enables joint approaches to be taken with other areas of local government work, including housing, transport, planning and children's services, and with other partners, including schools, the police, the NHS, early years services and voluntary organisations, recognised as being influential in determining how and whether people make the best choices for their health. The delivery of the public health system in England creates an unprecedented change to the way many dietitians have worked in the past.

National food and health strategy

A range of expert committees, including the Scientific Advisory Committee on Nutrition (SACN), determines national strategy.

Scientific Advisory Committee on Nutrition

The SACN is an advisory committee of independent experts that provides advice to the Department of Health as well as other government agencies and government departments. Its remit includes the nutrient content of individual foods, advice on diet and the nutritional status of people. This replaced the Committee on Medical Aspects of Food and Health Policy (COMA) in 2000.

National Institute for Health and Care Excellence

The National Institute for Health and Care Excellence (NICE) (England) provides guidance, sets quality standards and manages a national database to improve people's health and prevent and treat ill health.

Food Standards Agency

The Food Standards Agency (FSA) (England) was set up in 2000 as an independent government department to protect the public's health and consumer interests in relation to food. Following the last change of UK government, the FSA (England) is now responsible for food safety and food hygiene. Responsibility for nutrition and food policy issues, other than food safety and food hygiene, moved from the FSA to the Department of Health and Department for Food, Environment and Rural Affairs (Defra) in 2010.

Department of Health – nutrition policy

Since 2010 the Department of Health in England has been responsible for obesity and nutrition policy through the health and wellbeing directorate (Department of Health 2010b). Nutrition schemes managed by this directorate include:

- Healthy Start.
- Nursery milk.
- School fruit and vegetable schemes.
- Breastfeeding, nutritional science and delivery, and obesity programmes (including nutritional labelling, food promotion, and strategy).

Department for Environment, Food and Rural Affairs

The Defra (England) is the government department covering:

- The natural environment, biodiversity, plants and animals.
- Sustainable development and the green economy.
- Food, farming and fisheries – including food labelling.
- Animal health and welfare.
- Environmental protection and pollution control.
- Rural communities and issues.

It is developing the government's commitment to ensuring food procured by government departments, and eventually the whole public sector, meets British standards of production or their equivalent and nutritional quality, wherever this can be achieved without increasing overall costs. The government buying standards for food and catering aim to enhance the competitiveness and resilience of the whole food chain, including farms and the fishing industry, to ensure a secure, environmentally sustainable and healthy supply of food with improved standards of animal welfare (Defra, 2011a).

Health inequalities

The link between inequalities and poor diet is identified in the following strategies; Tackling Health Inequalities: A Programme for Action (Department of Health, 2003) and Fair Society Healthy Lives, A Strategic Review of Health Inequalities in England (Marmot, 2010).

Public health policy structures in devolved governments

All three devolved governments have a specialist public health agency to support the delivery of public health in the country.

Scotland

Food Standards Agency Scotland

Following the transfer of responsibility for nutrition and food labelling in England from the FSA to the Department of Health and Defra, the Scottish government established a review of services. The recommendations of that review

have been accepted by the Scottish government which has created a new independent FSA for Scotland responsible for food safety, food standards, nutrition, food labelling and meat inspection.

NHS Health Scotland (National Health Board)

In Scotland, NHS Health Scotland is the national agency for health improvement. The role and direction of NHS Scotland in prioritising health inequalities are described in A Fairer Healthier Scotland – Corporate Strategy 2012–2017 (NHS Scotland, 2012).

Wales

Public Health Wales

Public Health Wales is a specialist NHS Trust and it provides an expert public health resource as part of the NHS in Wales. In Wales, the FSA continues to lead on general food labelling policy and food labelling law enforcement, although responsibility for nutrition labelling policy is now with the Welsh government.

Northern Ireland

In Northern Ireland, the FSA has retained responsibility for all aspects of general food labelling and nutrition labelling policy, including liaison with food authorities.

A healthy diet

A healthy diet is one that provides adequate energy and nutrients to promote good health over a life time, delaying or reducing the risk of diet related disease. The goal for healthy living for the population is to promote healthy eating patterns combined with adequate physical activity, and to ensure these health enhancing behaviours become the norm among all individuals. Diets high in salt, saturated fat and sugar, and low in fruit and vegetables and fibre increase the risk of ill health. A poor diet is associated with increased risk of high blood pressure, cardiovascular disease (NICE, 2010) and some cancers (WCRE, 2007). Consuming foods and drinks that are high in fat and/or sugars too frequently can contribute to weight gain, which has many negative effects on health.

Recommendations and key messages for a healthy diet have been remarkably consistent over the last three decades. Quantitative dietary targets for the prevention of a range of diseases associated with affluence were first published in the UK in 1983 (NACNE). The targets outlined a reduced consumption of fat, saturated fat, sugar and salt, and an increase in fibre consumption by the general population. Until this time nutritional policy had focused on reducing the incidence of nutritional deficiencies.

New evidence has added to the understanding of the complexity of the interaction between nutrients and health, and provided answers as to why certain foods seem to be protective. Additional knowledge about the interaction of various nutrients and biologically active compounds in food build on the understanding that a

healthy diet should be met by eating a variety of foods in the right amounts. Only in a small number of instances may fortified foods and supplements be required to ensure an optimum nutrient intake.

What is eaten and attitudes to food have however changed markedly in recent years. In the UK, consumers are better informed and are more interested in the provenance, quality and other characteristics of foods and the impact these have on health and on the environment (Strategy Unit, 2008; FSA, 2012). This interest is reflected in the variety of produce in supermarkets, the growth of places to buy or eat food out of the home, the popularity of TV cookery programmes and the media's enthusiastic coverage of food issues (Strategy Unit, 2008). For consumers, many factors compete for a position in the decision of what foods to buy, including price, ingredients, quality, nutrition, provenance, and production and transportation methods.

Role of food price and choice

Changes in consumption and attitude to food have occurred in a period of relative affluence. Food costs, until recently, have been proportionately falling as consumers' disposable income has increased. Food prices have risen more slowly than the retail price index since 1975 and foods are significantly cheaper in real terms than in 1975 (Defra, 2009). Commodity prices are now rising and real food cost increases are starting to add to a family's cost of living. The price of wheat, maize and oilseed crops doubled between 2005 and 2007 and, whilst these prices have seen some falls, there are some permanent factors underpinning prices that will maintain these higher average levels (OECD-FAO, 2008). Recently, food prices have been rising more rapidly than prices generally; they rose by 5.5% on average during 2010 compared with 3.3% for overall inflation (Defra, 2011b). This price increase will hit those with the least income hardest. Households in the lowest income groups spend 16% of their disposable income on food (includes all foods and non-alcoholic drinks), whilst those with the highest income spend only 8% of their income on food (ONS, 2010). This is because low income consumers spend proportionately more on food staples such as milk, eggs and bread, which are hit hard by food price rises. Consumers see some food categories as an essential part of food shopping and will continue to buy them regardless of price; other food categories are more sensitive to price change and have shown a decline in sales; potato and fruit sales have fallen as prices have risen (Defra, 2009). Providing a healthy diet for families will be an additional challenge to those living in low income households who are already suffering a disproportionate amount of diet related ill health.

Environmental impact of food choice

Food not only has an impact on health; the way food is grown, processed, stored, distributed, retailed and disposed of has significant economic and environmental

impacts. Concerns about current food consumption in the UK and its impact on health and economic, social and environmental sustainability were raised by the UK government in 2008, which came to the conclusion that the way people currently eat is not sustainable for either health or the environment (Strategy Unit, 2008).

There is an increasing recognition that a healthy diet must also be one that is produced in a sustainable way. Definitions of sustainability differ but generally encompass the three domains of equitable economic development, participatory democratic structures and greater environmental integrity. A much quoted definition of sustainable development is development that *'meets the needs of the present without compromising the ability of the future generations to meet their own needs'* (WCED, 1987).

The Climate Change Act (2008) sets out targets for greenhouse gas emissions (GHGs). At present it is estimated that 18–20% of GHGs in the UK come from the food chain (Macdiarmid *et al.*, 2011). Changes in food production and food consumption will be needed to contribute to the necessary reductions in GHGs.

There is considerable debate about the recommendations for healthy, safe, sustainable, low environmental impact food. A sustainable food system has been defined as *'food associated with high levels of well-being, social justice, stewardship and system resilience'* (NEF, 2011); a vision that fits well with the holistic approach of public health. It is recognised that *'in terms of the environmental impact of household food consumption, the composition of our diet is more important than how and where food items are produced'* (NEF, 2011). Research has shown that diets would not need to change greatly from current recommendations for health to achieve this reduction in GHGs (Macdiarmid *et al.*, 2011). A single consistent message is needed to prevent confusing consumers. There is general agreement on a set of principles that meets the needs for health and the environment (Table 4.2.1).

The priorities for food and farming are to support and develop British farming and encourage sustainable production by increasing the resilience of the whole food chain, including farming and the fishing industry, to produce a healthy sustainable supply of healthy food with increased standards of animal husbandry (Department of Health, 2011a). The government has a role in encouraging all public sector catering to meet more sustainable standards for the food bought and prepared. More than 50% of the total energy consumption of the UK catering industry is in non-commercial catering such as schools, hospitals and defence organisations (Department of Health, 2011a). Government buying standards are starting to develop criteria to support a more sustainable food system.

Reducing food waste and excessive packaging, and ensuring efficient disposal where waste does occur, are also crucial to reducing the greenhouse gas effect of waste management and meeting the European Union landfill directive to divert biodegradable waste from landfill sites. In the UK 8.3 million tonnes of food and drink are thrown

Table 4.2.1 Principles that meet the needs for health and the environment

Principle	Health benefits	Climate change benefits
Eat more plants	More fruit and vegetables – known risk reduction for coronary heart disease and stroke	Replaces resource intensive animal production
Waste less food	Economic advantages. A healthy diet is perceived as expensive – buying less of better nutritional quality could be achieved	Reduce the 40% of food planted worldwide that is currently wasted
Eat less meat	May reduce saturated fat intake, especially if processed meats. High intakes increase risk of certain cancers. Potential for detrimental reduction in iron intakes must be considered	Reduces resource intensive animal production
Eat less processed foods	Often high in fats, salt and sugars	Resource intensive production, storage and distribution
Choose certified foods	No recognised health benefit	Improved animal welfare, maintenance of stocks

away each year. Most of this is avoidable and could be eaten if planning, storage and management improved [Waste and Resources Action Programme (WRAP), 2009]. Of the avoidable food and drink waste, 2.2 million tonnes is thrown away due to cooking, preparing or serving too much and a further 2.9 million tonnes is thrown away because it was not used in time. This equates to the average UK family spending around £480 per year, increasing to £680 for families with children, on food and drink that could have been used but is thrown away. The GHGEs that this waste food produces is 20 million tonnes; removing this waste is equivalent to the reduction in emissions from taking one in four cars off the roads (WRAP, 2009).

Population dietary guidance that takes nutrition, food safety and sustainability of the food supply into account is urgently needed to ensure that consumers are not confused by competing messages. The public is generally in support of making change to mitigate climate change, but when given a list of possible behaviours to achieve this, adopting a lower impact diet was one they were least likely to try (Defra, 2008). This will be a challenge for public health dietitians in the near future.

Scientific basis for a healthy diet

Clear consistent messages for the general public are important to maintain consumer confidence and support behaviour changes towards a healthier diet. Healthy eating advice for the general public is based on nutrient based guidelines for the population and a set of dietary goals.

Dietary reference values

These are quantified nutrient based guidelines for different population subgroups of the UK for the energy and essential macro- and micro-nutrients to prevent nutritional deficiencies. The COMA (Department of Health, 1991) published dietary recommended values (DRVs) and SACN (2011) revised the reference values for energy in 2011. The European Food Safety Authority (EFSA) sets

European DRVs for nutrients as a basis for consistency across Europe and as reference values in food labelling (EFSA 2010a,b). Recommended daily allowances (RDAs) are used across all European countries to provide a set of standard figures for food labelling. They are based on DRVs, with small differences, and are used only for food labelling.

Dietary reference values are benchmark intakes of energy and nutrients. They indicate the amount of energy or individual nutrients needed by a group of people of a certain age range (and sometimes gender) for good health. They are appropriate for assessing population intakes and should not be used for designing a diet for an individual (see Chapter 2.1).

The DRVs for energy are described as the estimated average requirement (EAR). Most other nutrients have an EAR and also a reference nutrient intake (RNI) and a lower reference nutrient intake (LRNI). These terms are described as:

- *Estimated average requirement (EAR)* – an estimate of the average requirement of energy or a nutrient needed by a group of people. Half the population will have needs greater than this, and half will have needs below this amount.
- *Reference nutrient intake (RNI)* – the amount of a nutrient that is enough to meet the dietary requirements of nearly all of a group of people (about 97%). If people get more than this amount, they will almost certainly be getting enough.
- *Lower reference nutrient intake (LRNI)* – the amount that is sufficient for the 3% of a group of people with the smallest needs. Most people will have needs greater than this.
- *Safe intake* is used where there is insufficient evidence to set an EAR, RNI or LRNI. The safe level is judged to be enough for almost everyone but is below a level that could have undesirable effects.

Nutritional requirements at different life stages are shown in Table 4.2.2 [Public Health Action Support Team (PHAST), 2008].

Table 4.2.2 Nutritional requirements at different life stages [source: Public Health Action Support Team (PHAST) (2008, Table 1). Reproduced with permission of Hannah Pheasant]

Age	Requirements
Infants	First 4–6 months of life (period of rapid growth and development) – breast milk (or infant formula) contains all the nutrients required Between 6–12 months – requirements for iron, protein, thiamine, niacin, vitamin B ₆ , vitamin B ₁₂ , magnesium, zinc, sodium and chloride increase Department of Health advice recommends exclusive breastfeeding until 6 months of age, with weaning introduced at 6 months
1–3 years	Energy requirements increase (children are active and growing rapidly) Protein requirements increase slightly Vitamins requirements increase (except vitamin D) Mineral requirements decrease for calcium, phosphorus and iron, and increase for the remaining minerals (except for zinc)
4–6 years	Requirements for energy, protein, all the vitamins and minerals increase, except vitamins C and D and iron
7–10 years	Requirements for energy, protein, all vitamins and minerals increase, except thiamine and vitamins C and A
11–14 years	Requirements for energy continue to increase and protein requirements increase by approximately 50% By the age of 11, the vitamin and mineral requirements for boys and girls start to differ: Boys: increased requirement for all the vitamins and minerals Girls: no change in the requirement for thiamine, niacin and vitamin B ₆ , but there is an increased requirement for all the minerals. Girls have a much higher iron requirement than boys (once menstruation starts)
15–18 years	Boys: requirements for energy and protein continue to increase, as do the requirements for a number of vitamins and minerals (thiamine, riboflavin, niacin, vitamins B ₆ , B ₁₂ , C and A, magnesium, potassium, zinc, copper, selenium and iodine). Calcium requirements remain high as skeletal development is rapid Girls: requirements for energy, protein, thiamine, niacin, vitamins B ₆ , B ₁₂ and C, phosphorus, magnesium, potassium, copper, selenium and iodine all increase Boys and girls have the same requirement for vitamin B ₁₂ , folate, vitamin C, magnesium, sodium, potassium, chloride and copper. Girls have a higher requirement than boys for iron (due to menstrual losses) but a lower requirement for zinc and calcium
19–50 years	Requirements for energy, calcium and phosphorus are lower for both men and women than in adolescents, and there is a reduced requirement in women for magnesium and in men for iron The requirements for protein and most of the vitamins and minerals remain virtually unchanged in comparison to adolescents (except for selenium in men which increases slightly)
Pregnancy	Increased requirements for some nutrients Women intending to become pregnant and for the first 12 weeks of pregnancy are advised to take supplements of folic acid Additional energy and thiamine are required only during the last 3 months of pregnancy Mineral requirements do not increase
Lactation	Increased requirement for energy, protein, all the vitamins (except B ₆), calcium, phosphorus, magnesium, zinc, copper and selenium
50+ years	Energy requirements decrease gradually after the age of 50 in women and after age 60 in men as typically become less active and with a reduced basal metabolic rate Protein requirements decrease for men but continue to increase slightly in women The requirements for vitamins and minerals remain virtually unchanged for both men and women After the menopause, women's requirement for iron is reduced to the same level as that for men After the age of 65, there is a reduction in energy needs but vitamins and minerals requirements remain unchanged. This means that the nutrient density of the diet is even more important

Dietary reference values are translated into dietary recommendations as shown in Table 4.2.3 (SACN, 2008). Values for total fat, saturated fat and non-extrinsic milk sugars are set as a percentage of food energy. Additional recommendations are included for maximum daily salt intakes for infants and children (SACN, 2003), as shown in Table 4.2.4.

Dietary guidelines

Dietary guidelines are food based advice for healthy eating. Food based guidelines for the general public translate the recommendations for nutrient intakes based on the DRVs and population goals described earlier into

foods. The NHS provides advice on nutrition and healthy eating at www.nhs.uk/homepage.aspx. This advice centres on the eatwell plate and eight tips for eating well, including advice on eating at least five portions of fruit and vegetables a day, the recommended maximum daily intake of salt for children and adults, and hydration.

The recommendations are that everyone should eat a diet that contains:

- Plenty of starchy foods, such as rice, bread, pasta and potatoes (choosing wholegrain varieties when possible).
- Plenty of fruit and vegetables; at least five portions of a variety of fruit and vegetables a day.

Table 4.2.3 Summary of the dietary recommendations for the UK (adapted from Webster-Gandy 2011, table 2.1, p. 26. Reproduced with permission of Oxford University Press)

Recommendation		Population group	Reason for recommendation
Fruit and vegetables	>5 × 80 g/day (400 g)	Adults	↓ Risk of some cancers, CVD and other chronic conditions
Oily fish	>1 portion/week (140 g)	Adults	↓ CVD risk
Red and processed meat	Consider ↓ intake	All red meat consumers	↓ Cancer risk
NMES	<11% food energy*	All	NMES contribute to development of dental caries
Fat	<35% food energy	All	↓ CVD risk, ↓ energy density of diet
Saturated fat	<11% food energy	All	↓ CVD risk, ↓ energy density of diet
Non-starch polysaccharide	>18 g/day	Adults	Improves gastrointestinal health
Alcohol	<3–4 units/day men <2–3 units/day women	Adults (>18 years)	↓ Risk liver disease, CVD, cancer, injury from violence or accidents
Salt	<6 g/day	Adults	↓ Risk hypertension and CVD
Vitamins and minerals	DRVs	All	To prevent deficiencies and promote growth
Dietary vitamin D	DRV for young children, adults >65 years, pregnant and breastfeeding women Others with limited sun exposure also require dietary vitamin D	All	To prevent deficiency
Supplements**	Vitamin D	Older adults, housebound or living in institutions or who eat no meat or oily fish	To achieve adequate vitamin D status and ↓ risk of poor bone health

*Energy consumed as food and drink excluding alcohol.

**Vitamin D supplements are also recommended for pregnant and lactating women.

CVD, cardiovascular disease; DRVs, dietary reference values; NMES, non-milk extrinsic sugars.

Table 4.2.4 Recommended maximum daily salt intakes

Age	Target for average salt intake (g/day)
0–6 months	<1
7–12 months	1
1–3 years	2
4–6 years	3
7–10 years	5
11+ years	6

- Some protein rich foods, such as meat, fish, eggs, beans and non-dairy sources of protein, e.g. nuts and pulses.
- Some milk and dairy products, choosing reduced fat versions or eating smaller amounts of full fat versions or eating them less often.
- A small amount of foods and drinks high in fat and/or sugar.

Avoiding dehydration is also considered with a recommendation that adults drink between six and eight glasses (about 1.2L) of water, or other fluids. Since this advice was published, the EFSA (2010) has published recommendations on water intake (see Chapter 6.6).

The eatwell plate

The eatwell plate (Department of Health, 2007) is a pictorial representation of the recommendations for a healthy diet for the population and is relevant for all adults and children over the age of 5 years. This food based guidance aims to help consumers understand how to achieve a healthy diet and reflects recommendations for nutrient intake based on advice from COMA and the SACN. The eatwell plate (Figure 4.2.2) gives a visual illustration of the types and proportions of foods needed for a healthy and well balanced diet. The sections of the plate show how much of each food group should contribute to a healthy diet. The sections include:

- Bread, rice, potatoes, pasta and other starchy foods.
- Fruit and vegetables.
- Milk and dairy foods.
- Meat, fish, eggs, beans and other non-dairy sources of protein, and foods and drinks high in fat and/or sugar.

Whether people are eating out, eating at work or cooking food at home, the eatwell plate is designed as a useful reminder of what types of foods to eat more of and which to eat less of.

The eatwell plate does not include references to frequency of serving or recommended portion sizes, other than in relation to:

Use the eatwell plate to help you get the balance right. It shows how much of what you eat should come from each food group.

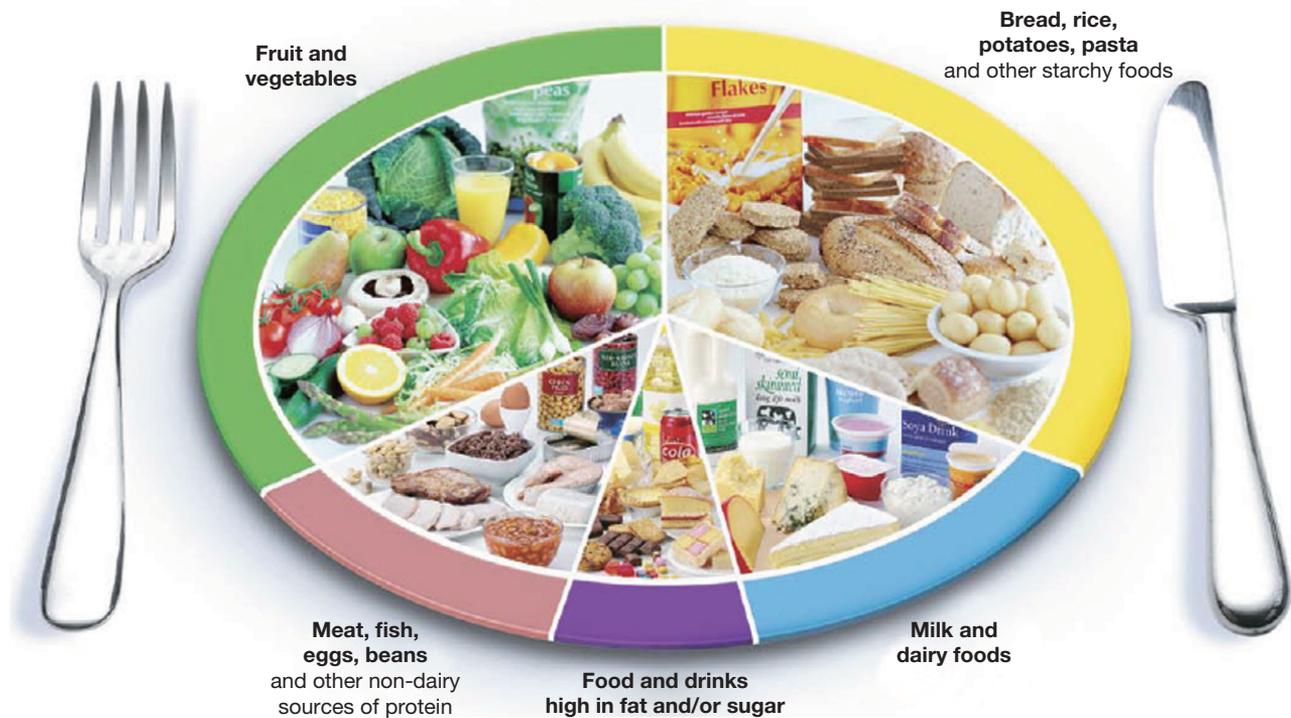

Figure 4.2.2 The eatwell plate (source: Department of Health 2012. Reproduced with permission of the Department of Health)

- Fruit and vegetables – at least five portions of a variety a day.
- Fish – eat two portions a week, one of which should be oily.

It is intended as a general educational model for use with most adult population groups (and children over 5 years). The calculation of each segment size was based upon quantitative guidelines for the consumption of foods within each of the five food groups to ensure a national average diet, that is consistent with DRVs. Portion size data were obtained from the Dietary and Nutritional Survey of British Adults (Gregory *et al.*, 1990) and was converted to amounts to be consumed on a weekly basis as a percentage of the total. The five food groups were as follows:

- Bread, other cereals and potatoes (34%).
- Fruit and vegetables (33%).
- Meat, fish and alternatives (15%).
- Milk and dairy products (12%).
- Fatty and sugary foods (7%).

NB: the total is 101% due to rounding of percentages.

The segments represent the proportion that the food group should make towards the whole diet. Individuals differ in the amount of energy they require and energy requirements will affect the total amount of food that an

individual needs. However much energy people need, the proportion of food from the different groups should remain the same, as shown in the eatwell plate (Hunt *et al.*, 1994a,b, 1995a,b; Gatenby *et al.*, 1995).

As the eatwell plate is a general model for the population based on the proportions of food needed, it is not appropriate to include specific frequency or portion advice. However, dietitians working with individuals can tailor advice in consultations, based upon the individual's current diet and food preferences, to include guidance on frequency of servings and appropriate portion size in line with the eatwell plate model, as shown in Table 4.2.5. A suggested number of servings is included but this should be used with caution; a serving is an imprecise measure and will be interpreted very differently by individuals. A good understanding of an individual's eating pattern and cooking habits is needed before offering advice in this way. Different population groups will need different serving sizes. It is the proportion of food on the plate that is important; the total amount will vary with each different population group. The eatwell plate model illustrates the following important key points:

- The need for a change in the proportions of food that should be eaten. Starchy foods and fruit and vegetables are an important part of the meal, and meals should be based on the starchy food supplemented with large amounts of fruit and vegetables and smaller amounts

Table 4.2.5 Suggested proportions of the food groups on which the eatwell plate is based

Food group	Food Included	Key messages	Proportion to be eaten	Amount to be eaten	Main source of nutrients
Bread, rice, potatoes, pasta and other starchy foods	Bread, rolls, chapattis, pitta bread, naan bread, crispbread, muffins, scones, crumpets Breakfast cereals Pasta, rice, potatoes	Eat plenty, choose wholegrain varieties when you can	About 33%	For most people this is between six and nine portions/day This is probably more than people commonly consume	Carbohydrate Fibre (particularly insoluble fibre) B vitamins Some calcium (added to bread products) and iron
Fruit and vegetables	All fresh, frozen, tinned, juiced, pulped and dried fruit and vegetables (except potatoes – which are included as a starchy food because of the function they serve in the diet) Includes concentrates and smoothies	Eat plenty, at least five portions of a variety of fruit and vegetables a day	About 33%	At least 400 g of a variety of fruit and vegetables Currently not achieved by many	Vitamin C, carotenes, antioxidants Folate, soluble and insoluble fibre Potassium
Milk and dairy foods	Milk, cheese, yogurt, fromage frais, crème fraîche	Eat some, choose lower fat alternatives whenever possible or eat higher fat versions infrequently or in smaller amounts	About 15%	Two to three servings per day (a serving = 200 mL of milk, a small piece of cheese (40 g) or a small pot of yogurt)	Calcium, protein, riboflavin, vitamins A and D (in full fat products only)
Meat, fish, eggs, beans and other non-dairy sources of protein	Meat, poultry, fish, offal, processed meat and fish products Soya, tofu and mycoproteins (Quorn™) Pulses Nuts	Eat some, choose lower fat alternatives whenever possible or eat higher fat versions infrequently or in smaller amounts Aim for at least two portions of fish a week, including a portion of oily fish	About 12%	Two servings per day Maximum of 70 g of red meat At least one portion of oily fish/week Commonly misunderstood as needing to be eaten in larger amounts	Protein, iron, B vitamins, zinc, magnesium
Foods and drinks high in fat and/or sugar	High in fat – butters, margarines, vegetable fat spreads, oils, mayonnaise and dressings, cream/cheese/curry sauces and fatty gravy, pastry, savoury snacks High in sugar – cakes, biscuits, puddings, ice cream, chocolate and other sweets, fizzy drinks	Eat a small amount	8%	Not a nutritional requirement but add variety and interest Most people eat too much	Some vitamins and essential fatty acids but usually combined with excess fat, sugar and/or salt

of protein rich meat or alternatives and dairy produce. The concept of meal planning should not revolve around meat and two vegetables (one of which, in this traditional model, was potato), but rather larger amounts of starchy carbohydrate with a small amount of meat and a large salad.

- All foods can be included as it is the proportion of foods over time. Some foods are eaten in larger amounts or more frequently and others in smaller amounts or less frequently.
- A healthy diet can be flexible and encourages a variety of foods.
- No one food is better than another – it is the balance of all foods that is needed to get the complement of all macro- and micro-nutrients. The concept of good and bad foods is not helpful as all foods can be included if the proportions are right.

An additional key message is to try to choose options that are lower in salt when possible.

The eatwell plate model is now increasingly well recognised. A recent survey exploring food attitudes and behaviours (FSA, 2011) showed that 21% of respondents, when shown a blank plate with the eatwell sections marked but not labelled, could place all the food groups in the correct proportions on the plate. Most respondents (64%) placed three food groups correctly. Younger people were more likely to place all foods correctly, as were people in professional/managerial households. Most people (84%) understood the messages about foods and drinks high in fat and/or sugar and could identify them as fitting in the smallest portion of the eatwell plate.

The most commonly misplaced sections were meat, fish and other sources of protein, which were judged to be eaten in too large amounts (placed in a large section rather than in a medium sized section), and starchy foods, which were judged to be eaten in too small amounts (placed in a medium section rather than in a large section). Fruit and vegetables were placed correctly in one of the largest sections by 82% of respondents. Similarly, 80% correctly placed the milk and dairy foods in a medium section.

Eight tips for eating well

In addition to the eatwell plate, the dietary guidelines include eight tips for healthy eating. The tips are:

1. Base meals on starchy foods.
2. Eat lots of fruit and vegetables.
3. Eat more fish.
4. Cut down on saturated fat and sugar.
5. Try to eat less salt.
6. Get active and try to be a healthy weight.
7. Drink plenty of water.
8. Do not skip breakfast.

Table 4.2.6 summarises the advice for each tip. Full details can be found at www.nhs.uk/Livewell/Goodfood/Pages/eight-tips-healthy-eating.aspx.

Additional guidance

There is additional guidance to support the eatwell plate and the tips for eating well.

Bread, rice, potatoes, pasta and other starchy foods

The advice is to eat plenty of bread, rice, potatoes, pasta and other starchy foods, and to choose wholegrain varieties when possible. Media attention to celebrity diets has resulted in many consumers believing these foods are high in energy or to be avoided to promote weight loss. Consumers' attitude surveys show that the required proportion of carbohydrate foods is often underestimated (FSA, 2011). People may need to be reassured that they need to increase the amount of these foods in their diet to reach the recommended amount. However, there is no scientific consensus on the optimal macronutrient composition for weight management diets (Abete *et al.*, 2010; SIGN, 2010; Grace, 2011). It has been shown that a reduced energy intake results in weight loss regardless of which macronutrients are emphasised (Sacks *et al.*, 2009). This group provides foods that have a low energy density and a high volume. Choosing foods that are less energy dense results in larger portion size, which helps to control hunger. The intake of total carbohydrate (primarily by this food group) should provide 50% of the total energy intake for both adults and children over the age of 5 years.

Traditionally, these foods are served with added fat, e.g. fried potatoes and butter on bread, and it is this added fat that increases the energy density and leads to a high energy content food item. Advice needs to focus on changing cooking styles and eating behaviours to increase these foods whilst using minimum amounts of fat (e.g. substituting butter for a lower fat spread, oven baking potatoes rather than frying, having larger amounts of rice or pasta and less fatty sauce). Wholegrain cereals and breads, brown rice and whole wheat pasta should be encouraged to increase fibre content, increase satiety and prevent constipation. Most breakfast cereals are fortified with additional micronutrients and can be a valuable dietary source of folic acid, other B vitamins and iron.

Fruit and vegetables

The advice is to eat plenty; at least five portions of a variety of fruit and vegetables a day. Fruit and vegetables are an important component of a healthy diet and if eaten regularly in sufficient amounts, can prevent major diseases such as heart disease, stroke and certain cancers. Low fruit and vegetable intake is estimated to cause 31% of ischaemic heart disease and 11% of strokes worldwide (WHO, 2002). In the UK, the message for 5 A DAY was developed from the joint FAO/WHO global strategy on diet, physical activity and Health (FAO/WHO, 2003). The recommendation was for a minimum of 400 g of fruit and vegetables per day (excluding potatoes and other starchy tubers) for the prevention of chronic diseases such as heart disease, cancer, diabetes and obesity, as well as for the prevention and alleviation of several micronutrient deficiencies, especially in developing countries. The FAO/WHO recommendation added to the already strong

Table 4.2.6 The eight tips for eating well (adapted from NHS Choices. www.nhs.uk/Livewell/Goodfood/Pages/eight-tips-healthy-eating.aspx)

Tip	Details
1. Base meals on starchy foods	Starchy foods include potatoes, cereals, pasta, rice and bread Choose wholegrain varieties when possible; they contain more fibre and can make you feel full for longer. Starchy foods should make up around one-third of the foods you eat Most of us should eat more starchy foods: try to include at least one starchy food with each main meal. Some people think starchy foods are fattening, but gram for gram they contain fewer than half the calories of fat
2. Eat lots of fruit and vegetables	It is recommended that we eat at least five portions of different types of fruit and vegetables a day. This is easier than it sounds. A glass of 100% unsweetened fruit juice can count as one portion, and vegetables cooked into dishes also count. Why not chop a banana over your breakfast cereal or swap your usual mid-morning snack for some dried fruit?
3. Eat more fish	Fish is a good source of protein and contains many vitamins and minerals. Aim for at least two portions a week, including at least one portion of oily fish. Oily fish is high in n-3 fats, which may help to prevent heart disease. You can choose from fresh, frozen and canned; but remember that canned and smoked fish can be high in salt Oily fish include salmon, mackerel, trout, herring, fresh tuna, sardines and pilchards Non-oily fish include haddock, plaice, coley, cod, tinned tuna, skate and hake Anyone who regularly eats a lot of fish should try to choose as wide a variety as possible
4. Cut down on saturated fat and sugar	We all need some fat in our diet. But it is important to pay attention to the type of fat we are eating. There are two main types of fat: saturated and unsaturated. Too much saturated fat can increase the amount of cholesterol in the blood, which increases your risk of developing heart disease. Saturated fat is found in many foods, such as cakes, pies, biscuits, sausages, cream, butter, lard and hard cheese. Try to cut down on these, and choose foods that contain unsaturated rather than saturated fats, such as vegetable oils, oily fish and avocados Most people in the UK eat too much sugar. Sugary foods and drinks are often high in calories and can contribute to weight gain. They can also cause tooth decay, especially if eaten between meals. Cut down on sugary fizzy drinks, cakes, biscuits and pastries, which contain added sugars: this is the kind of sugar we should be cutting down on rather than sugars that are found naturally in foods such as fruit and milk. Food labels can help: use them to check how much sugar foods contain. More than 15g of sugar/100g means that the food is high in sugar
5. Try to eat less salt	Even if you do not add salt to your food, you may still be eating too much. About three-quarters of the salt we eat is already in the food we buy, such as breakfast cereals, soups, breads and sauces. Eating too much salt can raise your blood pressure. People with high blood pressure are more likely to develop heart disease or have a stroke. Use food labels to help you cut down. More than 1.5g of salt/100g means the food is high in salt. Adults and children over 11 should eat no more than 6g of salt/day. Younger children should have even less
6. Get active and try to be a healthy weight	Eating well plays an important part in maintaining a healthy weight, which is an important part of overall good health. Being overweight can lead to health conditions such as high blood pressure, heart disease or diabetes. Being underweight could also affect your health. If you are trying to lose weight, healthy food choices will help: aim to cut down on foods that are high in fat and sugar, and eat plenty of fruits and vegetables. If you are worried about your weight, ask your GP or a dietitian for advice Physical activity can help you to maintain a healthy weight. Being active does not have to mean hours at the gym: you can find ways to fit more activity into your daily life. For example, try getting off the bus one stop early on the way home from work and walking
7. Drink plenty of water	Try to drink about six to eight glasses (1.2L) of water (or other fluids) a day to prevent dehydration. When the weather is warm or when you are active, you may need more. But avoid soft and fizzy drinks that are high in added sugars. Remember: When thinking about alcohol, there is nothing wrong with the occasional drink, but drinking too much can cause serious health problems. Alcohol is also high in calories, so cutting down could help you to control your weight
8. Do not skip breakfast	Some people skip breakfast because they think it will help them lose weight. In fact, research shows that eating breakfast can help people control their weight. A healthy breakfast is an important part of a balanced diet, and provides some of the vitamins and minerals we need for good health. Wholemeal cereal with fruit sliced over the top is a tasty and nutritious breakfast

evidence that fruit and vegetables had important health benefits and gave a quantified target for action. Up until this point, while the health benefits of fruit and vegetables were recognised, advice was to eat more fruit and vegetables with no guidance on the quantities required (Williams, 1995).

As further evidence emerges from large cohort studies, it is becoming clear that specific cancers (head, neck,

mouth, larynx, oesophagus, bowel and lung), although not all cancers, may be prevented by higher intakes of fruit and vegetables (Boffeta *et al.*, 2010). There may be additional benefits in eating larger amounts as there is an association between higher intakes of fruit and vegetables and the prevention of heart disease. Results from the large observational European Prospective Investigation into Cancer and Nutrition (EPIC) – Heart study (Crowe

et al., 2011) suggested that a higher intake of fruit and vegetables is associated with a reduced risk of ischaemic heart disease (IHD) mortality. Participants consuming at least eight 80-g portions of fruit and vegetables a day had a 22% lower risk of fatal IHD compared with those only consuming three portions a day. As with all observational studies, it remains unclear if this association is the cause of the reduced risk and what the biological mechanism might be.

The message of the 5 A DAY programme has received year on year recognition since it was launched in the UK in 2004. Eating at least five portions of a variety of fruit and vegetables is an important part of healthy eating and is the target for the UK population who, whilst improving their intakes, are still not achieving this recommendation. Current intakes are estimated to be 4.2 portions/day (Bates *et al.*, 2011) for adults (aged 19–64 years) and older adults (aged 65 years and over) consumed 4.4 portions. Thirty per cent of adults and 37% of older adults met the recommendation. There remain wide variations between different socioeconomic groups. Promoting fruit and vegetables as snacks is an important way to achieve the 5 A DAY target. Dried fruit is less suitable for between meal snacks because of its cariogenic potential.

Milk and dairy foods

Lower fat varieties of foods from this group (semi skimmed, 1% and skimmed milk and reduced fat cheeses and yogurts) should be chosen when possible. Lower fat varieties contain the same amounts of calcium, protein and riboflavin as the full fat equivalents, but less fat and energy. Due to their lower energy density and lower content of fat soluble vitamins, which are removed when removing the fat, they are unsuitable for children under 2 years, some older people and those who are nutritionally depleted.

Pregnant women should not drink unpasteurised milk, and should avoid soft blue cheese other soft cheeses such as brie and camembert and others with similar rind, whether they are pasteurised or not. These foods can contain high levels of *Listeria*, bacteria that can cause miscarriage, stillbirth or severe illness in a newborn baby.

Meat, fish, eggs, beans and other non-dairy sources of protein

These foods are all good sources of protein and a range of vitamins and minerals. Around 15% of dietary energy should come from protein.

Meat

Meat is a good source of protein, vitamins and minerals, such as haem iron, zinc and B vitamins; it is one of the main sources of vitamin B₁₂. Farming and butchering practices have changed over the last 20 years to ensure that leaner cuts of meat are available. Lean meat is relatively low in fat and approximately 50% of that fat is monounsaturated in composition. Processed meat products can contain high levels of fat.

In 1998 COMA (Department of Health, 1998) reported possible links between red and processed meat consump-

tion and risk of colorectal cancer. Since that time the accumulating evidence has generally supported that association. The SACN (2010) advised that it is not possible to quantify the amount of red and processed meat that may be associated with increased colorectal cancer risk because of limitations and inconsistencies in the data. However, it advises that adults with relatively high intakes of red and processed meat [defined as those consuming over 90 g (cooked weight) of red and processed meat/day] should consider reducing their intakes. Reducing this intake to the average intake of 70g/day is thought likely to have little impact on numbers of the population with low iron intakes.

Fish

The majority of the UK population does not consume enough fish, particularly oily fish, and should be encouraged to increase consumption to at least two portions of fish a week, of which one should be oily for the benefit of the n-3 fatty acids that they contain (SACN, 2004). Concerns about the risk of heavy metal contamination in large oily fish (shark, marlin, swordfish) has led to a recommendation that women of reproductive age and girls should not eat more than one to two portions/week of these.

Offal

Liver and kidney are good sources of haem iron. However, pregnant women should avoid liver or liver products due to their high levels of vitamin A; excess vitamin A is harmful to the foetus.

Eggs

Eggs are a good source of protein as well as vitamins and minerals, and can form part of an easily prepared meal. It is important to store, handle and prepare them properly to avoid any risk of food poisoning, particularly for vulnerable groups such as children, anyone who is immune suppressed and older people. There is no limit on the numbers of eggs a healthy person can consume as part of a healthy diet. Although eggs contain dietary cholesterol, this is not a significant concern and eggs consumed within the normal range of intake will have little effect on blood cholesterol. Eggs are relatively low in total and saturated fat.

Pulses

Pulses (beans and lentils) have a high protein content and a low glycaemic index, provide soluble fibre and are a good source of minerals and trace elements. They are useful either to supplement meat products to reduce fat and red meat content or to replace meat. Canned pulses (baked beans, red kidney beans and chickpeas) are a convenient and cheap source of protein. Pulses, despite being a vegetable, are included in the protein food group because of their role as a meat alternative. However, they can also count as one of the 5 A DAY. However, their inclusion is limited to being counted as only one of the five portions, regardless of how many portions are consumed, in recognition that they are less rich in vitamins and other phytochemicals than other vegetables.

Other non-meat alternatives

This includes soya, tofu and mycoproteins (Quorn™), which in their unprocessed forms are relatively low in fat, especially saturated fat, and are suitable alternatives for people wanting to eat less meat or for vegetarians. An increasing number of products are being developed for this expanding market. Although this range of products was developed and aimed at the healthier eater, they may still contain significant amounts of added fat and/or salt.

Foods and drinks high in fat and/or sugar

This group of foods are generally high in energy and add little nutritional value, but can be included in small amounts as they add palatability and variety to a healthy balanced diet. For products high in sugar, the frequency of intake should be low and limited to meal times to reduce dental caries (see Chapter 7.2). Foods high in fat are often highly processed and are also high in salt and sodium based preservatives, e.g. savoury snacks, crisps and pies. The range of lower fat versions of these products may help to reduce the amount of fat eaten, but these products may still have a high salt level. Other low or reduced fat and sugar products are useful alternative choices for some people.

Choosing healthier products – food labelling

Information on the nutritional content of foods is available on the back of most packaged foods in the UK. Full details can be found in Chapter 4.5. The back of pack nutritional information can be difficult for the consumer to interpret; therefore, front of pack (at a glance) information labelling has been developed and has proven to be valued by consumers. Two front of pack labelling schemes are commonly used in the UK to identify the nutritional content of food as a guide for consumers on four key nutrients, namely fat, saturated fat (saturates), salt and sugar, as well as energy. These are guideline daily amounts (GDAs) and the colour coded (traffic light) integrated label. Both systems are detailed in Chapter 4.5.

Current evidence shows that consumers value front of pack labelling (Malam *et al.*, 2009). Although levels of comprehension are generally high for all front of pack labels, standardising to one label format would enhance understanding. The integrated label, using a combination of text and colour codes, is better understood by consumers (Malam *et al.*, 2009) and this model has been advocated by many consumer and health promotion groups and recommended in NICE guidance (NICE, 2010a,b). Recommendations on one consistent scheme were published by the UK governments following a national consultation (Department of Health, 2013).

Nutritional supplements

Nutritional supplements have become increasingly popular and are now widely available in supermarkets. Although most individuals should be able to get all the nutrients they need from following a healthy balanced

diet, certain groups within the population may need to take supplements (NHS & Bazian, 2011). These include:

- Pregnant women and those trying to conceive should take 400 µg of folic acid daily until the 12th week of pregnancy. In addition to this, they should also eat folate rich foods such as green vegetables, brown rice and fortified breakfast cereals. Folic acid supplementation reduces the risk of neural tube defects, including spina bifida, in the foetus.
- Pregnant and breastfeeding women should take a daily supplement of 10 µg of vitamin D to ensure the mother's requirements for vitamin D are met and to build adequate foetal stores for early infancy.
- Children aged 6 months to 5 years should be given a supplement containing vitamins A, D and C.
- All infants and children aged 6 months to 5 years should take a daily supplement containing vitamin D in the form of vitamin drops.
- People aged 65 years and over and people who are not exposed to much sun should take a daily supplement containing 10 µg of vitamin D.

Healthy eating for very young children

The eatwell plate is an appropriate model for adults and children over the age of 5 years. It is not appropriate for younger children, as they require foods that are more nutrient dense; very young children have relatively high energy requirements and a small stomach capacity. However, introducing a variety of foods to provide different flavours and textures is an important part of weaning, and the range of foods offered should move gradually towards the model of the eatwell plate so that children are eating foods consistent with the recommendations for adults by 5 years (Department of Health, 2007).

Public health strategies

This section outlines the key issues, guidance and initiatives aimed at improving the health of specific groups through the life course.

Maternal health and the early years (0–5 years)

The nutritional status of a pregnant woman influences the growth and development of the foetus and provides the foundations for the child's later health. The mother's own health, both in the short and long term, is also dependent on how well nourished she is before, during and after pregnancy (NICE, 2008) (see Chapter 3.2).

Public health policy is targeted at women from disadvantaged groups who may find it challenging to meet recommendations for maternal and child health. These mothers are more likely to give birth to low birth weight babies. Breastfeeding is a strong indicator of social inequalities; women who are most disadvantaged are least likely to breastfeed. Less privileged mothers are also more likely to introduce solid foods earlier than recommended and their children are at a greater risk of both faltering growth in infancy and obesity in later childhood. Women

from disadvantaged groups have a poorer diet and are more likely to be obese or to show low weight gain during pregnancy.

Initiatives and guidance targeted at maternal health and the early years

Breastfeeding

Current UK policy is to promote exclusive breastfeeding (for the first 6 months) (Department of Health, 2003). Thereafter, it recommends that breastfeeding should continue for as long as the mother and baby wish, while gradually introducing a more varied diet. The continuation of breastfeeding whilst introducing gluten containing complementary foods at 6 months may reduce the risk of coeliac disease, type 1 diabetes and wheat allergies (ESPGHAN, 2008) (see chapter 7.11.2).

Diet during a child's early years also impacts on their growth and development. Poor diet is linked to the incidence of many common childhood conditions such as diarrhoeal disease, dental caries, and iron and vitamin D deficiencies. It may also influence the risk in adult life of conditions such as coronary heart disease, diabetes and obesity (Department of Health, 2003).

Recommendations for health professionals (NICE, 2008) include:

- Providing women with information and advice on the benefits of taking a vitamin D supplement (10 µg/day) during pregnancy and while breastfeeding.
- Providing Healthy Start vitamin supplements (folic acid, vitamins C and D) for eligible pregnant women.
- NHS commissioners and managers are advised to implement a structured programme to encourage breastfeeding within their organisations, which should include training for health professionals.
- Encouraging breastfeeding by providing information, practical advice and ongoing support, including the help of breastfeeding peer supporters and advice on how to store expressed breast milk safely.
- Once infants are aged 6 months, encouraging and helping parents and carers to progressively introduce them to a variety of nutritious foods in addition to milk.

Healthy Start

Healthy Start is a UK wide government scheme to improve the health of low income pregnant women and families on benefits and tax credits. It provides free vouchers to eligible families every week to spend on milk, fresh and frozen fruit and vegetables, and infant formula milk. In addition, free vitamins are provided to mothers (Healthy Start vitamin tablets for pregnant and breastfeeding mothers – folic acid and vitamins C and D) and children (Healthy Start children's vitamin drops – vitamins A, C and D) (see Chapter 3.2).

Children's centres

Children's centres provide a variety of advice and support for parents and carers. Their services are available to pregnant women and families with preschool children. They should be developed in line with the needs of the

local community; therefore, each children's centre is unique. However, there is a core set of services that must be provided:

- Child and family health services, ranging from health visitors to breastfeeding support.
- Most centres offer high quality childcare and early learning; those that do not can advise on local childcare options.
- Advice on parenting, local childcare options and access to specialist services for families, such as speech therapy, healthy eating advice or help with managing money.
- Help on finding work or training opportunities, using links to local Jobcentre Plus offices and training providers.

Recommendations for nursery food

In England all 3 and 4 year olds are entitled to 15 hours of free nursery education for 38 weeks of the year and so the majority of children will spend some time in early education. The Early Years Foundation Stage framework is a comprehensive statutory framework that sets the standards for the learning, development and care of children from birth to 5 years. It includes a recommendation for guidance on nursery food. The School Food Trust (SFT) has developed voluntary food and drink guidelines for early years settings in England (SFT, 2010). Implementation of this guidance means that children are given the right types of foods in the right portion sizes to meet their nutritional needs, and parents have a national benchmark to help when choosing a childcare place for their child.

Nursery milk scheme

In England (and on behalf of the devolved administrations in Scotland and Wales) the Department of Health administers the nursery milk scheme. The scheme is part of the Welfare Food Scheme and enables children under 5 years to receive, free of charge; 189 mL (1/3 pint) of milk for each day they attend approved day care facilities for 2 hours or more. Babies aged under 1 year may receive infant formula milk (dried baby milk) made up to 189 mL instead. Day care providers who have been approved to supply milk under the scheme are reimbursed the cost of the milk they supply.

Tackling obesity through the healthy child programme

The Healthy Child Programme is the early intervention and prevention programme that begins in pregnancy and continues through childhood. It offers every family a programme of screening tests, immunisations, development reviews, information and guidance to support parenting and healthy choices. Due to its universal reach to all families, it provides an opportunity to identify those families that need to receive additional help and services if they are to achieve optimum health. Tackling obesity through the Healthy Child Programme (Rudolf, 2009) provides supporting evidence, a framework for action and resources for practitioners who are working with families with preschool children.

Start4life

Start4life is a campaign for pregnant women and parents with babies. It is part of the Change4life social marketing campaign to support families in achieving behaviour change for a healthier life.

School aged children

In England 33% of 10–11-year old and 23% of 4–5-year old children are overweight or obese (NCMP, 2010). The importance of preventing obesity in childhood and the consequences of obesity in later adult life has resulted in a significant policy response from the government with the implementation of school based initiatives that have focused much PHN policy on this age group. Policies addressing obesity should also address other diet related problems such as dental disease, constipation and faddy eating.

*Initiatives and guidance targeted at school aged children**National Child Measurement Programme (England)*

The National Child Measurement Programme (NCMP), established in 2007, is part of the UK government's work programme on childhood obesity, and is operated jointly by the Department of Health and the Department for . Each year children aged 4–5 years (reception year) and 10–11 years (year 6) are weighed and measured during the school year to inform local planning and delivery of services for children; and gather population level surveillance data to allow analysis of trends in growth patterns and obesity. Although designed as a surveillance programme, local areas are encouraged to feed back a child's weight status to parents.

School fruit and vegetable scheme

Since 2004, every child aged 4–6-years old in state schools in England has received a free piece of fruit or vegetable each school day through the Department of Health's school fruit and vegetable scheme. This scheme was introduced as part of wider efforts to increase people's fruit and vegetable intake to the healthy 5 A DAY target.

Food and nutrition standards for schools

Each of the countries of the UK has introduced compulsory changes that prohibit or restrict food served at school that is high in fat, sugar and salt or made with poor quality meat. The UK standards are some of the most detailed and comprehensive in the world (Evans & Harper, 2009). The standards were developed following research showing that children were not making healthy food choices at lunchtime and that school meals did not meet their nutritional needs. The School Food Trust is a national charity and independent advisor to the government in England on school food, children's food and related skills. The Food for Life partnership brings together the expertise of four food focused charities, the Soil Association, Focus on Food Campaign, Health Education Trust and Garden Organic, to help English schools transform their food culture.

European school milk scheme

The aim of the European Union funded school milk subsidy scheme is to encourage children to drink milk and to develop a lasting habit of consuming milk. Milk must be distributed to children as a mid morning or afternoon drink and not used in the preparation of meals. Schools in England may provide subsidised milk to pupils and can claim reimbursement through the local authority, a milk supplier or an organisation specifically set up on behalf of schools. Free milk should be available for children entitled to free school meals. The Welsh government also funds the provision of free school milk for 5–7-year olds (key stage 1) in Wales.

Controlling food and drink TV advertising aimed at children

Television has a relatively modest impact on children's food preferences, and is only one among a number of factors affecting those preferences. Since 2008 the independent regulator and competition authority for the UK communications industries (Ofcom) and its coregulatory partner, the Advertising Standards Association, have had rules in place governing both the scheduling of adverts and their content for foods containing high fat, sugar and salt levels (HFSS); these are amongst the strictest in the world. Advertisements for foods deemed less healthy according to the FSA's Nutrient Profiling Model have not been permitted in or around programmes deemed of particular appeal to under 16-year olds. A programme is defined as being of particular appeal to children if the proportion of children under 16 years of age watching a programme is 20% higher than the general viewing population. These rules apply to all commercial and public service broadcast channels, including all cable and satellite channels.

A review of the advertising restrictions has shown them to reduce significantly the amount of HFSS advertising seen by children, and to reduce the influence of techniques in HFSS advertising that are considered likely to be particularly attractive to children (Ofcom, 2010). However, advertisements, promotions, product placements and sponsorship shown between programmes for older audiences also have a powerful influence on children and young people. Marketing bans have been successfully introduced in several other countries; evidence shows that a 9 pm watershed for such TV advertisements would reduce children and young people's exposure to this type of advertising by 82% (NICE, 2010a,b). Children are exposed to other media such as print and digital media and at present advertising in these media is not restricted.

Change4life

Change4life is a social marketing campaign in England that began in 2009 and is designed to help families make behaviour change and adopt a healthier lifestyle. It is the marketing component of the government's response to the rise in obesity and is supported by partnerships of major food and drink companies; these partnerships have

been seen as controversial because of the nature of the behaviour change required.

The adult population

Management of obesity dominates the PHN issues for the adult population because of its impact not only on the health and wellbeing of this group of the population but also because of the economic impact. Care of older people and the importance of preventing malnutrition is an increasingly important public health issue emerging from the dignity in care agenda.

Being overweight has become normal and Britain is an obese society as a response to exposure to a modern lifestyle. The complexities of the obesity epidemic, the challenges in addressing it and the public health policy responses thought to have the greatest impact are addressed in the Foresight Report *Tackling Obesity: Future Choices* (Foresight, 2007). Public health responses need to be multifaceted and aligned with other major policy issues to ensure the maximum number of potential stakeholders can be involved. Policies linked to climate change and health inequalities have been identified as particularly crucial in developing a strategy to tackle obesity (see Chapter 7.13).

Initiatives and guidance targeted at the adult population

Public Health Responsibility Deal (England)

The English government is aiming for a collaborative approach with businesses and other influential organisations to support lifestyle change. The responsibility deal is a voluntary agreement between businesses and the government to improve public health. There are five networks (alcohol, behaviour change, food, health at work and physical activity), each made up of a high level steering group and task specific working groups as required. The networks have developed a set of core principles and a series of pledges for businesses to demonstrate their commitment to public health. Businesses can sign up to one or more pledges (Department of Health, 2011b). The food network has pledged to encourage the food industry and caterers to remove *trans* fatty acids, reduce salt, label energy at point of purchase, reduce energy and increase fruit and vegetable content. However, health and consumer organisations have criticised the pledges for alcohol as not being robust enough to challenge binge drinking. Evaluation of this voluntary partnership with the food industry has yet to be reported and consumer groups are watching with interest.

Healthy Lives, Healthy People: A Call for Action on Obesity in England

This document sets out how action on obesity will be delivered in England with the ambition of achieving a downward trend in excess weight in both children and adults by 2020 (Department of Health, 2011c).

Front of pack food labelling

Front of pack labelling is seen as a useful way of allowing informed comparisons between convenience foods, par-

ticularly when these have a wide range of nutrient values (Chapter 4.5).

Change4life

As stated earlier this social marketing campaign started with an emphasis on children, but now includes adults and families.

Public health guidance for adults

The NICE has published the following guidelines for some aspects of public health.

Prevention of cardiovascular disease (PH 25)

This guidance includes recommendations for a broad range of policies that require a range of legislative, regulatory and voluntary changes, including the further development of existing policies (NICE, 2010a,b). The guidance addresses reduction of salt, saturated fat and *trans* fatty acids, as well as food marketing, commercial interests, European policies (front of pack labelling and the Common Agricultural Policy) and public sector catering and food from take aways.

Behaviour change (PH6)

This guidance is aimed at those responsible for helping people to change their behaviour to improve their health (NICE, 2007). This includes policy makers and those working in local authorities and the community and voluntary sectors. The guidance gives advice on how to plan and run relevant initiatives.

Maternal and child nutrition (PH 11)

This guidance relates to pregnant women (and those who are planning to become pregnant), mothers and other carers of children aged under 5 years and their children. It is particularly aimed at those on a low income or from a disadvantaged group. It includes recommendations for vitamin D supplementation, Healthy Start, breastfeeding programmes and introduction of a variety of nutritious weaning foods (NICE, 2008).

NICE quality standards

NICE quality standards are a set of standards designed to drive and measure priority improvements in a particular area. They are developed independently by NICE in collaboration with health and social care professionals, their partners and service users. The standards are designed to help professionals, service providers, commissioners and people receiving health and social care to identify the service that delivers the best outcomes. The quality standard for nutrition support in adults has been developed (NICE, 2006).

Common agricultural policy

The Common Agricultural Policy (CAP) is the framework used by countries of the European Union to form their own agricultural policies. The burden of diet related disease has grown considerably since CAP was first

implemented. The Common Agricultural Policy reform offers a significant opportunity to address diet related illness. A number of significant distortions in relation to certain food prices and production processes still remain in CAP policies, which potentially increase the burden of disease. Change in these distortions to promote health and wellbeing is recommended for UK policy to address obesity and other diet related illness. Plans for the reform of CAP to strengthen the competitiveness and the sustainability of agriculture and guarantee healthy quality food production, to preserve the environment and to help develop rural areas were announced in 2013 (European Commission, 2013).

Measuring change

There is a growing interest in healthy eating with an increasing proportion of the UK population claiming that eating a healthy diet is important to them (FSA, 2011). However, knowing what is good for us does not necessarily lead to a shift in dietary patterns; this requires a long term process of cultural and behavioural change. Consumption patterns still fall far short of aspirations. It is important to measure changes in knowledge and attitudes. Several national surveys are conducted on a regular basis to measure such changes. These are shown in Table 4.2.7. It is also important to measure change when imple-

Table 4.2.7 Key sources of knowledge and attitudes data related to healthy eating (adapted from NOO 2010. Reproduced with permission of Public Health England, Obesity Knowledge and Intelligence)

Survey	Details
Adults	
Health Survey for England	Attitudes to one's own weight; attitudes to healthy eating; knowledge about healthy eating; knowledge about healthy physical activity levels; attitudes to physical activity; self efficacy in relation to physical activity
National Diet and Nutrition Survey	Eating habits and patterns; attitudes to one's eating habits; attitudes to one's own physical activity levels; attitudes to one's own weight; attitudes to dieting
Low Income Diet and Nutrition Survey	Attitudes to organic foods, knowledge of, and competency in, cooking; attitudes to appetite; attitudes to variety of foods consumed; attitudes to physical activity levels at work; weight status over time; attitudes to one's own weight status; influences on food choice; attitudes to one's current diet; attitudes to children's diet; knowledge of healthy eating; self efficacy in relation eating healthily
British Social Attitudes Survey	Attitudes to eating and physical activity as a reliever of stress; attitudes to taking part in games or sports; attitudes to national culture relating to sport; attitudes to individual responsibility and health; attitudes to active transport
Food and You survey (FSA) Consumer Attitudes Survey	Attitudes to importance of healthy eating; self efficacy with regards to cooking; attitudes to convenience foods; attitudes to eating healthily; attitudes to importance of healthy eating for children; knowledge of healthy eating; patterns of eating, including reduction and increase of consumption of certain foods; understanding of food labels; attitudes to food safety and hygiene; sources of information on healthy eating
Sodexo School Food Survey	Parents' attitudes to food provided by school; parental concerns about children's diets; parental attitudes to physical activity; parents' motivation to exercise; parental opinion of own weight status; parental opinion of child's weight status. The latest available survey data are from the 2005 survey
Change4life Tracking Survey	Attitudes to adopting a healthy lifestyle; attitudes to getting children to lead a healthy lifestyle, including healthy eating and being active; attitudes to overweight; knowledge of consequences of overweight; attitudes to changing physical activity and dietary habits; attitudes to changing physical activity and dietary habits of one's child; attitudes to breastfeeding; knowledge about healthy weaning. (Not in the public domain)
Children	
Health Survey for England	Attitudes to one's own weight; attitudes to healthy eating; knowledge about healthy eating; knowledge about healthy physical activity; attitudes to physical activity; self efficacy in relation to physical activity
TellUs	Attitudes to advice on healthy foods; attitudes to how leisure time is spent; attitudes to provision of sports and leisure activities in the local area
Sodexo School Food Survey	Attitudes to one's own diet; knowledge about healthy eating; motivation to eat healthily at school; healthy eating messages at school; attitudes to food provided in school; motivation to exercise outside school
National Diet and Nutrition Survey	Eating habits and patterns; attitudes to one's own eating habits; attitudes to one's own physical activity levels; attitudes to one's own weight; attitudes to dieting
Low Income Diet and Nutrition Survey	School meal entitlement, school provision of food and cooking lessons; competency
Take up of School Meals in England	Annual survey of number of children eating a school meal, catering provision in schools and compliance with school food standards

menting local changes; it is essential that a baseline measurement is made before implementing any intervention aimed at changing knowledge, practice or attitudes.

The key findings of these surveys are:

- People are eating less saturated fat, *trans* fat and added sugar than 10 years ago [National Diet and Nutrition Survey (NDNS)].
- Saturated fat intake in adults has dropped slightly to 12.8% of food energy, but is still above the recommended level of 11%. *Trans* fat intakes, having also fallen slightly, were within recommended levels; mean intake of *trans* fat was 0.7–0.9% of food energy (NDNS).
- People were eating too much non-milk extrinsic sugar (added sugar and sugar released from food during processing); currently 12.5% of food energy intake compared with the recommended 11% (NDNS).
- Adults (aged 19–64 years) consumed on average 4.2 portions per day of fruit and vegetables, older adults (over 65 years) consumed 4.3 portions, and 30% of adults and 37% of older adults met the 5 A DAY recommendation (NDNS).
- People were not eating enough fibre; mean intakes were 14g/day for adults, below the recommended 18g (NDNS).
- Families living on low income were less likely to consume wholemeal bread and vegetables, and more likely to consume fat spreads and oils, non-diet soft drinks, beef, veal, lamb and pork dishes, pizza (except males aged 19–64 years), processed meats (children and adults aged 19–64 years), whole milk (children and adults aged 19–64 years) and table sugar [Low Income Diet and Nutrition Survey (LINDNS)].
- Consumption of oily fish, which is the main source of n-3 fatty acids, remained substantially below the recommended one portion per week (LINDNS).
- Adults who consumed alcohol (61% of adults and 53% of older adults) obtained 9% of energy intake from alcohol (NDNS).
- Only 3% of children and 15% of adults reported eating oily fish and dishes containing oily fish (excluding canned tuna) (LINDNS).
- Iron intakes among teenage girls and women were low. However, overall vitamin and mineral intakes among the population are slightly improved (NDNS).
- The majority of respondents rated a variety of factors as important for a healthy lifestyle: 99% reported eating fruit and vegetables was very or fairly important, 94% that eating less salt was important and 92% that limiting foods high in saturated fat was important (Food and You survey).
- About a fifth of respondents were able to identify the types and proportions of foods needed for a healthy balanced diet (based on the eatwell plate) (Food and You).
- Almost one in 10 (9%) correctly stated that the maximum daily intake of salt for an adult was 6g (Food and You).

4.3

Sports nutrition

Louise Sutton

Key points

- An optimal diet for sport is one that assists the athlete to maximise training and competition performance whilst maintaining good health.
- Energy and macronutrient needs, particularly carbohydrate and protein, must be met during training and competition to maintain body mass, recover energy stores and provide adequate protein for tissue growth and repair.
- Fat intake should contribute appropriately to energy demands within the context of weight management.
- Good hydration practices are important to health and performance in sport.
- Vitamins and minerals should be included in the diet to at least the recommended levels for the population as a whole.
- Individualised nutritional plans subsequent to comprehensive nutritional assessment will benefit all athletes, but particularly elite performers.

Sports nutrition remains an emerging discipline within the fields of sports science and dietetic practice. It is now well recognised that physical activity, athletic performance and recovery from exercise are enhanced by optimal nutrition. Individuals participate in sport at different levels and for different reasons, but all athletes, whatever their level, can benefit from making good food choices that support consistent training, maximise performance and maintain good health.

Athletes, especially elite athletes, have widely accepted the need for well designed systematic training programmes, but have seemingly been slower to adopt well planned dietary strategies, with some tempted by the use of supplements or ergogenic aids to boost performance. This is changing with coaches and athletes now clearly recognising that unbalanced and inadequate nutritional intakes can lead to poor training and competition performance, lethargy, increased risk of injury and illness, and unfavourable gains or losses in body mass.

Appropriate selection of foods and fluids, timing of intake and supplement choice, where appropriate, will benefit both health and performance. The foundations of sports nutrition lie in sensible healthy eating approaches. There should be no conflict between eating for health and eating for performance. Nutrition is likely to have its biggest impact on performance by supporting athletes to train consistently and effectively to produce the desired adaptations in response to training. The recreational to elite athlete will benefit from sound nutritional practices,

whilst individualised nutrition direction and advice subsequent to a comprehensive nutritional assessment will particularly benefit elite performers. The recommendations summarised in this chapter relate to performance sport. Due to the diversity of sporting activities and levels of performance, it is beyond the scope of this chapter to provide detailed guidelines for every sport. However, there are some generic sports nutrition principles applicable to all athletes:

- Energy and macronutrient needs, particularly carbohydrate and protein, must be met during training and competition to maintain body mass, recover energy stores and provide adequate protein for tissue growth and repair.
- Fat intake should contribute appropriately to energy demands within the context of weight management and be adequate to supply essential fatty acids and fat soluble vitamins.
- Micronutrient intakes should at least match the requirements for the population as a whole.
- Commence exercise euhydrated and drink enough fluid during and after exercise to balance fluid losses through a customised approach.

The International Olympic Committee (IOC, 2010) advises athletes to adopt specific nutritional strategies before, during and after training and competition to maximise performance. Evidence based guidelines exist on the amount, composition and timing of food intake, and

athletes are advised of the benefits of seeking qualified guidance to formulate sport specific nutritional strategies. Adequate amounts of food and fluid consumed before, during and after exercise will help maintain blood glucose during exercise, maximise performance and speed recovery post exercise.

Energy metabolism during exercise

In order to appreciate the relationship between diet and performance, it is helpful to summarise the effects of exercise on energy metabolism. Energy is largely stored in the body as glycogen and fat. The body stores an average of 375–475 g of glycogen, up to a maximum of approximately 600 g in muscle and a further 100 g in the liver. This is sufficient to run about 20 miles. The body's reserves of fat for all practical purposes are unlimited, even in the leanest of athletes. A third fuel is phospho-creatine. Very small amounts of this are stored in the muscle, sufficient to run for 5 or 6 seconds.

During exercise the working muscles convert stored energy into kinetic energy to fuel movement. The energy needs of the muscles are covered by accelerating the rate of adenosine triphosphate (ATP) resynthesis to match the rate at which ATP is utilised. ATP is produced when muscle cells metabolise carbohydrate and fatty acids in the presence of oxygen; this is aerobic metabolism. It can also be produced without the presence of oxygen, but during this anaerobic metabolism only carbohydrate can be utilised. Therefore, the two main fuels for muscle metabolism are carbohydrate and fat. Fatigue often coincides with depletion of the carbohydrate reserves.

In simple terms, as exercise intensity increases, there is increased reliance on carbohydrate but, as exercise duration increases, there is a declining contribution from carbohydrates. This is partly due to progressively depleted muscle glycogen and glucose as exercise continues, but also to the increased availability of free fatty acids. Training enables the working muscles to take up more oxygen from the blood supply and produce more energy aerobically, i.e. utilising more free fatty acids and therefore sparing the limited glycogen stores.

Energy requirements and availability

Energy expenditure due to physical activity generally accounts for 25–35% of daily energy turnover, but can account for as much as 75% during intense training of long duration. Energy intakes can therefore vary from 1500 kcal/day for young female gymnasts to 6000–7000 kcal/day for competitive cyclists, e.g. Tour de France. In sports where a specific body image is required, e.g. gymnastics, bodybuilding and ballet, or where a sport requires athletes to compete in a weight category, such as judo, boxing or lightweight rowing, athletes may restrict energy intake to lose weight or maintain a particular body composition.

Athletes repeatedly restricting energy intake for competition, then regaining weight afterwards (weight cycling) may find it increasingly hard to lose weight but weight

regain is easier. Female athletes who follow intensive training programmes while restricting energy intake may experience other related problems, such as menstrual dysfunction, decreased bone density and iron deficiency anaemia. Lower energy intakes may also be associated with micronutrient intakes below recommended values. The American College of Sports Medicine (ACSM, 2007) has made recommendations for screening, diagnosis, prevention and treatment of the condition known as the female athlete triad.

Beyond the usual factors that affect energy expenditure, energy expenditure for different sports is largely dependent on the duration, frequency and intensity of activity and prior nutritional status of the athlete. Meeting energy requirements should be the main nutritional concern for athletes. During periods of high intensity and/or high duration training, athletes need to consume adequate energy to maintain health, body weight and composition, and to maximise training effects. Low energy intake or availability can result in losses of lean mass, loss or failure to gain bone density, disturbance in menstrual function, increased risk of injury, illness and fatigue, and delayed recovery from training and competition. Inadequate energy intake relative to energy expenditure has the potential to compromise performance and counteract the benefits of training. Losses in lean tissue as a result of inadequate energy intake can result in losses in strength and endurance, as well as compromised musculoskeletal, endocrine and immune function in addition to poor overall nutrient intakes. Most athletes will have a weight management concern whether this is gains in lean mass, losses in fat mass or weight maintenance. As such, energy requirements may need to be considered alongside sensible body weight and composition targets.

The concept of energy availability, the amount of energy available to perform all other functions after exercise training expenditure is subtracted, is defined as dietary intake minus energy expenditure normalised to fat free mass (FFM). It has been proposed that 30 kcal/kg of FFM/day might be the lower threshold of energy availability for women. The IOC (2010) advises that low energy availability be avoided and dieting discouraged, whilst athletes at risk of disordered eating patterns and reproductive disorders should be referred promptly to relevant health professionals for evaluation and treatment.

Macronutrient requirements for sport

Essentially, athletes do not need to eat substantially differently from the recommended diet for the general population; however, for athletes there has been a shift away from using percentage recommendations for carbohydrate and protein intake goals in favour of prescriptions relative to body weight.

Role of carbohydrate in training and recovery

It is important to appreciate that whatever exercise is performed, some carbohydrate will always be used. The longer or harder the exercise, the greater the demands

placed on carbohydrate stores to maintain the desired rate of ATP resynthesis. Consequently, without adequate muscle glycogen reserves, the ability to perform high levels of work is markedly impaired.

Muscle glycogen becomes totally depleted after 2–3 hours of continuous exercise at intensities of 60–80% maximal oxygen uptake ($\text{VO}_2 \text{ max}$). Severe depletion can also be achieved after only 15–30 minutes of exercise at intensities of 90–130% $\text{VO}_2 \text{ max}$ when intervals of 1–5 minutes of exercise followed by rest are repeated. This type of short intermittent, high intensity exercise is a pattern found typically in many individual and team sports, such as football, hockey and tennis, and demonstrates the importance of carbohydrate as a fuel for all types of sport, not just the endurance sports. Athletes who train and compete regularly need to ensure adequate carbohydrate consumption if they are to avoid residual fatigue and poor performance.

Definition of $\text{VO}_2 \text{ max}$

As an individual moves from rest to running their oxygen uptake increases in an almost linear fashion until they reach a point where there is no further increase in O_2 consumption. This is the maximum O_2 uptake or $\text{VO}_2 \text{ max}$ for the individual. When the exercise intensity is expressed as a percentage, $\text{VO}_2 \text{ max}$, it is called the relative exercise intensity and it reflects the physiological and psychological demands on the individual.

Glycogen stores are depleted with training. These limited stores must be restocked adequately before the next training bout. Glycogen is restored at a rate of about 5%/hour. After exhaustive exercise, up to and beyond 20 hours may be needed to fully replenish stores. During the first 2 hours after exercise, muscle glycogen resynthesis proceeds at the rate of 7%/hour, making it important that athletes consume sufficient carbohydrate during this time. If glycogen reserves are low, the point at which glycogen becomes limiting may be attained more rapidly. If the process of incomplete refuelling continues, there is a progressive depletion of glycogen stores within the working muscles, resulting in a feeling of continual lethargy. Quality and quantity of training will be impaired, leading to a decrease in overall performance. There is also the potential for blood sugar levels to fall during training, affecting brain function, concentration and coordination, and resulting in an increased injury risk.

Dietary carbohydrate recommendations

Guidelines suggested in The International Olympic Committee Consensus Statement on Sports Nutrition (IOC, 2004) are summarised in Table 4.3.1. These guidelines need to be personalised to take account of total energy needs, phase of training and feedback on performance.

Sufficient foods containing carbohydrate should be consumed on a regular basis to maintain glycogen levels. In most cases, starchy foods are the best choice; however, athletes may also need to include sugary sources of carbohydrate, such as sweets, jam or sugar, or sports food such as drinks, bars and gels, to meet high overall energy

Table 4.3.1 Carbohydrate requirements to aid recovery (IOC, 2004)

Type of training	Carbohydrate requirements for daily recovery (g/kg body weight/day)
Moderate duration/low intensity	5–7
Moderate to heavy endurance training	7–12
Extreme exercise programmes (4–6+ hours/day)	10–12

requirements within the context of achieving an overall balanced intake. As this is where sports nutrition advice can wander from the usual healthy eating message, athletes and parents of younger athletes may require an explanation for the appropriateness of this.

Training versus competition

Different sports operate within different time frames for training and competition, and therefore require distinctive energy and carbohydrate intakes. Generally, endurance athletes such as long distance runners or cyclists and triathletes will train and compete for long periods. Sprinters will compete over very short periods but train for longer periods, and multisprint sports such as rugby, football or netball require training and competition over 1–2 hours, but have periods of relative inactivity within that time period. Each sport will have complex training programmes, including strength and conditioning, endurance, speed and skills specific elements. When assessing requirements before, during and after training, it is important to remember that each training session will affect nutritional requirements differently.

Prior to exercise

Athletes should aim to begin every bout of training and competition fully recovered, with glycogen stores that are adequate to cope with the workload to be undertaken. This may be more difficult to achieve for athletes with multiple bouts of training and/or competition in one day. Eating a meal rich in carbohydrate 3–4 hours prior to exercise increases glycogen stores in the muscles and liver. The quantities of carbohydrate that are appropriate at this time will vary according to the sport, the athlete, their prior nutritional status and overall daily needs.

Endurance events require optimal glycogen stores to maximise performance. The traditional *carbohydrate loading* method popular during the late 1960s and 1970s is no longer used, having been replaced with a tapering of training and an increase in carbohydrate intake over the 3–5 days prior to competition. Subsequent increases in glycogen stores not only benefit the endurance athlete but also may help in sport situations where competition may last for several days. Commencing competition with high glycogen stores may assist in offsetting progressive depletion with each bout of competition. A possible dis-

advantage of increasing glycogen stores is the commensurate increase in body weight through the associated storage of water with glycogen. This may be an important consideration where an athlete competes in a weight category sport such as judo or in events covering significant distance, e.g. marathon running.

During exercise

The consumption of carbohydrate during competitions of long duration or between bouts of intermittent competition will enhance performance. Muscle glycogen stores and the availability of carbohydrate during exercise are major determinants of endurance performance. The delivery of carbohydrate during exercise becomes more significant when muscle glycogen stores are low at the onset of exercise.

During exercise, the ingestion of carbohydrate is often limited to that which can be taken in fluid form. If exercise duration continues beyond 1 hour, it is recommended that carbohydrates be ingested at a rate of 30–60 g/hour to maintain oxidation of carbohydrates and delay fatigue. Mixing different forms of carbohydrate has been shown to increase carbohydrate oxidation up to 90 g/hour, which may be required to optimise performance in events lasting >3 hours.

Athletes are advised to practise consuming carbohydrate during training and to develop individual strategies, making use of sports foods and drinks containing carbohydrate combinations that will allow for maximal absorption from the gut with minimal gastrointestinal disturbance.

Post exercise

Immediately after exercise, the body resynthesises glycogen at a faster rate. Athletes should aim to consume carbohydrate at the rate of 1.0–1.5 g/kg body weight within 30 minutes and again every 2 hours for 4–6 hours for adequate replacement of glycogen stores. Adequate refuelling is particularly important when there are 8 hours or less before the next training or competition bout. The addition of protein may have additional benefits in enhancing both muscle protein and glycogen synthesis.

Many athletes find solid food immediately after exercise unpalatable, and therefore drinks containing carbohydrate may be useful. Foods with a high glycaemic index (GI) are generally thought to be beneficial during this initial post exercise period. When longer periods of recovery time are available, the athlete may move on to meals containing lower GI foods.

Regular exercise

Regular exercise has been shown to increase protein needs. Athletes should consume daily amounts greater than those recommended for the general population, but a varied diet that meets energy requirements will usually provide a protein intake in excess of requirements. The current consensus evidence suggests that endurance athletes require 1.2–1.4 g of protein/kg body weight/day, whilst strength or speed athletes may require as much as

1.7 g of protein/kg body weight/day. The high energy intakes typical of most athletes make these recommendations easy to attain without dietary manipulation. Athletes with restricted energy intake may require dietary manipulation to achieve their protein requirements. Those who are vegetarian, and particularly vegans, may also need some guidance to ensure adequate protein intake, particularly if also consuming low energy diets.

To maximise protein synthesis foods that contain high quality proteins are recommended to be consumed regularly throughout the day as part of the athlete's total daily consumption. In particular, consumption is recommended soon after exercise in quantities of 15–25 g to aid the repair of damaged tissue and long term maintenance or gain of muscle mass. The consumption of adequate energy, particularly from carbohydrate, is important to protein metabolism to ensure amino acids are spared for protein synthesis.

Fat

Fat (as a source of energy, fat soluble vitamins and essential fatty acids) is an important nutrient in the diet of athletes. However, there is no need to supplement the normal diet with additional fat; intakes of >30% of total energy are likely to indicate an inadequate intake of carbohydrate. In addition intakes of <20% of total energy do not appear to benefit performance.

Athletes should aim to avoid excessive amounts of fat in the diet, and would normally be encouraged to look to lower fat versions of foods where appropriate unless they have exceptionally high overall energy requirements. Athletes, like the general population, should be encouraged to include mono- and poly-unsaturated fats in their diets. Whilst many athletes are familiar with the concepts around the need for carbohydrate in the diet, the issue of including adequate and appropriately healthy fats may not always be fully understood.

Fluid balance

Considerable care should be taken by all athletes to ensure adequate hydration before, during and after exercise to avoid thermal distress. Dehydration, a loss of >2% of body mass, can compromise aerobic performance, particularly in hot and high altitude conditions, and may also impair cognitive performance.

Sweat rates for any given activity, and therefore fluid losses, will vary according to ambient temperature, humidity, body mass, genetics, state of heat acclimatisation, metabolic efficiency and even clothing. Sweat rates can range from as little as 0.3 L/hour to typically maximum rates of 2–3 L/hour. It is important to recognise that large interindividual variation in sweat losses can occur even when the same or similar exercise is carried out in the same conditions.

Where sweat losses greatly exceed replacement, the circulatory system is unable to cope and skin blood flow slows. With this comes a reduction in sweating and the ability to lose heat; thus, body temperature will rise with

potentially fatal consequences. Although sweating is a very effective way of losing heat, care must be taken to ensure that this process is not impaired through dehydration.

The addition of sodium to sports drinks aids the absorption of water and thus the process of rehydration. Further, this sodium prevents a drop in plasma sodium concentration and plasma osmolality that would occur during exercise with the ingestion of large volumes of plain water. A drop in plasma sodium concentration and plasma osmolality would result in diuresis with an accompanying decline in desire to drink, resulting in a lower fluid consumption. Athletes participating in long endurance events, particularly ultra endurance events, can be at risk of hyponatraemia if they drink copious amounts of plain water. This is most often reported in the non-elite.

The ACSM (2007) position statement on exercise and fluid replacement provides a comprehensive review of research and recommendations for maintaining hydration before, during and after exercise.

Fluid intake

Hydration strategies should be individualised, the ideal strategy covering the athlete's daily fluid requirements plus additional requirements of each bout of training or competition. Drinks used for exercise lasting more than an hour or sports that stimulate heavy sodium losses through sweating should include sodium. There is a range of commercial sports drinks available that athletes can use around training and competition. These contain carbohydrate and electrolytes at levels that will be acceptable for use before, during and after most sports; these will typically be labelled as isotonic. Hypertonic drinks contain more carbohydrate and may be useful where the focus is on refuelling. Where rehydration is a priority, hypotonic drinks may be beneficial where the carbohydrate content is low and sodium content higher. Emphasis should be placed on good oral hygiene when using sports drinks.

Prior to exercise

Euhydration should be strived for prior to training or competition. This can be achieved by:

- Constantly being aware of fluid status and maintaining good fluid intake at all times.
- drinking 5–7 mL/kg body mass of water or sports drink at least 4 hours before exercise.

Markers of urine osmolality, specific gravity and colour can be used as a guide to euhydration.

During exercise

The achievement of fluid balance during exercise is not always possible as a result of maximal sweat rates exceeding maximal gastric emptying. The aim of drinking during exercise is to limit dehydration to <2% of body mass. The amount and rate of fluid replacement achieved will be dependent on individual sweat rate, exercise duration and intensity, and opportunities to consume fluids. The

Table 4.3.2 Weighing before and after sport to ascertain sweat rate

Stage	Procedure
1	Pass urine prior to weighing
2	Wear minimal clothing and remove socks and trainers (preferably nude body mass)
3	Weigh on solid floor with accurate scales prior to exercise
4	Record the amount of fluid consumed during exercise
5	After exercise dry the body of any sweat by rubbing down with a towel
6	Weigh immediately after exercise and drying before passing urine
7	If: Initial weight = a (kg) Final weight = b (kg) Weight difference = c (kg) Fluid drunk during session = d (L) Fluid loss (F) during session is: $c = a - b$ $F = c + d$ This is fluid loss per unit of time measured, e.g. if training session lasts 1 hour, it is loss per hour 1 kg of weight loss equals 1 L of fluid; therefore kg and L can be added or subtracted together

use of beverages containing carbohydrate and electrolytes can help to maintain fluid and electrolyte balance, especially during the performance of endurance exercise. Regular assessment of pre–post exercise body weight can assist dietitians and athletes in determining sweat rates and customising individual hydration programmes (Table 4.3.2).

When exercise lasts less than an hour and temperatures are not high, fluid may not be needed during the exercise period. However, when exercise of long duration or results in excessive sweating, it is advisable to drink during the exercise period. In such cases, hydration strategies during exercise should:

- Aim to match fluid losses through sweat with fluid intake.
- Aim to minimise body weight losses to 1–2% – especially in hot and humid conditions.
- Ensure individualised hydration plans based on the knowledge of sweat rates.
- Encourage consumption of 150–250 mL of fluid every 15–20 minutes during prolonged exercise where practical and within tolerance.
- Use palatable drinks.
- Use training sessions to practice drinking during exercise.

Post exercise

Athletes will complete most exercise bouts with some degree of dehydration. The volume of fluid consumed following exercise needs to replace that lost as sweat, but should also take account of the ongoing sweat losses

during the immediate recovery period. Therefore, fluid intake during this period should exceed losses by as much as 50%, i.e. for every litre lost, 1.5L should be drunk. Strategies implemented following exercise should ensure that:

- Rehydration starts immediately, particularly when repeated bouts of exercise have to be performed.
- Sweat rates calculated from before and after weighing are taken into account.
- Athletes carry their own supply of fluid in their kit bag.
- Drinks contain some sodium to assist rehydration by stimulating thirst.
- Drinks contain some carbohydrate to help replace energy needs where appropriate.

Other considerations

Weight control

In most cases the aim of a weight loss diet for an athlete is to decrease body fat stores without affecting glycogen, water or lean body mass content. The diet must contain sufficient carbohydrate to restock glycogen stores between each bout of training. It will need to be low in fat and may require a proportionately high protein content, as well as providing all essential nutrients in a total energy intake that will achieve the desired weight loss over a sensible period.

If loss of performance due to dehydration and glycogen depletion is to be avoided, rapid weight loss by dietary or non-dietary methods should be discouraged. Despite the importance of maintaining hydration and glycogen stores in preparation for competition, strategies for *making weight* are still practised in some sports by increasing rather than tapering training, fasting, restricting fluids and use of saunas, sweat suits, laxatives and diuretics. Where weight loss is a long term goal, well planned weight reduction programmes are essential if athletes are to maintain training and not impair performance.

Where weight gain is required, the athlete will want to increase lean body mass rather than body fat content. Muscle mass is determined by training effect and adaptation. Advice for the athlete desiring weight gain is to ensure an adequate overall diet with a high proportion of carbohydrate and adequate protein that achieves a 500kcal/day positive energy balance. A conscious effort may be required to increase food intake. Meals should not be missed and high carbohydrate snacks should be consumed between meals as appropriate.

Micronutrients

Careful selection of nutrient dense foods should reduce the risk of micronutrient deficiencies; however, the vitamins and minerals commonly found to be of concern in the diets of athletes are vitamins D and B group, calcium, iron and zinc. The IOC (2010) warns that athletes should be particularly aware of their needs for calcium, iron and

vitamin D, but that the use of large amounts through supplementation may be harmful.

Micronutrient supplementation will not enhance performance in athletes who are already consuming an adequate diet; however, there may be situations where intakes should be increased by dietary manipulation or recommending the use of supplementation. Supplementation should not compensate for poor food choices, but may provide a short term option when food intake or choice is restricted due to constant travel, giving rise to limited food choice, or restriction of food intake to maintain low body weight.

Single nutrient supplementation may be necessary for specific medical or nutritional purpose, e.g. iron supplementation to correct anaemia. Female athletes with amenorrhoea or dysmenorrhoea have an increased risk of developing osteoporosis due to reduced levels of oestrogen. Improved calcium intakes are particularly important in athletes with low bone density, menstrual irregularities and low calcium intakes, since stress fractures are particularly common in this group of athletes.

Athletes who run the greatest risk of poor micronutrient status are those who restrict energy intake or undertake severe weight loss practices, or through choice or need eliminate one or more food groups, or who repeatedly consume unbalanced low nutrient density diets. These athletes may benefit from a daily low dose multivitamin and mineral supplement. Theories are emerging that supplemental dietary antioxidants may reduce oxidative stress and skeletal muscle damage associated with strenuous exercise, but athletes are advised to maintain an adequate intake through good nutrition.

Supplementation

Sports dietitians need to constantly update their knowledge in this area. The supplement market is worth millions, but the manufacture, processing, labelling and marketing of these products is poorly regulated with variable quality control. The vast array of available products make convincing claims – better recovery, increased strength and size, loss of body fat and enhanced immune function. As such it is easy to appreciate the attraction of such products for the athlete.

The list of supplements is exhaustive, but they can essentially be broken down into two main categories. Nutrient supplements can be used to assist the athlete in meeting their overall nutritional needs. This might be by way of providing a practical alternative to food or to help to meet higher than average requirements for nutrients, in particular carbohydrate and protein. Ergogenic aids are assumed to enhance performance above and beyond that which would normally be expected. Nutritional ergogenic aids generally aim to enhance performance through effects on energy, body composition and alertness.

Nutrient supplements

Nutrient supplements can assist athletes to achieve optimal nutritional requirements. These products include sports drinks, gels and bars, liquid meal and protein

supplements, carbohydrate loaders and powders, and multivitamin and mineral supplements. Athletes may find these products useful in helping them to meet their nutritional goals during particularly demanding periods of training and competition. For instance, products such as sports drinks have a genuine role to play, presenting a convenient way to meet the high energy demands of training or competition.

The key question with nutrient supplements is knowing how and when to use them to maximum benefit to support the attainment of nutrition goals. If used appropriately, nutrient supplements can play a role in assisting athletes to train and compete at their best, but the support of a sports dietitian may be required to develop optimum nutritional strategies where these products feature. They are generally more expensive than similar everyday food items, but in some circumstances the extra expense may be worth it.

Nutritional ergogenic aids

There is scientific support for performance enhancement with creatine and caffeine. Other products such as colostrum and HMB (beta-hydroxy-beta-methylbutyrate) are still under scientific scrutiny to assess their benefits or practical uses. Creatine phosphate is used as a fuel source in the first few seconds of a sprint. Creatine supplementation can increase muscle creatine phosphate levels and as such may assist athletes to recover more quickly between repeated bouts of high intensity effort. It may also lead to increases in muscle bulk. Caffeine is a central nervous system stimulant commonly available in a wide range of foods and beverages. Several studies have shown a performance enhancing effect for caffeine during exercise of varying intensities and duration. Sensitivity to caffeine varies between individuals and over consumption can produce a range of side effects, such as insomnia, headache, abdominal discomfort, impaired coordination and muscle tremors, all of which can have a negative impact on training and competition performance. The mild diuretic effect of caffeine needs to be considered when exercising for prolonged duration or in hot and humid conditions.

Points to consider

Supplement use in sport is widespread but the majority of supplements are deemed ineffective or unnecessary. The decision to take supplements is not always a rational one. Not only is supplement usage a common feature, but recommended doses often are exceeded, sometimes simply to outdo whatever the opposition or even team mates are taking. Excessive intakes and cocktails of consumption have the potential to do more harm than good and indiscriminate use carries the risk of contamination and positive doping offences.

Athletes considering the use of a supplement should ensure that it is legal, is backed by sound scientific reason and has sound guidelines for its use, and can be obtained through a reliable source. Indiscriminate use of supplements is unwise. Before deciding to use any supplement,

athletes should be cautioned to undertake a cost-benefit analysis in terms of the potential performance benefits weighed against the costs, not only in terms of finance but also the adverse effects on health and performance and the likelihood of contamination with banned or other undesirable substances.

Contaminated supplements have often been blamed for an athlete testing positive for a banned substance, with subsequent claims that the prohibited substance was not declared in the product list of ingredients. With the inception of the World Anti-Doping Code (World Anti-Doping Agency, 2009) and the implications of strict liability, the athlete is strictly held responsible for any prohibited substance found in their system. As such, athletes are strongly advised to be cautious and vigilant about the use of any supplement and to consider that diet, lifestyle and training should all be optimised before turning to supplements to rectify any shortfall in performance potential. Generally, products manufactured within the food and pharmaceutical industries are safer as standards are more rigorous. If in doubt, athletes should consider asking the manufacturer for a written declaration that the product only contains what is stated on the label and to check carefully where ingredients are sourced from and how and where the product is packaged.

UK Anti-Doping has responsibility for ensuring sports bodies in the UK are compliant with the World Anti-Doping Code through the implementation and management of the UK National Anti-Doping Policy. Athletes are advised to be vigilant in choosing to use any supplement. No guarantee can be given that any particular supplement is free from prohibited substances. A number of initiatives to support athletes have been created globally to identify whether a prohibited substance can be identified in a supplement. In the UK, HFL Sports Science has taken the lead to create a scheme to support athletes in assessing the risk of supplement use. The Informed Sport programme is designed to evaluate the integrity of supplement manufacturer process and screening of supplements and ingredients for the presence of prohibited substances that are cited on the World Anti-Doping Code prohibited list. Further information can be found at www.informed-sport.com.

Practical issues

The general recommendations summarised in this chapter can be adjusted to accommodate the unique concerns of individual athletes regarding health, sports nutrition needs, food preferences, and body weight and composition goals. Athletes will benefit from the guidance of qualified professionals who can advise on individual energy, nutrient and fluid needs to develop sports specific nutritional strategies for training, competition and recovery. To achieve this they may need very practical advice concerning shopping, food preparation and cooking to meet their requirements. On a practical level, one of the greatest difficulties facing the athlete is simply finding time for food, whilst coping with training, travel, competition and employment or education.

Nutritional needs for special populations, including children and young athletes, and those with special needs (e.g. athletes with diabetes, gastrointestinal disorders and disabilities) are beyond the scope of this chapter but are discussed in detail in Burke & Deakin (2010).

4.4

Food service

4.4.1 Hospitals and institutions

Richard Wilson

Key points

- Food service is 50% food and 50% service. The service and eating environment elements play an important role in getting food eaten.
- The nutritional value of food not eaten is nil. Above all, food must be attractive, appealing and appetising for the patient if it is to be consumed.
- The menu is the blueprint for success; good menu planning is the key to meeting nutritional goals in institutions.
- The social and rehabilitative value of meal times complements their nutritional importance in the day – make meal times special.
- Modern food production and distribution techniques can be used to improve the patient experience and care or they can be abused to the detriment of the patient experience.
- Getting the right food to the right person at the right time and in perfect condition is an information intensive activity. New technology lends itself to handling that information and enabling its constructive use.

It is important to not lose sight of the fact that 80–100% of patients in hospitals and institutions depend solely on the food provided for their nutritional support (Hiesmayr *et al.*, 2009; Stephen *et al.*, 1997). Ensuring that the food is of good nutritional quality, is appealing to patients and is eaten is a complex and difficult challenge for the dietitian and the caring team. If dietitians do nothing else but maximise the amount of food patients eat while in hospital, they will have achieved a great deal.

General issues

Malnutrition in hospitals

The provision of artificial nutrition has been the focus of much attention in recent decades and has developed considerably. Nutritional support is now possible in all clinical situations but despite these advances, malnutrition in hospitals remains common (Elia, 2009; McWhirter & Pennington, 1994; Stratton *et al.*, 2003) and is often unrecognised (Lennard-Jones *et al.*, 1995).

In the hospital setting, malnutrition is malpractice and it is costly and indefensible (Tucker, 1996; Löser, 2010); managing this risk is an important part of corporate and

clinical governance and is widely recognised to be a human rights issue (Kondrup, 2004). In England it is also unlawful, with the Health and Social Care Act: Regulation 14 stating that ‘. . . *the registered person must ensure that service users are protected from the risks of inadequate nutrition and dehydration . . .*’. The clinical and management team need to recognise this and act when poor food consumption compromises patient nutrition.

Public concern about food in hospitals and institutions

The public and the media are very interested in hospital food. Almost everyone has an anecdote about how a friend or relative *starved* in hospital (Birkett, 2005). Innumerable newspaper articles have highlighted this public concern over the years. The ability of the NHS to deliver this basic human need continues to be a hot topic (Care Quality Commission, 2011; Health Service Ombudsman, 2011). It is clear that food and beverage services in institutions are a *shop window* activity; the funders expect an excellent level of service for the three Cs; catering, cleaning and car parking!

Why good quality food service is important

Providing food in hospitals and other institutions is fundamental to the success of that organisation. There are no other services delivered to every patient, every day that affect their wellbeing so profoundly. Failures in food service can kill and can close hospitals within hours. If food service fails to nourish, the process of identifying and addressing that failure is complex and difficult (Wheatley, 1999). Patients often cannot tell the difference between good treatment and bad treatment but they can always identify poor food.

Guidance and opinion in the UK

A number of reports regarding food service in hospitals and institutions have been published since 1990 and a

summary of their recommendations is given in Table 4.4.1.

Gap between guidance and implementation

Operating and maintaining the performance of high quality food service is a dynamic and iterative process. More research on the cost efficiency of improving food intake in hospitals and institutions is needed (Council of Europe, 2002; NICE, 2006). Although the work that has been published is very convincing (Ödlund-Olin *et al.*, 1996; Gall *et al.*, 1998; Kondrup *et al.*, 1998; Teal *et al.*, 2012), it is difficult and costly to do and the evidence base remains sparse. Public and payer pressure for improvement is an important influencing factor for hospital management teams.

Table 4.4.1 Guidance and opinion on food service in the UK: a review of documents produced since 1990

Year	Organisation and report title	Main recommendations
1992	Department of Health Committee on Medical Aspects of Food Policy <i>The Nutrition of Elderly People</i>	Health professionals should be made aware of the often inadequate food intake of elderly people in institutions Effective methods of ensuring adequate nutrition need to be developed and evaluated for elderly people in hospital or institutions
1992	King's Fund (Lennard-Jones, 1992) <i>A Positive Approach to Nutrition as Treatment</i>	Every hospital should organise its nutrition services to link management, catering and all the clinical disciplines involved Managers should take account of the potential cost of complications and increased hospital stay due to malnutrition when assessing the cost of nutritional support
1993	British Dietetic Association/Nutrition Advisory Group for Elderly People (NAGE) <i>Dietetic Standards of Care for the Older Adult in Hospital</i>	The dietitian advises on nutritionally adequate food which is acceptable to patients and appropriate to patient needs The dietitian advises on hospital policies that affect nutritional care of the older adult
1993	Royal College of Nursing <i>Nutrition Standards and the Older Adult</i>	The client has an initial assessment made of their food and fluid intake and eating and drinking patterns The ward/unit team works towards ensuring that the organisation of the ward and staff is responsive to and meets the requirements of the client in order to satisfy their eating and drinking needs The nutritional goals set for the client and the care received are continually evaluated and revised
1993	South East Thames Regional Health Authority <i>Service Standards: Nutritional Guidelines: The Food Chain</i>	Best practice guidelines on hospital food service Recommendations aiming to get as much food eaten by patients in hospital as possible
1993	South East Thames Regional Health Authority <i>Service Standards: Nutritional Guidelines: Menu Planning</i>	Help and advice on menu planning in the institutional setting Recommendations aiming to ensure that an appealing and attractive menu is constructed which can be delivered and will be eaten
1993	The Patients Association (1993) <i>Catering for Patients in Hospital</i>	Meals should be served at times that reflect the normal eating patterns of the majority of patients Patients should be able to order as close to the time of serving the meal itself as possible The children's menu should reflect the foods they are used to at home Snacks should be available There should be adequate staffing so that patients who cannot feed themselves, or who need encouragement, have the full attention of a member of staff Staff should have responsibility to monitor and report on patients' intake of food and liquid Nurses should collect trays from patients for monitoring of intake There should be a regular evaluation of food and catering services, looking at quality, content and presentation

(Continued)

Table 4.4.1 (Continued)

Year	Organisation and report title	Main recommendations
1994	British Association for Parenteral and Enteral Nutrition (BAPEN) <i>Organisation of Nutrition Support in Hospitals</i>	All UK hospitals should have a nutrition support team (NST) All major UK hospitals or hospital groups should appoint a Nutrition Steering Committee Nutrition Steering Committees should be responsible for setting standards for catering services, dietary supplements and nutritional support All Nutrition Steering Committees should appoint at least one NST to implement standards of nutritional support they recommend
1994	Health of the Nation Nutrition Task Force <i>Nutrition and Health: A Management Handbook for the NHS</i>	Makes suggestions for managers about how they can develop and improve nutrition services in their institution
1995	English National Board for Nurse Education (ENB) <i>Nutrition for Life: Issues for Debate in the Department of Education Programmes</i>	Nutrition themes should be integrated through both preregistration and continuing postregistration programmes Every student should be able to conduct a detailed nutritional assessment of a healthy person
1995	Health of the Nation Nutrition Task Force <i>Nutrition Guidelines for Hospital Catering</i>	Makes recommendations on the nutritional content of hospital food based on the Committee on Medical Aspects of Food Policy recommendations for healthy individuals Provides guidance on best practice in food service and delivery, aimed at getting as much food eaten as possible
1996	BAPEN <i>Standards and Guidelines for Nutritional Support of Patients in Hospitals</i>	Purchasers of healthcare should insist on standards for the organisation and provision of nutrition support There should be an interdepartmental and multidisciplinary Nutrition Steering Committee There should be a catering liaison group with representative caterers, doctors, nurses and dietitians
1996	BDA/Parenteral and Enteral Nutrition Group (PENG) <i>Dietetic Standards for Nutritional Support</i>	Dietitians should actively promote the identification and treatment of protein energy malnutrition and increase awareness of this issue among other healthcare professionals Managers of nutrition and dietetic services ensure that resources are available for the provision of nutritional support within both the hospital and community
1996	National Health Service Executive <i>Hospital Catering: Delivering a Quality Service</i>	Contractors should provide meals which meet patients' dietetic and nutritional requirements Catering procedures should comply with the Nutrition Task Force's guidelines for hospital caterers Chefs should be trained in nutrition to meet dietary needs Contractors should keep prescribed records to demonstrate that nutrition and dietetic requirements are monitored and met The Trust's dietetic manager should ensure that nutrition standards are satisfactory An annual independent audit should be conducted to show meal quality to be satisfactory and to meet patients' needs A guide should be provided for each patient explaining the hospital's catering policies and catering services Patients' meals should not be ordered more than two meals in advance The catering managers name should be made available to patients Help should be readily available for patients where required to allow them to make use of the catering service
1996	British Dietetic Association (BDA) <i>Malnutrition in Hospitals</i>	Dietitians should be actively involved in menu planning to ensure that a nutritionally adequate diet is provided in hospital and that patients requiring special or therapeutic diets are catered for Patients who require artificial nutritional support or a supplemented diet should have access to a dietitian Adequate resources should be available to ensure that high quality nutritional care, whether via the oral, enteral or parenteral route, can be delivered and monitored Dietitians should foster close links with other healthcare professionals involved in the detection and management of malnutrition
1997	Association of Community Health Councils for England and Wales <i>Hungry in Hospital?</i>	Accusations that patients are starving to death must be investigated Roles and responsibilities at meal times must be defined Existing guidance with regard to hospital catering must be enforced

Table 4.4.1 (Continued)

Year	Organisation and report title	Main recommendations
1997	Centre for Health Services Research, University of Newcastle upon Tyne (Bond, 1997) <i>Eating Matters</i>	Meal provision should be responsive to the patients' needs Patients should be asked for their opinions about the meals provided Multidisciplinary and cross departmental dietary care groups should be created All other ward activities should stop when meals are being eaten Audits of dietary care should be carried out regularly
1997	United Kingdom Central Council for Nursing and Midwifery (UKCC) <i>Responsibility for Feeding of Patients</i>	Nurses have an implicit responsibility for ensuring that patients are appropriately fed
1997	British Dietetic Association <i>National Professional Standards for Dietitians Practising in Health Care</i>	Dietitians will liaise with catering concerning the production of food to specified nutritional standards, the development of menus (including choice), food delivery systems (inhouse or outside caterers), and that the food service encourages and enables the client to eat the food provided Dietitians will be involved in documentation relating to the provision of food and its service to clients Dietitians will advise on the provision of nutritionally adequate food specific to clients' needs and in accordance with national standards Dietitians will ensure catering and other staff have accurate information and receive appropriate training Dietitians will liaise with other members of the multiprofessional team to ensure that all aspects of the individuals care are considered in the nutrition care plan
1999	The Nuffield Trust <i>Managing Nutrition in Hospital: A Recipe for Quality</i>	Makes recommendations on the management of nutrition services to the Department of Health, NHS Executive, National Institute for Health and Care Excellence (NICE), The Audit Commission, health professional bodies, research funding agencies, health authorities and primary care groups and hospital trusts Food provision should be managed as an integral component of clinical care rather than a 'hotel' function
1999	BAPEN <i>Hospital Food as Treatment</i>	Doctors should acknowledge a responsibility for patient nutrition as an important part of overall management The chief dietitian should have an executive, not just an advisory, input into the catering services Consideration should be given to a new Nutrition Directorate with overall responsibility for all aspects of nutritional care Consideration should be give to transferring the catering and nutritional care service from the hotel/facilities directorate to the clinical support and treatment service budget
2001	Department of Health <i>Better Hospital Food</i>	This 4-year campaign produced a wide range of resources which are now archived and available for download on the Hospital Caterers Association website (www.hospitalcaterers.org)
2002	Council of Europe <i>Food Service and Nutritional Care in Hospitals: How to Prevent Undernutrition</i>	Undernutrition is common in hospitals across Europe Action to improve the identification and treatment of undernutrition Action to improve the training of staff providing nutritional care Action to improve the provision of hospital food Action to understand the health economics of food and nutritional care in hospitals
2002	Royal College of Physicians (Kopelman and Lennard-Jones, 2002) <i>Patient Nutrition: A Doctor's Responsibility</i>	Recognition of the important role doctors have to play in ensuring that their patients are adequately nourished Recognition that more emphasis on nutrition is needed in undergraduate and postgraduate training of doctors in the UK
2002	British Dietetic Association <i>Food Service a Consensus Statement</i>	Standard methodologies for the nutritional analysis of recipes and menus using food tables
2003	Quality Improvement Scotland (Scottish Executive, 2003) <i>Food, Fluid and Nutritional Care</i>	Set of standards covering assessment, screening and nutritional care planning; and the provision of food and fluid to patients
2003	Council of Europe Resolution ResOP (2003)3	The 19 Council of Europe member states that participated in the 2002 report <i>Food Service and Nutritional Care in Hospitals: How to Prevent Undernutrition</i> formally endorsed the recommendations of the report This commits governments to implementing the recommendations
2003	<i>Catering Services for Children and Young Adults</i>	This report was produced as part of the Department of Health 'Better Hospital Food' campaign Resources are produced by the BDA Paediatric Dietitians specialist group

(Continued)

Table 4.4.1 (Continued)

Year	Organisation and report title	Main recommendations
2004	British Dietetic Association, Hospital Caterers Association and Royal College of Nursing <i>10 Key Characteristics of Good Nutritional Care</i>	This short report distils the 100+ recommendations made in the Council of Europe report and resolution into 10 simple actions that can be understood clearly at operational and managerial levels
2004	Hospital Caterers Association and Royal College of Nursing <i>Protected Meal times Policy</i>	Ensuring that meal times are a priority in the hospital day and are recognised as an important part of care and treatment delivery
2006	<i>Hospital Caterers Association Good Practice Guide Healthcare Food and Beverage Services</i>	This is a useful guide to the team working required at ward level if food and beverage services are to be successful
2006	British Dietetic Association <i>Delivering Nutritional Care Through Food And Beverage Services, A Toolkit for Dietitians</i>	This report was produced by the Food Counts Interest group of the British Dietetic Association It includes a whole set of useful tools for those charged with delivering food and beverage services in hospitals and other institutions
2007	<i>Improving Nutritional Care, A Joint Action Plan from the Department of Health and Nutrition Summit stakeholders</i>	This report was produced following two 1-day conferences of stakeholder groups facilitated by the Department of Health in England The report makes many recommendations for joint action to improve nutritional care
2010	Nutrition Action Plan Delivery Board <i>End Of Year Progress Report</i>	The Delivery Board was convened to ask stakeholders how the recommendations made in the <i>Joint Action Plan</i> could be implemented There are recommendations on screening, training and the provision of information resources Many of the resources produced can be found on the website of the Social Care Institute for Excellence (www.scie.org.uk)
2010	Department of Health <i>Government Response to the Nutrition Action Plan Delivery Board End of Year Progress Report</i>	The government broadly endorsed the recommendations of the Delivery Board
2010	Essence of Care <i>Benchmarks for the Fundamental Aspects of Care</i>	This guidance on the delivery of nursing care includes a section on standards for the delivery of nutrition and hydration
2011	<i>All Wales Nutrition and Catering Standards for Food and Fluid Provision for Hospital Inpatients</i>	Sets out quality standards for food and beverage provision in hospitals in Wales
2011	<i>Care and compassion? Report of the Health Service Ombudsman on Ten Investigations into NHS Care of Older People</i>	Report raises concerns about the basic level of care delivered to older people and calls for improvements, particularly in the provision of nutritional care (help and assistance with eating and drinking).
2011	<i>Promoting Good Nutrition. A Strategy for good nutritional care for adults in all care settings in Northern Ireland 2011–2016</i>	A strategy document for the improvement of nutritional care in hospitals in Northern Ireland
2011	<i>Dysphagia Diet Food Texture Descriptors</i>	This report produced by the National Patient Safety Agency and endorsed by the BDA, RCN and RCSLT defines textures of food for the management of dysphagia
2011	Care Quality Commission <i>Dignity and Nutrition Inspection Programme National Overview</i>	This report presents the results of the inspection of nutritional care at 100 hospitals in England; 55 of 100 were found to be below the standard expected
2012	BDA <i>The Nutrition and Hydration Digest: Improving Outcomes through Food and Beverage Services</i>	<ul style="list-style-type: none"> • A comprehensive source for standards, coding, guidance and good practice • An evidence document for tenders and specifications • A tool providing a common language for clinicians, caterers, industry, etc. • The definitive approach in food service in care settings for professional (and other) bodies • A quick reference document on a multitude of food related topics

How to get more food eaten

Getting the food that is served eaten by the intended consumer is the principal goal of any food service system as the nutritional value of food not eaten is nil. The dietitian must understand the principles of food service in order to help achieve this goal. The process begins with menu planning.

Menu planning

The menu is the blueprint of food service and time spent planning the menu is never wasted. A dietitian's expertise is their knowledge of the nutritional requirements of the client group to be served and understanding how these might be met by the food supplied.

Knowing the client group

The first step in menu planning is gathering information about the client group:

- What do they like to eat?
- What are their cultural and religious preferences?
- What are their physical needs and personal preferences?
- When do they like to eat?
- How do they like to eat?
- What assistance will they need with eating?

Knowing what resources are available

It must be possible to deliver the menu you are planning:

- Can it be afforded?
- Is the kitchen equipment needed to produce the recipes available, i.e. enough oven space, crockery, cutlery, serving utensils?
- Is the necessary staffing and expertise available?
- Are the food storage facilities sufficient?
- Are food supplies secure?
- Can the items required be delivered in time and on a regular basis?
- Can the food be distributed to the patients accurately and safely?

Nutrition support team and policy

Menu planning is best practised as a team. Input from the dietitian, caterer, nurse, doctor, pharmacist, speech and language therapist and patients' representative is required to bring the necessary knowledge and expertise to the planning process. This core team will be recognisable to most dietitians as the core membership of the nutrition support team (NST). The reports of the Nuffield Trust (Maryon-Davis & Bristow, 1999), the British Association for Parenteral and Enteral Nutrition (BAPEN, 2007) and the Council of Europe (2002) all recommend that such a group be formed to oversee the nutritional health of the inpatient population in all hospitals or groups of hospitals.

It is recommended that such a cross department and interdisciplinary team develops nutritional policy for the hospital and oversees the implementation and monitor-

ing of the effectiveness of that policy. It is further recommended that nutritional support policy extends to policy related to the provision of food. The NST's involvement in menu planning ensures that this responsibility is executed.

Menu structure

Once the team has gathered the information on policy, patient requirements and resources, the next step is to plan the structure of the menu:

- Over how many days will the menu run?
- Will the menu change daily over a cycle or will it be 'à la carte'?
- How many meals are to be provided each day?
- Will the meals be hot or cold?
- What is the structure of each individual meal?
- Will a starter be offered?
- How many choices will be offered?
- What types of dish are to be offered, i.e. meat, fish, vegetarian, egg, cheese, salad, sandwiches, soft choices, etc.?
- Can each item of the meal be chosen separately or is a meal to be offered as a single choice?

Developing the structure of the menu is the most difficult part of the planning process and it is important to spend time getting it right. Regardless of the dishes offered, a menu with a poor structure will not meet the patient's needs and desires (Table 4.4.2).

Selection of suitable dishes

Once the structure of the menu is determined, decisions can be made about individual dishes that will make up

Table 4.4.2 Outline structure of a menu for a large hospital

Breakfast	Lunch	Supper
Fruit juice	Fruit juice	Fruit juice
Fresh fruit	Soup	Soup
Wholemeal cereal	Main meat or fish dish	Main meat or fish dish
Low residue cereal	Soft dish (suitable for those with no teeth)	Snack dish
Porridge		Soft dish
	Vegan dish	Vegan dish
Wholemeal bread	Salad	Sandwich
White bread	Suitable staple	Suitable staple
Butter	Mashed potato	Mashed potato
Low fat spread	Vegetable 1	Vegetable 1
	Vegetable 2	Vegetable 2
Boiled egg		
Jam	Baked pudding	Baked pudding
Marmalade	Milk pudding	Milk pudding
	Custard	Ice cream
Milk	Fresh fruit	Cheese and biscuits

the menu. It is useful to put the menu structure on a large sheet of paper on the wall at this stage, write the names of the dishes available on sticker notes and assemble the menu. This visual technique allows a degree of interactivity within the planning team and highlights the way in which individual dishes complement one another. A visual prompt such as this will also bring to light any repetitions in the menu, particularly at the beginning and end of the menu cycle.

Information required for each dish

Detailed information about nutritional composition, cost and availability of preprepared dishes and standard recipes for dishes that are to be prepared on site will be needed. The British Dietetic Association (BDA, 2006) provides consensus guidance on the calculation of nutritional composition of recipes from food tables. This process requires professional judgement and interpretation at several stages, and variation and error can be introduced. The guidance aims to standardise methodology and reduce variation and error.

Nutrition information

Nutrition information required by the menu planner will depend on the requirements of the client group. A renal dietitian will be more interested in the electrolyte composition of foods than a dietitian responsible for the care of elderly people, whose focus of interest is more likely to be food consistency and energy density. Information about other aspects of food composition, such as whether it contains gelatine, gluten, milk, nuts or peanuts, etc., is also likely to be required. The menu planning team should agree on information requirements at an early stage in the planning process.

An increasing amount of nutrition information is demanded by a food and health conscious public. The planning team have a duty to meet these needs, e.g. this means knowing if any food item on the menu contains ingredients derived from genetically modified organisms. The NHS Supply Chain (www.supplychain.nhs.uk) provides comprehensive information on food purchased on NHS contracts.

Ratification of the menu

Once the first draft of the menu has been agreed, it will need to be ratified by analysis of its nutritional composition and cost. It is recommended that nutritional analysis is carried out and interpreted by a registered dietitian. The BDA provides consensus guidance on the methodologies involved in this process (BDA, 2006). The dietitian needs to be sure that the menu will meet the nutritional requirements of the client group, including the needs of those requiring modified diets. The ratification process will lead to a fine tuning of the menu, ensuring that the final menu represents the best available in terms of nutritional content, cost and practical deliverability.

Publishing the menu

Once completed, the menu needs to be published. At this point the team needs to consider how patients are going

to make their choice from the menu. It is important to make sure that patients understand what is being offered to ensure their active participation in food choice. Patients are much more likely to eat food they have chosen themselves.

Systems and food service

The chain of events from provisions arriving at the hospital gate to completed dishes being presented to the patient is often referred to as the food chain. The best planned menu can fail at any point if the food delivery system is not robust. No one wants to eat cold food that should be hot or hot food that should be cold, or food which is poorly presented.

There are many new systems and technologies available to assist in the delivery of food service in hospitals. Different types of food service systems together with a summary of their benefits and drawbacks are summarised in relation to the following areas:

- Ways in which food can be prepared and stored (Table 4.4.3).
- Ways in which food can be distributed to the ward (Table 4.4.4).
- Methods of food service at ward level (Table 4.4.5).

Ward hostesses

Well trained and dedicated staff at ward level can dramatically improve food service (Stephen *et al.*, 1997). Staff whose main function is to ensure that patients are fed appropriately can make a great deal of difference to the amount of food eaten. By ensuring that all the administration related to securing patient meal choices is carried out, liaising with the kitchen in a timely manner, having time to discuss meal choices with patients and reporting food intake to nursing staff, a significant input to patients' nutritional support can be made. In addition, trained staff can implement food hygiene regulations on the ward and assure food safety.

Eating environment

The environment and ambience on the ward can make a dramatic difference to the acceptability of food and the amount eaten. Meal times should be regarded as special and important times in a patient's day and every effort should be made by ward staff to ensure that patients are uninterrupted and have time to enjoy their meals. Protected meal times give staff on the ward explicit permission to focus all their efforts on nutritional care, allowing other responsibilities to take a lower priority.

Decisions made at the time when new buildings or new food service systems are being planned can have considerable influence on the subsequent quality of food provision. Particular thought should be given to the amount of space required on wards for food preparation, service and consumption; inadequacies in these respects can ultimately affect the amount of food eaten (Bond, 1997).

Table 4.4.3 Food service systems ways in which food can be prepared and stored

System of food preparation and storage	Benefits	Concerns
<p>Cook/serve 75% of hospitals in the UK prepare most food on site from fresh, raw ingredients. Increasingly items such as pies, puddings, preprepared vegetables and cooked meats are used</p>	<p>Flexibility, capable of adaptation to most situations Food preparation skills maintained on site Recipes can be adapted quickly to meet unusual requirements Traditional and regional variability</p>	<p>Depends on a well trained, skilled and motivated workforce Production facilities are expensive to maintain and take up a lot of space</p>
<p>Cook/chill Food is cooked and blast chilled to between 0 and 4°C. Food can be stored and distributed at this temperature for up to 5 days after production. It is then reheated (regenerated) ready for food service</p>	<p>Requirement for skilled cooks is reduced Requirement for expensive cooking equipment is reduced Can reduce 'hot holding' of food and improve nutritional value when served Fewer peaks and troughs in the kitchen working day Can increase variety of food available on the menu</p>	<p>Food costs increase to pay for preprepared food Regeneration must be done skilfully to optimise food quality 5-day shelf life Greater distribution leads to increased food safety risks Increased dependence on outside supplier Some dishes are not suitable for this type of service, e.g. pastry Less flexible service if no production facilities are maintained on site</p>
<p>Steamplicity® This is a variation on cook/chill in that the food is plated and packed in an outer container that includes a patented valve. The whole package is regenerated in a microwave oven and the valve enables steam pressure cooking to take place</p>	<p>Requirement for skilled cooks is reduced Requirement for expensive cooking equipment is reduced Reduces 'hot holding' of food and improves nutritional value when served Can increase variety of food available on the menu Food waste is reduced as a result of the 'plated system'</p>	<p>Food costs increase to pay for preprepared food Regeneration must be done skilfully to optimise food quality 5-day shelf life Increased dependence on outside supplier Some dishes are not suitable for this type of service, e.g. pastry Less flexible service if no production facilities are maintained on site</p>
<p>Cook/freeze. Food is cooked and quickly chilled to -18°C. Food can be stored and distributed at this temperature for periods of up to 3 months. It is then reheated (regenerated) ready for food service</p>	<p>As per cook/chill Increased shelf life makes distribution logistics easier</p>	<p>As per cook/chill Energy costs associated with freezing, storage and regeneration</p>
<p>Cook/conservesous vide Cook/chill and cook/freeze are often described as cook/conserves systems. This term is also used to describe <i>sous vide</i> systems. Food is cooked, sealed in an air free, oxygen impermeable, multilayered plastic bag. It is then chilled or frozen prior to storage and distribution. The food is then reheated (regenerated) ready for service</p>	<p>As per cook/chill Sealed package makes handling easier and safer Increased shelf life makes distribution logistics easier</p>	<p>As per cook/chill Increased cost of packaging</p>

Table 4.4.4 Food service systems: ways in which food can be distributed to the ward

Method	Benefits	Concerns
<p>Plated service Food is served onto the plate centrally and distributed</p>	<p>Good portion control Food safety risks contained in one area Fewer staff required on the ward Tight control of waste</p>	<p>Difficult to maintain food temperature and quality during distribution Logistics of collecting data on patient choice Difficult to cater for out of hours requirements Serving staff do not know who they are serving</p>
<p>Bulk food service Food is distributed in large containers and is served onto the plate at ward level</p>	<p>Food choice takes place at bedside Food temperature and quality easier to maintain during distribution 'You can have your gravy where you want it' Greater flexibility in terms of portion size Serving staff get to know the patients Patients can participate in the food service process</p>	<p>More space required at ward level More food handling risks at ward level Portion control more complex More ward based time required More staff required at ward level</p>

Table 4.4.5 Food service systems: methods of food service at ward level

Method	Benefits	Concerns
Trayed service Food is assembled on a tray and the patient eats at the bedside or in bed	No communal ward areas needed Tight control of modified diets more practicable May be preferred by patients with eating difficulties Privacy Suitable for bedbound patients	Second helpings more difficult to provide Lack of social interaction Monitoring of food intake more difficult Problems unpacking some food items If whole meal is served, parts of it may go cold
Cafeteria style service	More normal Flexibility of service and portion size available at point of service Possibility of social interactions Food choice at point of service	Communal eating area needed Patients need to be mobile
Family meal service	As above Meal times more of an occasion, breaking up the ward day Mealtime can be used as a rehabilitative activity	More food service equipment needed at ward level Requires a degree of patient independence or increased staffing Communal eating area needed

Food waste

Up to 40% of food provided to patients is wasted (Stephen *et al.*, 1997; Edwards & Nash, 1997; Fenton *et al.*, 1995; Kelly, 1999). Full dustbins and empty patients are not successful nutritional support and care! Systems for the monitoring of food waste are a valuable performance indicator and act as a proxy measure for the amount of food that is being eaten. It is important to distinguish between plate waste, i.e. where a patient has attempted to eat a meal and not eaten all of it, and trolley or tray waste, i.e. food that was surplus to requirements and was never offered to patients.

High levels of plate waste may indicate either that the patient has a poor appetite, in which case a different approach to nutritional support needs to be considered, or that the taste, presentation or temperature of the food was at fault.

High levels of tray or trolley waste indicate that there is a food delivery problem. Information on needs may be poor, meal times may be inappropriate or portion control may need to be studied more carefully. *Managing Food Waste in the NHS* is a useful guide (Department of Health, 2005).

Audit of food service

Food service is a large scale, hospital wide operation, and the monitoring and auditing procedures are complex. It is important at the policy setting stage or the contract specification stage that patient centred output measures are agreed that will truly reflect the quality of the service. The NST should play a pivotal role in receiving, reviewing and recommending Hospital Board action on these output measures. Closing the audit loop in food service is difficult and resource intensive, but it is an important part of ensuring that the food service plays its full role in the nutritional support of patients. Developments in information technology are improving the ability to capture data on a large scale and interpret them appro-

priately. These developments need to be applied to food service monitoring to make it operationally practicable (Teal *et al.*, 2012).

Future of food service in the NHS

Each of the UK home countries recognises the important role of food in the nutritional support of patients in hospital and all are signatories to the Council of Europe Resolution ResAP 2003(3), which makes recommendations for the improvement of food and nutritional care in hospitals in 19 Council of Europe member states. The recommendations are being implemented through the setting of quality standards in each of the home countries. The Care Quality Commission is the regulatory body responsible for standards of healthcare provision in England and Northern Ireland. In Wales, inspection is carried out by Healthcare Inspectorate Wales and Healthcare Improvement Scotland sets and assures the standard in Scotland.

4.4.2 Prisons

Joan Gandy

Key points

- Depending on the category of prison, all food and drink, apart from some snacks and soft drinks, consumed by prisoners is provided by the institution.
- The prison governor has responsibility for catering and enforcing Ministry of Justice instructions.
- Food has a significant role in prisoners' lives; it can be the source of complaints, contribute to dissension and become a catalyst for aggression.
- Prison populations are at particular risk of obesity and associated health risks.

Unlike other institutions, prisons provide all the food and drink, apart from some snacks and soft drinks, consumed by prisoners. This depends on the category of the prison, with prisoners in lower security category prisons, e.g. open prisons, having more opportunity to supplement

their intake. The primary objective of prison catering is '... to provide a varied and healthy menu which takes account of prisoners' preferences whilst maintaining compliance with all relevant food safety legislation' (Department of Justice Northern Ireland, 1995). In

December 2011 there were record numbers of prisoners, including those held in Immigration Removal Centres, of over 88 000 in England and Wales. In March 2012 the Scottish prison population was nearly 8500 (Berman, 2012).

Meal provision and dietary quality

The provision of meals and food is seen as a key issue in helping to maintain order in prisons and in improving prisoners' health. In the UK Instruction PS44/2210 (Ministry of Justice, 2010) details prison catering services. All prisons use a preselected, multichoice, cyclical menu for lunch and dinner, which covers a minimum 4-week cycle. Portion sizes are tightly controlled to meet budgetary demands and for consistency. In 2004–2005 the UK Prison Service spent £94 million on catering; £43 million of which was spent on food. The average daily allowance for food is £1.87, although this varies between prisons and the type of prison. In Scotland the prison service spends £1.57 per head on food, compared with £2.50 per head in hospitals [National Audit Office (NAO), 2006].

The Ministry of Justice (2010) instruction on catering states that *'The food provided shall be wholesome, nutritious, well prepared and served, reasonably varied and sufficient in quality'*. The NAO report found that food served to prisoners was in line with national recommendations as given in the Balance of Good Health [this has been superseded by the eatwell plate (see Chapter 4.2)]. The food is varied, different dietary requirements are catered for and at least one meal at each serving is labelled as healthy. Religious and cultural requirements are also considered. Some groups have been set up by prisoners to educate and assist prisoners in obtaining specialist diets, e.g. the Vegan Prisoners Support Group. However, the report highlighted that food is often not served within 45 minutes of preparation, leading to decreased palatability and nutritional content. Meal times vary and some meals are served early, such as 11.15 AM for lunch and 4 PM for the evening meal, resulting in some prisoners exceeding the 14-hour interval standard between meals overnight. The NAO commissioned a survey into the diet of prisoners in England that found that prisoners were able to access and choose a nutritionally balanced diet and that most do so (Edwards *et al.*, 2007). However, there were minor dietary deficiencies in some micronutrients in some prisoners, including of vitamin D and zinc. Some dishes were not as healthy as they could be, with significant amounts of fried food being on offer; annotation was not always accurate.

Food has a significant role in prisoners' lives and sometimes symbolises their experience of prison (Smith, 2002). It can be the source of complaints and contribute to dissension and become a catalyst for aggression (Blades, 2001). It is therefore important that where queuing is inevitable, operational measures are taken to ensure that prisoners at the end of the queue are able to obtain their chosen meals; this reduces conflict and confrontation at the serving point.

The prison governor has overall responsibility for catering standards and the kitchens are inspected daily by the prison governor or an assistant. The catering manager at each prison is responsible for implementing standards. Her Majesty's Inspectorate of Prisons and the Independent Monitoring Board are responsible for monitoring all aspects of prison life including catering.

Non-communicable diseases

The prevalence of non-communicable diseases (NCDs) such as obesity, cardiovascular disease (CVD), diabetes and cancer is increasing and vulnerable groups are especially affected. Prisoners are one such vulnerable group. A recent systematic review by Herbert *et al.* (2012) of studies in 15 countries, including >60 000 prisoners, showed an increase in some risk factors for NCDs. They found that women prisoners were more likely to be overweight or obese, although men were less likely to be. However, the heterogeneity of the studies meant that no summary calculations could be reported. Women prisoners consumed more energy than the recommended intake and all prisoners had sodium intake two to three times that recommended. UK prisoners were less physically active than the general population. One of the studies reviewed was that of Plugge *et al.* (2009) which surveyed CVD risk factors in women prisoners in the UK. They found that 30% were obese, 86% did not eat five or more pieces of fruit and vegetables per day, 85% smoked and 87% were insufficiently active. The authors repeated the survey a month into the women's sentences and found few improvements in risk factors.

Plugge *et al.* (2009) highlighted that there are currently no systematic approaches to educate prisoners on healthy lifestyles and address health problems within UK prisons. This is despite the NAO (2006) report recommending that the Prison Service should raise awareness of healthy eating by educating prisoners, using posters and actively promoting healthy eating on a regular basis. Following its report, the NAO produced guidance on promoting healthier lifestyles in prisons. Programmes exist in other countries, e.g. the WISEWOMAN programme in the USA. This programme provides heart disease screening and interventions for low income women and now works in women's prisons (Khavjou *et al.*, 2007). It has helped identify undiagnosed hypertension and dyslipidaemia, and offers interventions to improve health and discharge planning.

Dietetic practice in prisons and with prisoners

Given the rising levels of nutrition related diseases and number of prisoners, it is likely that dietitians will increasingly be asked to advise prisons or to advise prisoners in prisons or hospitals. Currently there is no guidance for dietitians working in prisons on how to deal with situations such as patients in restraints, lack of privacy and the prison regimen. In addition, dietitians may be asked to counsel prisoners as hospital patients; both as in- and out-patients. The British Medical Association (2009) pro-

vides guidance on the medical care for prisoners that dietitians may find useful. The guidance states:

- Detained prisoners must have the same standards of care as the rest of society, including respect for patient dignity and privacy.
- Risk assessment must be carried out prior to a prisoner going into hospital to determine the degree of supervision. Risk assessment includes: the prisoner's condition, any medical objection to the use of restraints, nature of the prisoner's offence, security of the consulting room and risk of violence to self or others.
- Where escape is unlikely, escort and bed watch by one prison officer, without restraints, is sufficient.
- Hospitals should be informed in advance about the levels of escort and restraint envisaged, and hospital staff should have the opportunity to discuss when level of restraint is clinically unacceptable.

More recently, prisons are increasingly using telemedicine for consultations between prisoners and healthcare professionals, including dietitians.

Nutrition and behaviour

The relationship between nutrition and criminal or delinquent behaviour is receiving increasing attention; however, evidence is still sparse. In addition, some studies are poorly constructed and there are few intervention trials. Benton (2007) reviewed the evidence and performed a meta analysis looking at the impact of diet on antisocial, violent and criminal behaviour. An analysis of five well designed randomised controlled studies showed that elimination diets reduced hyperactivity related symptoms and polyunsaturated fatty acid supplementation decreased violence in children. Three well designed studies showed that vitamin and mineral supplements reduced antisocial behaviour and aggression was linked to low blood glucose levels in adults. Benton (2007) concluded that the reactions to foods were inconsistent and not observed in all participants. Clearly there is a need for more well designed research in this area.

Diet and nutrition in prisons is an area that will undoubtedly become an increasingly important area of dietetic practice, as there is a need for health screening, promo-

tion and education on healthy lifestyles. Further well constructed research studies are needed to look at the relationship between diet and criminal and delinquent behaviour.

4.4.3 Armed forces

Joan Gandy

Key points

- Food is provided to non-operational, operational and civilian personnel.
- Contractors are expected to conform to a standard to provide choice and follow the healthy eating policy.
- Personnel are provided with nutrition guidance when enlisting and commanders are provided with information in order to support personnel.
- Dietitians in the UK are more likely to work in liaison with forces medical services than be employed by them.

Food is provided in three areas; non-operational (UK bases), operational (overseas bases, active theatres and ration packs) and civilian. The Defence Food Services Team (DFS) is responsible for food provision, meal type and quality for the armed forces in all areas including ships and submarines. The DFS also helps develop operational ration packs (ORPs). The Defence Catering Manual (Joint Services Publication 456) covers every aspect of food provision. Contractors must conform to a quality standard (Ministry of Defence, 2011), and supply products that provide choice and meet the healthy eating policy.

The Pay as You Dine (PAYD) system provides catering for non-operational food service. This system replaced the daily food charge, which was deducted from service personnel's salary regardless of whether or not it was taken. The PAYD system provides three core meals and personnel pay only for food that is taken; they also have access to other foods. The core meals must provide at least six items at breakfast and lunch and a three course dinner. Many members of the armed forces live off base or self cater.

The Ministry of Defence has developed military dietary reference values for macro- and micro-nutrients, but these are not readily available to the general public. All advice is based on the eatwell plate (see Chapter 4.2). The Expert Panel on Armed Forces Feeding (EPAFF) UK produces nutrition and hydration guidance for personnel, which emphasises increasing and maintaining performance, reducing the chance of injury, staying fit and healthy, and quick recovery from activity. All new recruits are provided with nutrition education materials. The emphasis is on the importance of nutrition and the grueling and physical nature of military training, rather than weight and fat reduction. Recruits are treated as athletes and are given the necessary support and advice to achieve fitness. This is accompanied by the Commander's Guide to Nutrition; a more complex guide aimed at senior personnel. It gives more detail and offers nutritional guidance for operation packs (Wilcox, 2005).

The Armed Forces Nutrition Advisory Service offers expert advice and information on nutrition, diet and military feeding; this is only available to UK military personnel and Ministry of Defence civil servants. Dietitians are rarely employed in the UK Armed Forces, although they may be employed in institutes such as the Institute of Naval Medicine. Other dietitians work in liaison with military medical services in settings such as the Royal Centre for Defence Medicine in Birmingham (formerly Selly Oak Hospital).

In other countries, e.g. the USA, dietitians are members of the armed forces. The US military also conducts research into nutrition and has established research institutions for this, e.g. the U.S. Army Research Institute of Environmental Medicine.

Operational ration packs

All personnel are issued with these packs when operational, although field catering facilities are provided as soon as possible after deployment. The packs provide between 3788 and 4996kcal with approximately 57% carbohydrate, 33% fat and 10% protein. Vegetarian meals and other specific diets, e.g. kosher and halal, are available. Packs always contain instant coffee, tea, fruit biscuits, brown biscuits, tabasco sauce, chewing gum and water purification tablets. Matches are also included for lighting the hexiburner cooker that every soldier carries.

The NATO Nutrition Science and Food Standards for Military Operations also covers UK military personnel working as part of a North Atlantic Treaty Organization (NATO) force.

4.5

Food law and labelling

Fionna Page and Ruth Birt

Key points

- Many laws relating to food in the UK, e.g. labelling, additives and claims, are now of European Union (EU) origin.
- The Food Standards Agency (FSA) is responsible for food safety and food hygiene across the UK.
- Responsibilities for food labelling are split between the FSA, the Department of Health and the Department for Environment, Food and Rural Affairs (Defra).
- The European Food Safety Authority (EFSA) is responsible for food safety risk assessment and advises the European Commission (EC) on the scientific aspects of food legislation.
- Legislation and guidelines regarding food and nutrition labelling, and claims are changing, and can be complex. Readers can keep up to date by referring to the Department of Health, Defra, EC, EFSA and FSA websites.

History of food legislation in the UK

After years of attempts at food regulation since 1266, the Food and Drugs Act 1938 was the first to combine specific food legislation with public health measures; at this time, food poisoning became notifiable across the UK. The act introduced controls for new areas such as misleading labelling and advertising, and powers were introduced to regulate the composition and labelling of foods as well as on the sanitary conditions of food on sale for human consumption. The act was suspended for the duration of World War 2, but with concerns about food substitutes being passed off as originals and insufficient nutrition being provided to ensure a staple diet to keep people fit and healthy, emergency powers were introduced. In 1955, a consolidating Food and Drug Act came into being, which was to remain the basis for food legislation until general legislation covering the composition, labelling, hygiene and safety of food in the UK was introduced in 1984 with the Food Act. (The Medicines Act superseded the drug aspect in 1968). However, during the 1980s there was a general increase in the number of reported cases of food poisoning and a number of well publicised food scares linked to *Salmonella* infection in raw eggs, *Listeria* contamination in foods such as soft cheeses and pâtés (believed to increase the number of miscarriages and stillbirths), and an outbreak of botulism caused by hazelnut yoghurt. In July 1989, the government announced far reaching proposals to change the law in its White Paper

Food Safety – Protecting the Consumer. As a result, food legislation underwent its first major review since the 1940s, culminating in the Food Safety Act 1990.

In the UK there is now an extensive array of legislation, codes of practice and guidance covering the whole area of food from production to distribution, packing, labelling and sale, and it may be of UK origin or be influenced or driven by European or international standards.

International food legislation

Since food is both imported into and exported from the UK, legislation on standards of composition and on labelling has to be compatible with, and in some instances comply with, international standards.

The European Union

Membership of the European Union (EU) means that the UK is required to implement European Commission (EC) regulations and directives, and this is now a major influence on UK food legislation.

Codex Alimentarius Commission

Codex, as it is usually known, has a fundamental mandate to develop international standards and norms for consumer health protection and fair practices in the food trade. It is comprised of the two United Nation bodies,

the Food and Agriculture Organization (FAO) and the World Health Organization (WHO), and has a wide membership of the majority of developing and developed countries. Codex recommendations have no statutory force but members are encouraged to apply its norms to the widest extent possible as a basis for domestic regulation and international trade. In general, Codex standards are incorporated into European, and hence UK, legislation and, in recent years, have been important in the resolution of trade disputes across the continents.

Current UK food legislation

An understanding of the different types of legislation gives an insight into how and when food legislation becomes effective in the UK. Since the UK is a member of the EU, all EU regulations and directives have to be implemented into the UK regulatory system. This is possible under the Food Safety Act 1990 (classed as primary legislation), which not only provides the framework for all domestic food legislation, but also the powers to make secondary legislation to implement EU laws.

Regulations and directives

EC regulations are effective in all member states as soon as the EC Council adopts them. EC directives, on the other hand, do not become effective until they are written into a country's own legislation, and in the UK are actually also called regulations. For example, to allow for enforcement and execution of the EU Novel Foods Regulation, EC 258/97, the UK had to introduce its own regulations, called The Novel Foods and Novel Food Ingredients Regulations 1997 (SI 1997/1335). European legislation is denoted by EC followed by the number (in this case 258) and the year of publication. The UK regulation is denoted by SI (Statutory Instrument), the year of publication and the number (in this case 1335). These unique identifying numbers are important for citing the correct piece of legislation.

Most of the key provisions in food law are contained in legislation which sets out the specific details governing matters such as:

- Food labelling.
- Food hygiene.
- Animal, meat and meat products, e.g. those concerned with the examination for residues and maximum residue limits.
- Registration of food premises.
- Regulations on milk and dairies.
- Food composition.
- Use of food additives.
- Use of food packaging materials.

Regulations are kept under review and are subject to change (in the form of amendments), either as a result of that review or in order to harmonise food law within the EC.

Some important regulations are those concerning labelling, sweeteners, colours, flavouring, miscellaneous

food additives and organic foods. As well as these general (horizontal) regulations that apply across food categories, there are specific (vertical) regulations applying to the composition of specific foods, such as bread and flour, chocolate and chocolate products, milk and soft drinks. There are also specific hygiene regulations relating to the production of milk, meat and other animal products.

Some categories of foods for particular nutritional uses (dietetic foods) have specific compositional and labelling rules as laid down in the European Foods for Particular Nutritional Uses (PARNUTS) directive. These include foods intended for energy restricted diets for weight reduction such as slimming foods; foods for special medical purposes (FSMPs) such as sip and tube feeds amongst others; foodstuffs suitable for people intolerant to gluten; and infant formulae, follow on formulae and weaning foods. Individual European directives that have been implemented into UK law as regulations currently govern each of these food categories.

Emerging issues

In June 2011 the EC published a proposal to revise the current PARNUTS Framework Directive, which may abolish the concept of dietetic foods and put in place a single regulation covering only food intended for infants and young children, and food for special medical purposes, although this approach is still under debate. General food law could in future cover the remaining food categories.

The Food Safety Act

The Food Safety Act 1990 is the main piece of UK legislation on food safety and consumer protection in Great Britain (GB); a separate but similar law applies in Northern Ireland. The act provides the framework for UK food law but does not, in itself, contain the specific rules governing matters such as the safety, quality, description or labelling of food. These details are set out in regulations and orders (classed as secondary legislation) made under the act. Codes of practice can also be issued under Section 40 of the Food Safety Act 1990. These are documents issued by ministers for the guidance of food authorities, the provisions for which can be enforced by direction and court order.

The aims of the Food Safety Act are to:

- Ensure that all food produced for sale is safe to eat, meets quality expectations and is not misleadingly presented.
- Provide legal powers and penalties.
- Enable the UK to fulfil its responsibilities in the EC.
- Keep pace with technological change.

The Food Safety Act 1990 has four main parts; preliminary, main provisions, administration and enforcement, and miscellaneous and supplemental.

Part I: Preliminary

This sets out the full scope of the act and the responsibilities for those involved in enforcing it. It covers the whole of GB and provides for regulations covering all aspects of food production, processing and selling, from the farm to the retailer. Its definitions of food have been widened to include slimming aids, dietary supplements and tap water, and premises now include most Crown properties, ships and aircraft. The act also sets out the principle that local authorities are responsible for enforcing most aspects of food law.

Part II: Main provisions

The main provisions of the act, namely food safety, consumer protection, regulation making powers and defences, are covered in this part of the act.

Offences

The main offences under the Food Safety Act are:

- Selling, or possessing for sale, food that does not comply with food safety requirements.
- Rendering food injurious to health.
- Selling, to the purchaser's prejudice, food that is not of the nature or substance or quality demanded.
- Falsely or misleadingly describing or presenting food.

Food safety requirements apply to food throughout the food chain, not just that for retail sale. Food is injurious to health if it could harm part of the population either in the short term, e.g. cause food poisoning, or long term, e.g. contaminated with lead. 'Not of the nature or substance demanded' means that it is illegal to sell cod described as haddock, or cola instead of diet cola. A purchaser can range from a customer at a shop to one supplier buying from another. 'Falsely or misleadingly described or presented' applies to written statements or pictorial representations which are untrue. Additional constraints are also laid down in food labelling regulations.

Defences

One significant aspect of food legislation introduced under the 1990 act was that due diligence became grounds for defence. Thus, for example, a retailer who unwittingly sold a contaminated food would not be guilty if it could be shown that the contamination occurred at an earlier stage in the supply chain and that the retailer could not have known that the product was unfit for sale. In practice, this means that the onus is on the food industry and food importers to supply safe food, and is considered to be a far reaching and important aspect of the act.

Novel foods

The act also contains powers to make regulations covering the sale of novel foods, i.e. those that are new or have only been rarely eaten in this country. Another significant piece of legislation then introduced was the EU Regulation (EC) 258/97 concerning novel foods and novel food

ingredients, which applies to the placing of novel foods or ingredients onto the EU market that have not previously been used for human consumption to a significant degree. Detailed rules for the authorisation of novel foods, ingredients and processes were laid down, including the introduction of a means of mandatory notification for foods or ingredients containing, consisting or produced from genetically modified organisms (GMOs), subsequently updated over the years.

Part III: Administration and enforcement

This lays down procedures for the sampling and analysis of products, powers of entry, obstruction and enforcement. It also deals with the legal aspects of prosecution and appeal procedures.

Part IV: Miscellaneous and supplemental

This covers the issuing of codes of practice to food authorities on the execution and enforcement of legislation, and directions on specific steps to be taken to comply with a code. Other details pertain to areas of coverage of the act and other aspects of its implementation.

Other food related UK legislation

A number of other Acts of Parliament, and their subsidiary regulations, also impact in various ways on the provision, sale or safety of food. It was the Food Standards Act 1999 that set up the FSA and transferred functions and powers relating to food standards and safety to it. The FSA is an independent department working at arm's length from the government, which provides advice and information to the public and government on food safety from farm to fork. It also protects consumers through effective food enforcement and monitoring. The FSA is accountable to parliament through health ministers, and to the devolved administrations in Scotland, Wales and Northern Ireland for its activities within their areas. The FSA obtains independent expert advice from its scientific advisory committees and commissions research to support its functions.

European legislation on general food safety is contained in the General Food Law Regulation (EC) 178/2002), which introduced many key procedures for food safety matters, including the establishment of the European Food Safety Authority (EFSA). In the UK, the General Food Regulations 2004 No 3279 (and amendments) provides for the enforcement of certain provisions of Regulation (EC) 178/2002 (including imposing penalties) and amends the Food Safety Act 1990 to bring it in line with Regulation (EC) 178/2002. Similar legislation applies in Northern Ireland.

An excellent guide to food law is supplied by the FSA as *The Food Law Guide* (www.food.gov.uk). It covers legislation in effect in the UK and lists Statutory Instruments that apply in only one UK country, but gives the details of any equivalent legislation in the other UK countries. It is updated every 3 months. It also provides a link to relevant guidance documents.

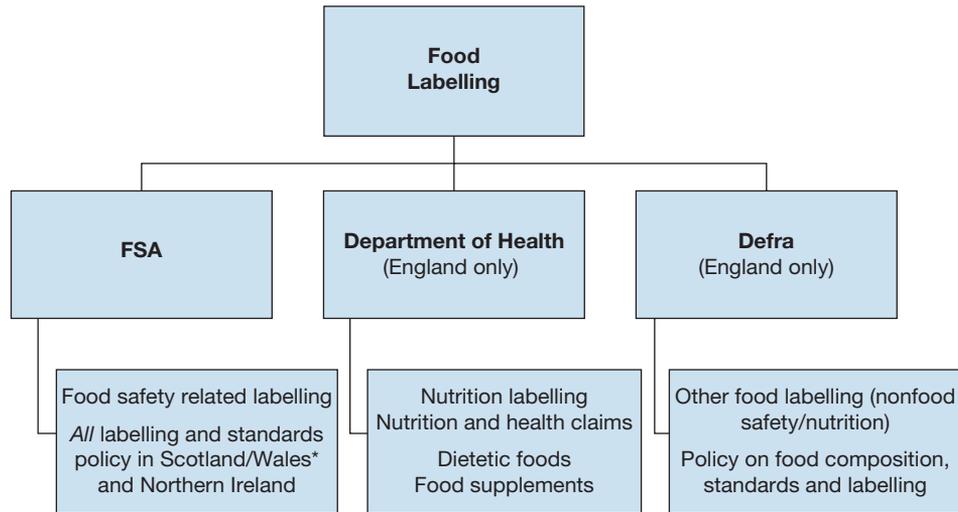

Figure 4.5.1 Food labelling responsibility in the UK

Law enforcement

The FSA works with enforcement officers to ensure that food (and feed) law is applied across the entire food chain as a result of its statutory powers to strengthen enforcement of food standards, and to ensure national objectives are delivered. The responsibilities of all the enforcement authorities in the UK are set out and agreements are in place that provide a structure to the FSA's supervision of local authority enforcement work.

The Food Law Code of Practice sets out the way local authorities should apply food law, and how they should work with food businesses. The FSA provides guidance on specific regulations that are relevant to enforcement officers and food businesses to ensure that the law is clear. A new body, Local Government Regulation (formerly LACORS, the Local Authorities Coordinators of Regulatory Services), provides one link between local food enforcement and central government, giving advice and guidance to local authorities as well as advising the FSA on food enforcement issues.

Local enforcement officers have wide powers to inspect any stage of the production, manufacturing, distribution and retail chain, and have a responsibility to investigate any food complaints passed on to them by consumers. Food premises are inspected at a frequency dependent upon risk. Frequency of physical inspections can vary from once every 6 months to once every 2 years. Enforcement officers also have the power to take samples of food for testing to ensure compliance with food legislation, as well as powers to take action against a food premise that does not comply with food law. This enforcement action can range from issuing warnings and improvement or prohibition notices, to instigating prosecutions. The courts can inflict heavy penalties for non-compliance, including the closure of a business where conditions are particularly bad.

Food labelling

Food labels are the principle method by which a consumer gets information about their food. Labels must be accurate and must not mislead, so consumers can make informed choices about the food they buy. From October 2010, responsibility for food labelling was divided between three government departments in the UK as illustrated in Figure 4.5.1. The FSA leads on food safety related labelling. Nutrition labelling sits with the Department of Health to help towards a consistent approach to nutrition policy. Other areas of non-safety related food labelling are the responsibility of the Defra whose role also includes coordination of labelling policy across government. NB: Responsibilities for food labelling differ across the UK home countries.

Labelling regulations

Food information regulation

Food labelling in the UK is principally controlled by the Food Labelling Regulations 1996 (and later amendments, incorporating EC directives and regulations) made under the Food Safety Act 1990. However, in November 2011, following a European wide review of general food labelling and nutrition labelling rules, a new Food Information for Consumers Regulation No 1169/2011 (FIR) was published. The FIR consolidates and simplifies existing food labelling legislation and will replace current UK food labelling law after a 3-year transitional period. The general principle of the new FIR remains primarily to provide a basis for consumers to be able to make informed choices about the food they consume and to prevent misleading practices. It also continues to prohibit claims that foods prevent, treat or cure human disease, so-called medicinal claims.

Table 4.5.1 Mandatory information on food labels as required by the Food Information Regulation

Mandatory food information	Notes*
Food name	A legal name, customary name or descriptive name must be used See Product name section for examples
List of ingredients	Must include all the ingredients in the food in descending order of weight (an ingredient list or certain ingredients can be omitted in some circumstances) Annexes to the regulation give detailed rules for listing ingredients by weight, names of ingredients, food additives, enzymes and flavourings, and compound ingredients
Ingredients or processing aids causing allergies or intolerances	Annex II of the regulation lists the substances or products causing allergies or intolerances that must be indicated in the list of ingredients and given special emphasis, e.g. by the use of bold font The rules will extend to foods sold loose and foods sold by caterers
Quantity of ingredients	See Ingredients section for more detail
Net quantity of the food	Continues to allow some foods to be sold by number, e.g. bread rolls or eggs
Date of minimum durability or the use by date	Best before and use by will continue to be used A date of first freezing will be included for foods such as meat or fish See Durability section for more detail
Special storage instructions and/or conditions of use	See Durability section for more detail
Name and address of the food operator marketing or importing the food into the European Union	
Country of origin or place of provenance	The rules have been tightened and will also extend to fresh and frozen meat Scotland and other areas may be referred to without the use of UK on the label
Instructions for use	Particularly where without instructions it would be difficult to make appropriate use of the food
For alcoholic drinks with >1.2% by volume of alcohol	Actual alcoholic strength labelled as X% vol, preceded by the word alcohol or alc
Nutrition declaration	See Nutrition labelling section for more detail

*Refer to Regulation (EU) No1168/2011 and relevant annexes for full details.

The main changes to the legislation include new rules on nutrition labelling, provision of allergen information, labelling clarity, added caffeine in foods and high caffeine drinks, country of origin labelling, the labelling of water content of some meat and fish products, and voluntary calorie labelling on alcoholic drinks. The FIR requires that all foods intended for the final consumer, including foods supplied to or delivered by mass caterers (subject to certain exceptions), be marked or labelled with the mandatory food information shown in Table 4.5.1. A notable change is that by 2016 nutrition labelling will be mandatory on most prepacked foods.

Additional mandatory information is required on some foods, e.g. foods packaged in certain gases, foods containing sweeteners, certain frozen meat and fish products, and foods containing liquorice. Drinks high in caffeine (>150mg/L) (other than those based on tea or coffee or their extracts) will need to show the caffeine content in milligram per 100mL and carry the warning '*High caffeine content – Not recommended for children or pregnant or breastfeeding women*'. Foods with added caffeine will need to carry the warning '*Contains caffeine – Not recommended for children or pregnant women*' and also show the caffeine content.

The FIR specifies that food information should be available, easily accessible and visible, and where appropriate indelible, but now also places special emphasis on the legibility of the mandatory information on food labels and specifies a minimum font size of 1.2 mm (0.9 mm for small packages).

Product name

This is required to be a clear description of the product, e.g. pilchards in tomato sauce. If the product has a non-descriptive brand name, e.g. Marmite, some indication of its nature must be given, e.g. yeast extract. The name must also indicate if the product has undergone any form of processing, e.g. UHT milk or smoked mackerel. Descriptions must also not be misleading; if a product is described as raspberry yogurt, then it must contain raspberries, not just raspberry flavouring. Some foods have customary names, e.g. cream crackers, which do not contain cream but the name is considered to be sufficiently familiar not to be misleading. Other foods have prescribed names with strict rules governing their use, e.g. margarine has to contain 80% fat; if the product contains less than this, it must be called something else such as a spread.

Ingredients

These are given in descending order of content so, for example, if water is the first item listed, then water is the most abundant ingredient. In the past, food ingredients lists only provided a limited guide to food quality, e.g. whether a hamburger contains cereal filler as well as meat. In 2000, this ability was strengthened by the EC requirement for Quantitative Ingredients Declaration (QUID). Most food products now have to state the quantity of any ingredients that:

- Appear in the name of a food or which are usually associated with that name by consumers.
- Are emphasised on the label in words, pictures or graphics.
- Are essential to characterise the food and to distinguish it from products with which it might be confused because of its name or appearance.

Declarations must appear in, or next to, the name of the food, or in the ingredients list, and must be shown as a percentage (based on the amount of the ingredient used at the manufacturing stage). The aim is to help the consumer compare the quality of similar foods by being able to see how much ham and mushroom is in a ham and mushroom pizza or pork in pork sausages.

Allergens

In the past, substances that were part of a compound ingredient comprising <25% of the finished product did not have to be itemised separately. This meant that potentially allergenic substances, such as small amounts of milk, wheat or gluten, did not appear in the ingredient list, making it difficult for individuals to avoid potentially allergenic substance. New food labelling regulations, implementing a 2003 EU directive, came into force in the UK at the end of 2005. One of the main purposes of the changes was to remove the 25% rule and ensure that all allergenic ingredients, as defined in the directive, are included in ingredient lists (see Chapter 7.11.2). The 14 allergenic food ingredients, and derivatives, that must be declared are:

- Cereals containing gluten.
- Crustaceans.
- Eggs.
- Fish.
- Peanuts.
- Soyabeans.
- Milk (including lactose).
- Nuts (from trees).
- Celery.
- Mustard.
- Sesame seeds.
- Sulphur dioxide >10 ppm.
- Lupin.

Highly processed ingredients derived from these allergens are exempt if they no longer contain allergenic proteins.

The composition and labelling of foodstuffs for people intolerant to gluten is also covered by specific European

legislation that came into force in January 2012. It stipulates set levels of gluten that are permitted in foods, making gluten free claims as follows:

- *Gluten free* – the gluten content of foods bearing this claim must not exceed 20 ppm.
- *Very low gluten* – the gluten content of foods bearing this claim must not exceed 100 ppm (only foods with cereal ingredients that have been specially processed to remove the gluten may make this claim).

These rules apply to all foods, including prepacked foods, food sold loose and foods sold in health food shops or catering establishments.

Durability

This must be indicated either by a *use by* or *best before* date, and there is an important difference between the two. Highly perishable fresh foods, e.g. dairy products, must have a use by date, and after this time it should be assumed that the food is no longer safe to eat. To minimise the risk of food poisoning, use by dates should be strictly observed.

The best before date applies to foods with a shelf life of weeks, months or even years, e.g. breakfast cereals or canned foods. After this date there may be some deterioration in the quality of the texture and flavour of the product, but the food will not necessarily be unsafe to eat.

If any special storage conditions such as refrigeration are necessary, these must be shown close to the use by or best before date.

Food additives and E numbers

A food additive is defined as any substance not normally consumed as a food by itself and not normally used as a typical ingredient in a food, which is intentionally added to a food for functional purposes. Types of food additives are preservatives, antioxidants, emulsifiers and stabilisers, colours, sweeteners, flavour enhancers and flavourings. The safety of food additives is rigorously tested and periodically reassessed. The FSA is the responsible authority in the UK for giving advice on the safety of additives. At EU level, all additives currently allowed have been evaluated by the EFSA, or its predecessor, the Scientific Committee for Foods (SCF), and given an E number.

It is perhaps ironic that the E number classification system, originally intended as a way of providing assurance that an additive's safety had been evaluated, came to be regarded by the general public as a symbol of undesirable food. As a result of the bad image associated with E numbers, food manufacturers are increasingly declaring additives in ingredients lists by their chemical name rather than their E serial number (a permitted option under food labelling legislation). From a dietetic viewpoint, this can make it more difficult for any client who may need to avoid particular additives, as they now have to memorise complex chemical names rather than simple numbers. The E number classification system for food additives is summarised in Appendix 5.

The Food Labelling Regulations 1996 determine the way in which additives present in foods are declared on food labels. Those used as ingredients in prepackaged foods must be listed in an ingredients list by:

- The appropriate category name of the function, e.g. preservative.
- This must be followed by their specific name, e.g. sulphur dioxide, or E number, e.g. E220.

If an additive has more than one function, e.g. emulsifier and thickener, the category name that describes its principal function should be used.

Flavourings are slightly different because there are so many of them and they are harder to categorise. They may therefore be declared by the term flavourings, while natural flavourings may be declared if in line with the provisions of the new EU definitions introduced in 2008.

Foods containing artificial sweeteners require a declaration that the food contains sweeteners or, if sugars (any added mono- or di-saccharide) are also present, a declaration of sweeteners and sugars. There are additional labelling requirements for foods containing aspartame (stating that it is a source of phenylalanine) and polyols (excessive consumption of which may have a laxative effect).

Consumer attitude to additives

Many consumers view the presence of additives in foods with great suspicion, believing them to be undesirable in principle, synthetic in nature and a common cause of allergies. However, many of these anxieties are misplaced. Food additives fulfil a useful purpose in retarding microbial spoilage, prolonging shelf life and improving taste, colour and texture. Many food additives are natural or nature identical substances, or even nutrients such as beta-carotene (used as a food colour) or vitamin C (used as an antioxidant). While some people can react to certain additives, this type of food intolerance is relatively rare (see 7.11.2).

The food industry has responded to consumer concerns by carefully assessing the necessity for additives and reducing the level of usage as much as possible, particularly the use of azo food dyes in soft drinks and sweets, and substituting synthetic compounds with more natural alternatives. An interesting development came from the FSA recommendations to government ministers for a ban on the use of certain colours after a study that looked into the effects of six colours and their effect on children's behaviour. The colours are tartrazine (E102), quinoline yellow (E104), sunset yellow (E110), carmoisine (E122), ponceau 4R (E124) and allura red (E129) ((McCann *et al.*, 2007). Over the past few years, the FSA has worked with the UK food industry to voluntarily remove these six colours from food and drink, and to make this information available to consumers. A mandatory warning laid down in EU legislation will make it easier for people to choose products that are free from these colours. Legislation was introduced in 2010 that all food placed on the market containing any of these six colours should carry additional label information that '*consumption may have an adverse effect on activity and attention in children*'.

Nutrition labelling

The Food Labelling Regulations 1996 lay down a prescribed format for the nutrition labelling of foods. Nutrition labelling is currently voluntary under these rules, except where a nutrition or health claim is made. Group 1 or the *Big 4* represents the minimum level of nutrition information that can be given; alternatively, more information can be given using the Group 2 or the *Big 8* format. By 2016 nutrition labelling will be mandatory on the majority of foods under the rules introduced by the new FIR, which also includes new requirements for the content, calculation, expression and presentation of the nutrition declaration.

Table 4.5.2 shows a comparison of the current FLR 1996 and the new FIR nutrition declaration. Due to the

Table 4.5.2 Comparison of the current Food Labelling Regulations (FLR) 1996 and new Food Information Regulation (FIR) nutrition declarations*

FLR 1996 Group 1 (<i>Big 4</i>)	FLR 1996 Group 2 (<i>Big 8</i>)	FIR 2011 nutrition declaration**
Energy (kJ and kcal)	Energy (kJ and kcal)	Energy (kJ/kcal)
Protein (g)	Protein (g)	Fat (g)
Carbohydrate (g)	Carbohydrate (g)	Of which
Fat (g)	– of which sugars (g)	– saturates (g)
	Fat (g)	– monounsaturates (g)
	– of which saturates (g)	– polyunsaturates (g)
	Fibre (g)	Carbohydrate (g)
	Sodium (g)	Of which (g)
		– sugars (g)
		– polyols (g)
		– starch (g)
		Fibre (g)
		Protein (g)
		Salt (g)
		Vitamins and minerals†

*These rules do not apply to food supplements or natural mineral waters.

**Mandatory energy and nutrients shown in bold.

†Units are specified in the Annex of the Regulation.

transitional periods in the FIR, a manufacturer who chooses to present nutrition information *voluntarily* on pack could, between 13 December 2011 and 13 December 2014, opt to present nutrition information according to either the rules in the FLR 1996 or the new FIR. However, after 13 December 2014, the FLR 1996 will be repealed, so manufacturers will have to comply with the rules stipulated by the FIR from this date. A nutrition declaration for most foods only becomes *mandatory* in 2016.

The new FIR stipulates seven key nutrients, listed in a different order to the FLR 1996 options. Inclusion of monounsaturates, polyunsaturates, polyols, starch, fibre (previously a requirement in Group 2) and vitamins and minerals are voluntary. Salt is now included in place of sodium to aid consumer understanding. Values per quantified serving may be given as well as, but not instead of, values per 100 g or 100 mL under the FLR 1996. In the FIR there are options for presenting the nutrition declaration on a per portion basis or per consumption unit in certain circumstances.

The new FIR gives the option to express the energy value, fat, saturates, carbohydrate, sugars, protein and salt as a percentage of the reference intakes (Table 4.5.3), which are similar to the guideline daily amounts (GDAs). Under FLR 1996 if a vitamin or mineral is declared in the nutrition labelling panel, or a claim is made, Group 1 nutrition information must be given. If a claim is made relating to a Group 2 nutrient, e.g. high in fibre, information on all Group 2 nutrients should be given.

The rules governing the labelling of vitamins and minerals are more complex. The content of these nutrients can only be declared if a food will provide a significant amount (7.5% for beverages and 15% for products other than beverages) of the nutrient reference values (NRVs) for each vitamin and mineral, as listed in the annex of the regulation (Table 4.5.4). These were previously known as

Table 4.5.3 Comparison of guideline daily amounts (GDAs) (IGD, 2006) with new reference intakes for energy and selected nutrients other than vitamins and minerals (adults). Differences are highlighted in bold

Energy or nutrient	Reference intake	Guideline daily amount*
Energy (kcal)	2000 (8400 kJ)	2000 kcal
Total fat (g)	70	70
Saturates (g)	20	20
Carbohydrate (g)	260	230
Sugars (g)	90	90
Protein (g)	50	45
Salt (g)	6	6
Sodium (g)	–	2.5
Dietary fibre (AOAC) (g)	–	25

*GDA for an adult woman. GDAs for men and children aged 5–10 years are also available (see www.gdalabel.org.uk)

the recommended daily amounts (RDAs). The EC has committed to look at the issue of *trans* fats and may in due course introduce legislative proposals for the labelling of *trans* fats on foods.

Issues relevant to nutrition labelling in the UK

Aspects of nutrition labelling information that should be noted are:

- **Energy** – for nutrition labelling purposes, energy content is derived using a conversion factor of 4 kcal/g for carbohydrate and sugars, rather than 3.75 kcal/g used by standard UK food tables. The energy content declared on food labels will therefore be slightly higher than food table values. The new FIR also introduces additional new conversion factors for the calculation of energy values for labelling purposes (Table 4.5.5). NB: Fibre now has a conversion factor of 8 kJ/g or 2 kcal/g.
- **Fibre** – a new definition of fibre was introduced in 2008 which expanded the definition to include carbohydrate polymers with three or more monomeric units, which are neither digested nor absorbed in the human small intestine. The Association of Official Analytical Chem-

Table 4.5.4 Nutrient reference values (NRVs)

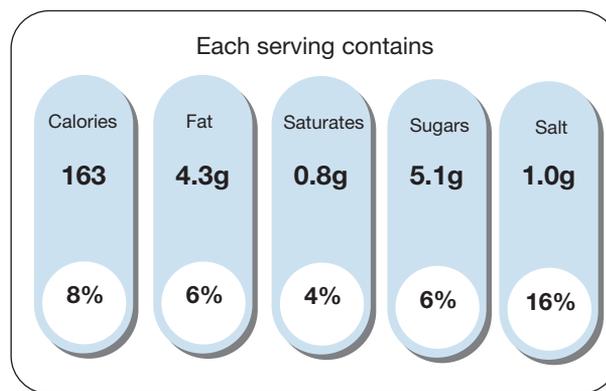

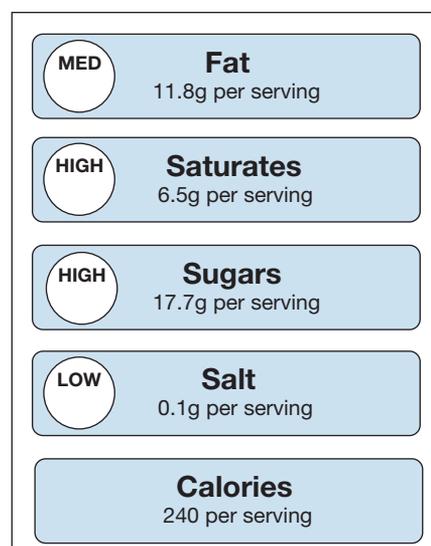

Nutrient	NRV
Vitamin A (µg)	800

Organic acid	13	3
Fibre	8	2
Erythritol	0	0

ists (AOAC) method for analysis of fibre should be used. However, UK food tables mainly give dietary fibre (non-starch polysaccharide) values using the Englyst method and the AOAC method only for a very limited number of foods.

- **Salt** – the FLR 1996 labelling requirement is to list the content of sodium in grams, this will change under FIR to salt in grams to aid consumer understanding. UK food tables provide sodium content in milligrams.
- **Accuracy** – nutrition information on food labels is mainly estimated using published data on food composition as the alternative laboratory analysis is expensive for food manufacturers and is prone to sampling errors, especially for non-homogeneous foodstuffs. There will therefore be some variability between the declared values and those determined by analysis of a sample of the foodstuff. An acceptable margin for error is not specified by law and should reflect the type of foodstuff. For example, a foodstuff consisting of chunks of meat and vegetables in a sauce will be inherently more variable than a homogenous foodstuff such as chocolate and this has to be reflected in the acceptable margin for error.
- **NRVs** – the NRVs for vitamins and minerals, against which the amounts in food are compared in the nutrition panel, are a set of adult data produced specifically for labelling purposes. These were updated in 2008 and were previously known as RDAs.
- **GDA**s – Table 4.5.2 shows what is known as the back of pack nutrition declaration. In the UK manufacturers have been using front of pack labelling for a number of years and several different presentations have emerged, spearheaded by the Institute of Grocery Distribution (Figure 4.5.2) and the FSA traffic light colour coding system (Figure 4.5.3). The new FIR allows the option to continue to voluntarily repeat front of pack information on nutrients of importance to public health (energy value or energy value plus fat, saturates, sugars and salts). It is not yet clear if the term GDAs will be permitted once the FIR is fully in force.

Nutrition and health claims

Nutrition and health claims can be a useful way of conveying information to consumers and help them choose foods with particular nutritional features and health benefits. However, people need to be able to do so without being misled. In December 2006, Regulation No 1924/2006 on nutrition and health claims made on foods was published with the aim of protecting consumers from false or misleading claims, in addition to harmonising the legislation on claims across the EC to facilitate trade. It applies to nutrition and health claims made in commercial communications to the final consumer, including claims made in the labelling, presentation and advertising of food. It also applies to foods supplied to restaurants, hospitals, schools and other mass caterers. The legislation defines what is meant by a claim, and defines the different type of claims (Table 4.5.6).

Table 4.5.6 Key definitions included in Regulation 1924/2006 on Nutrition and Health Claims Made on Foods

Term	Definition
Claim	A claim is defined as “any message or representation, which is not mandatory under Community legislation or national legislation, including pictorial, graphic or symbolic representation, in any form, which states, suggests or implies that a food has particular characteristics”
Nutrition claim	Any claim that states suggests or implies that a food has particular beneficial nutritional properties due to the energy it: <ol style="list-style-type: none"> 1. provides 2. provides at a reduced or increased rate 3. or does not provide and/or the nutrients or other substances it: <ol style="list-style-type: none"> 1. contains 2. contains in reduced or increased proportions 3. or does not contain
Health claim	Any claim that states, suggests or implies that a relationship exists between a food category, a food or one of its constituents and health
Reduction of disease risk claim	Any claim that states, suggests or implies that the consumption of a food category, a food or one of its constituents significantly reduces a risk factor in the development of a human disease

The regulation is complex and sets out many requirements for the authorisation and use of nutrition and health claims. In 2011 the Department of Health issued an extensive guidance document giving regulatory and best practice advice on how to comply with the regulation (Department of Health, 2011). It covers the whole of the UK. Along with the regulation itself the Department of Health guidance document is essential reading for anyone involved in this area.

The regulation sets out general principles for all claims and further specific conditions for nutrition and health claims, which include:

- Claims must *not* be false, ambiguous or misleading; suggest a balanced and varied diet cannot provide appropriate quantities of nutrients; encourage or condone excess consumption of a food; or refer to changes in bodily functions that could exploit fear in the consumer.
- Claims must be based on generally accepted scientific data and be well understood by the average consumer.
- In most cases if a claim is made, nutrition labelling is mandatory.
- Only nutrition claims listed in the annex to the regulation are permitted and only if they meet the conditions of use stipulated for that claim (Table 4.5.7).
- Only authorised health claims included in the EU Register can be used on food and claims must meet the conditions of use (see Table 4.5.8 for examples of authorised claims).
- Claims must not be made on alcoholic beverages containing >1.2% by volume of alcohol (see regulation for limited exceptions).
- Health claims not permitted include those that suggest that health could be affected by not consuming the food or make reference to the amount or rate of weight loss.

- Health claims that make reference to recommendations of individual doctors or health professionals are not allowed on food labelling. This is covered by Article 12(c) within the regulation and is explained in more detail within the Department of Health guidance document. However, there is still debate about what is permitted. The British Dietetic Association (BDA) has been active on this topic and can provide an update for anyone concerned about the issue.
- Nutrient profiles (restrictions on the use of claims on certain foods or categories of foods based on their nutritional composition) have still not been adopted and are the subject of much debate.

Health claims require authorisation under the regulation. The Panel on Dietetic Products, Nutrition and Allergies (NDA) of the EFSA is responsible for scrutinising the scientific substantiation for health claims submitted by food business operators. Specific rules apply for claims for disease risk reduction and those that refer to children’s health and development. EFSA’s opinions inform EC decisions about whether a claim will be included in the EU Register. Claims that a food can treat, prevent or cure (medicinal claims) continue to be prohibited.

Addition of nutrients

In December 2006 Regulation (EC) 1925/2006 on the addition of vitamins and minerals and certain other substances to foods was published to provide the same rules throughout the EC. *Other substances* are those, other than vitamins and minerals, that have a physiological effect. The regulation prohibits the addition to unprocessed foods such as fruit, vegetables, meat, poultry and fish, and to beverages containing >1.2% by volume of alcohol. It includes lists of the vitamins and minerals that may be added to foods and the form in which they may be added.

Table 4.5.7 Nutrition claims and conditions applying to them as listed in the Annex of Regulation 1924/2006 on Nutrition and Health Claims Made on Foods

Claim	Condition
Low energy	No >40 kcal (170 kJ)/100 g or 20 kcal (80 kJ)/100 mL
Energy reduced	At least 30% reduction
Energy free	No >4 kcal (17 kJ)/100 mL
Low fat	No >3 g of fat/100 g or 1.5 g/100 mL (1.8 g for semi skimmed milk)
Fat free	No >0.5 g fat/100 g or 100 mL. 'X% fat free' prohibited
Low saturated fat	No >1.5 g/100 g or 0.75 g/10 mL. No >10% of energy
Saturated fat free	No >0.1 g/100 g or 100 mL
Low sugars	No >5 g/100 g or 2.5 g/100 mL
Sugars free	No >0.5 g/100 g or 100 mL
With no added sugars	No added mono- or di-saccharides or any other food used for its sweetening properties. If sugars naturally present, the label should include CONTAINS NATURALLY OCCURRING SUGARS
Low sodium/salt	No >0.12 g of sodium (or the equivalent value for salt)/100 g or 100 mL. Note the rules for waters differ
Very low sodium/salt	No >0.04 g of sodium (or the equivalent value for salt)/100 g or 100 mL. Note not permitted for waters
Sodium or salt free	No >0.005 g of sodium (or the equivalent value for salt)/100 g or 100 mL
Source of fibre	At least 3 g/100 g or 1.5 g/100 kcal
High fibre	At least 6 g/100 g or 3 g/100 kcal
Source of protein	At least 12% of energy
High protein	At least 20% of energy
Source of [named vitamin/s and/or mineral/s]	Significant amount (15% RDA/100 g)
High [named vitamin/s and/or mineral/s]	At least twice the value of source (30% RDA/100 g)
Contains [name of nutrient or other substance]	For vitamins and minerals same level as 'source of'. Article 5 of particular importance for claims relating to other substances and nutrients
Increased [name of nutrient]	Meets requirements for 'source of' and at least 30% more than a similar product
Reduced [name of nutrient]	At least 30% less than a similar product. For micronutrients: 10% difference in reference values. For sodium (or the equivalent value for salt) 25% difference
Light/Lite	As 'reduced'
Natural/naturally	Prefix 'natural/naturally' may be used where food naturally meets the conditions for nutrition claims
Source of n-3 fatty acids	At least 0.3 g of alpha-linolenic acid/100 g and 100 kcal or at least 40 mg of EPA and DHA/100 g and 100 kcal
High n-3 fatty acids	At least 0.6 g of alpha-linolenic acid/100 g and 100 kcal or at least 80 mg of EPA and DHA/100 g and 100 kcal
High monounsaturated fat	>20% energy. At least 45% fatty acids present derived from monounsaturated fat
High polyunsaturated	>20% energy. At least 45% fatty acids present derived from polyunsaturated fat
High unsaturated fat	>20% energy. At least 70% of fatty acids derived from unsaturated fat

See <http://ec.europa.eu/nuhclaims/> for a full up to date list of nutrition claims.

Table 4.5.8 Examples of authorised health claims listed in the EU Register on Nutrition and Health Claims

Claim type	Nutrient, substance, food or food category	Claim	Conditions of use of the claim
Function health claim [Article 13(1)]	Calcium	Calcium is needed for the maintenance of normal bones	The claim may be used only for food which is at least a source of calcium as referred to in the claim SOURCE OF [NAME OF VITAMIN/S] AND/OR [NAME OF MINERAL/S] as listed in the Annex to Regulation (EC) No 1924/2006
Disease risk reduction claim [Article 14(1)(a)]	Oat beta-glucan	Oat beta-glucan has been shown to lower/reduce blood cholesterol. High cholesterol is a risk factor in the development of coronary heart disease	Information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 3g of oat beta-glucan. The claim can be used for foods that provide at least 1g of oat beta-glucan per quantified portion
Children's development and health claim [Article 14(1)(b)]	Vitamin D	Vitamin D is needed for normal growth and development of bone in children	The claim can be used only for food that is at least a source of vitamin D as referred to in the claim SOURCE OF [NAME OF VITAMIN/S] AND/OR [NAME OF MINERAL/S] as listed in the Annex to Regulation 1924/2006

See <http://ec.europa.eu/nuhclaims/> for a full up to date list of authorised and non-authorised health claims.

SECTION 5

Other topics relevant to practice

5.1

Genetics and nutritional genomics

Joanna Instone and Kevin Whelan

Key points

- Dietitians should be able to recognise modes of inheritance, gather and use multigenerational family history and communicate genetic information relevant to their area of work.
- Modes of inheritance vary for single gene conditions and chromosomal conditions, but patterns can be detected that enable traits to be detected and risk to be estimated.
- Nutritional genomics is the investigation or application of the interaction between genetics, diet and nutrition specifically in relation to the maintenance of health and prevention or treatment of disease.
- Nutrigenomics relates to how diet and nutrients affect gene expression, whereas nutrigenetics relates to how genetic variation modifies an individual's response to diet and nutrients.
- There is increasing evidence for the role for nutritional genomics in dietetic practice, especially in cardiovascular disease, including the use of low fat or low saturated fat diets in people carrying the apolipoprotein ε4 allele.

Genetic activities in clinical dietetic practice

Diet plays a role in the treatment of many conditions that have a genetic component, e.g. phenylketonuria (PKU), cystic fibrosis and familial hypercholesterolaemia. Technological advances enable better understanding of these conditions as well as the discovery of the genetic basis for an increasing number of conditions. Such advances allow the development of new therapies, including in many instances dietary manipulation. To ensure patients have access to genetic advances now and in the future, dietitians must be able to conduct a number of genetic based activities. Examples of such activities include recognising modes of inheritance in families, gathering multigenerational family history information to draw a family tree (pedigree) and communicating genetic information to individuals, families and healthcare staff (Skills for Health/NGEDC, 2007).

Recognising a mode of inheritance

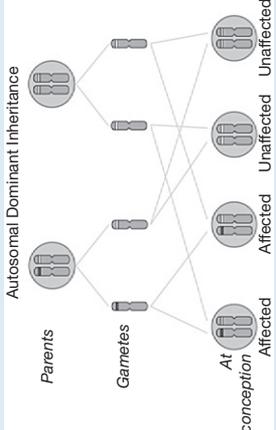

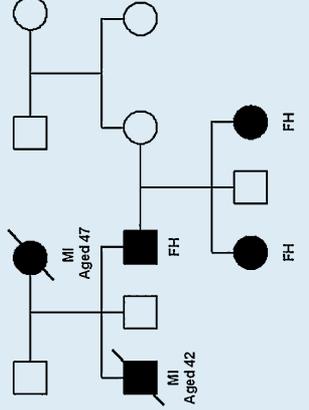

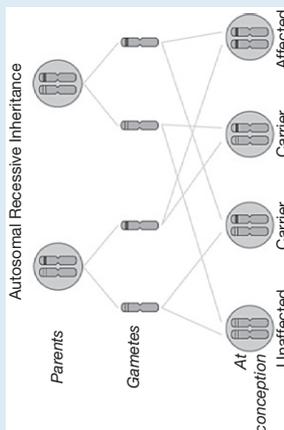

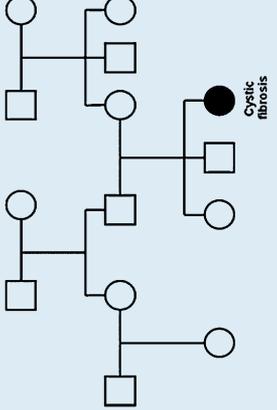

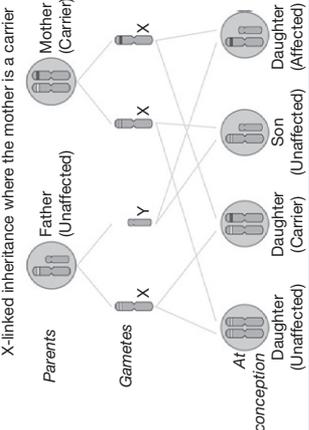

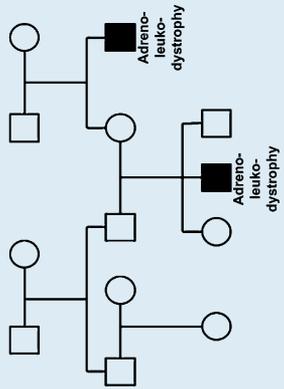

Genes are short sections of deoxyribonucleic acid (DNA) that code for the production of a specific protein. DNA consists of a series of nucleotide molecules bound in a long double helical structure. Nucleotides consist of a five carbon sugar unit bound to one of four potential bases; adenine, guanine, thymine or cytosine. The order of these

four nucleotide bases on the DNA is the code responsible for defining the order of amino acids during protein synthesis.

Proteins have a wide range of functions, including transport (e.g. haemoglobin), structure (e.g. actin and myosin) and metabolism (e.g. enzymes such as lipase). Genes come in pairs, which are called an allele (one from each parent), and are located on chromosomes. In a gene, both alleles can be the same (homozygous) or they can be different (heterozygous). A mutation in a gene, or pair of genes, can result in the absence or insufficient amounts of that particular protein, or synthesis of a malformed protein that does not function properly. This can cause disorders such as sickle cell disease, muscular dystrophy or cystic fibrosis, and these can be passed on to future generations via meiosis and fertilisation.

Being able to recognise the mode of inheritance of a particular mutation, and hence a condition, enables the dietitian to give dietary advice to the individual and their family appropriately, e.g. cholesterol lowering advice in familial hypercholesterolaemia, and also to explain the process should a patient ask about the genetic basis of their condition. There are several modes of inheritance and these are explained below. Table 5.1.1 summarises the different conditions that result from the different modes of inheritance, along with an example pedigree for each.

Table 5.1.1 Examples of inheritable conditions with different modes of inheritance (source: reproduced with permission of the NHS National Genetics Education and Development Centre)

Type of inheritance	Example conditions	Clinical clues and features of inheritance	Probability of having a child with the condition	Example pedigree
Single gene: autosomal dominant	Familial hypercholesterolaemia (FH) Adult polycystic kidney disease Huntington's disease	Males and females are affected in equal proportions The condition is seen in multiple generations All forms of inheritance are observed, e.g. male to male, female to male, etc.	One in two where one parent is affected Autosomal Dominant inheritance 	
Single gene: autosomal recessive	Cystic fibrosis MCADD Haemochromatosis Phenylketonuria	Males and females are affected in equal proportions Affected individuals are usually in a single sibship in one generation Parents of an affected individual will both be carriers for the condition	One in four where both parents are carriers Autosomal Recessive inheritance 	
Single gene: X linked recessive	Adrenoleukodystrophy Duchenne muscular dystrophy Haemophilia	Males are affected almost exclusively The mutation is transmitted through female carriers to their sons Affected males cannot transmit the condition to their sons	One in two in males where the mother is a carrier X-linked inheritance where the mother is a carrier 	

Chromosoma	Down's syndrome	A higher number of miscarriages in a family than would be expected The presence of congenital anomalies, dysmorphic features, intellectual disability and developmental delay in family members	This varies widely depending on the nature of the chromosomal condition	
Multifactorial	Coronary artery disease Diabetes mellitus Obesity	The condition affects one organ system only There is no clear pattern of inheritance in the family	<p>Difficult to calculate due to the interaction of genetic and environmental factors Probabilities can be calculated using tables of empiric risk</p> <p>Recurrence risk increases as the number with the condition in the family increases</p> <p>Recurrence risk increases if the condition in the family is severe</p> <p>Recurrence risk increases the more closely related an individual is to an affected person, e.g. higher risk for first degree relatives than second degree relatives</p>	

MCADD, medium chain acyl CoA dehydrogenase deficiency.

Single gene conditions

Single gene conditions are individually rare, but their high recurrence in affected families means that it is important for people with these conditions to be identified and supported. Single gene conditions are caused by a mutation in one particular gene or pair of genes that significantly affects the production or function of its resulting protein. The probability of children inheriting a single gene condition depends upon the mode of inheritance exhibited by the condition. There are three main modes of inheritance associated with single gene conditions.

In autosomal dominant conditions, if one gene of the pair has a mutation it is sufficient for the condition to be present. At conception, a child will either inherit the usual copy of the gene or the gene with the mutation from the affected parent, therefore having a one in two probability of inheriting the condition, e.g. familial hypercholesterolaemia and adult polycystic kidney disease.

In autosomal recessive conditions, both genes of the gene pairs need to have a mutation for the condition to occur, and therefore a mutated gene is inherited from both parents. When both parents are carriers for the condition (i.e. they each have only one gene with a mutation, so are not affected by the condition), they have a one in four probability of having a child who does not inherit a mutation from either parent, a one in two probability of having a child who is a carrier (but is not affected by the condition) and a one in four probability of having a child who has the condition, e.g. cystic fibrosis, PKU, medium chain acyl CoA dehydrogenase deficiency (MCADD) and hereditary haemochromatosis.

X linked recessive conditions are caused by gene mutations on the X chromosome. Males have one X chromosome (XY) and females have two X chromosomes (XX). Therefore, in X linked recessive conditions, males are affected almost exclusively as the gene mutation only needs to be present on their one X chromosome, whereas females are usually unaffected as they have the usual copy of the gene on their other X chromosome. For a mother who is a carrier for an X linked condition, sons have a one in two probability of inheriting the condition and daughters have a one in two chance of being a carrier. For a father who is affected by an X linked condition, all sons will be unaffected and all daughters will be carriers, e.g. adrenoleukodystrophy.

Chromosomal conditions

Chromosomal conditions are caused by alterations in gene dosage, usually due to changes in the number of copies of genes. They are caused by unusual events during meiosis that results in cells with extra chromosomes (more than two copies), too few chromosomes (fewer than two copies) or chromosomes containing the incorrect amount of DNA, e.g. Down's syndrome is caused by the presence of an extra copy of chromosome 21 [three copies in total (trisomy)]. Whilst chromosomal conditions are usually one-off events, some can be inherited and may be indicated within a family by recurrent miscarriages and clustering of individuals with learning difficulties.

Multifactorial or common complex conditions

The majority of conditions develop due to the interplay of multiple factors. Multifactorial conditions are caused by the additive effects of minor alterations in many genes combined with a range of environmental factors. Multifactorial conditions, e.g. type 2 diabetes, obesity and cardiovascular disease, are seen to cluster in families but with no obvious pattern of inheritance, partly because environmental factors (diet, exercise, smoking behaviour, etc.) also influence the risk of developing the condition.

Epigenetic conditions

The term epigenetic describes heritable influences on gene function that are not accompanied by alteration in the underlying nucleotide sequence on the DNA. Instead, exposure to environmental factors (including diet) can alter the levels of methylation of the DNA and therefore switch gene expression on or off, thus modifying protein production. Epigenetic conditions can still be passed on to offspring and influence their susceptibility to developing those disorders.

Somatic mutations (cancer)

Cancers are caused by gene mutations, but these are not all inherited. Some cancers result from the accumulation of new gene mutations in somatic cells during the lifetime of that person, leading to uncontrolled cell division and growth. As these alterations are not present in the germ cells (reproductive cells, i.e. egg and sperm), they are not usually passed on to children.

People can inherit a cancer risk gene from a parent, which is then present in all cells, including the germ cells. Therefore, this gene mutation can be inherited, resulting in a family with an inherited cancer syndrome. The gene *BRCA1* is expressed in breast tissue and produces breast cancer type 1 susceptibility protein that is involved in repairing faulty DNA. People with this mutation therefore have an impaired ability to repair faulty DNA and as a result are at greater risk of breast cancer. It is important that individuals with the *BRCA1* mutation from families with inherited cancer syndrome are identified so that they can be offered genetic testing, increased screening and appropriate clinical management.

Gathering and using multigenerational family history and family tree

Gathering a multigenerational family history can be useful to healthcare professionals, including dietitians, because it can enable identification of other affected family members and can be used to predict the probability that the condition may be passed on to offspring. Patients with a condition with a genetic component may ask dietitians about the risk of their children also developing the condition. Thus, dietitians must identify the patients in whom taking a family history is an important part of the assessment process.

It is recommended that a genetic family history is gathered and drawn in a particular way to make interpretation easier, as well as to facilitate the sharing of the resultant pedigree with other healthcare professionals. Figure 5.1.1 shows the symbols that are used to draw a pedigree. It also shows the specific order that is recommended for collecting a family history to enable drawing a pedigree, e.g. it is best to ask about and draw the history of the relatives in box 1 before those in box 2, etc. The completed three generation pedigree should be dated and signed by the healthcare professional who recorded it.

Genetic family history information is confidential; recording relevant information (conditions, cause of death, etc.) in a family is permissible without the explicit consent of all those shown on the pedigree, as long as it is necessary to do so for health purposes. Many individuals expressly state that they wish pedigree information to be available to other family members and professionals to assist diagnosis and care, and this consent should be obtained and recorded.

Communicating genetic information

Dietitians may be asked by patients and their families to explain genetic concepts and diagnoses, and must therefore have a thorough understanding of the issues surrounding the communication of information of this nature. The amount of information given at any one time needs to be tailored to the preferences and needs of the individual (Burke *et al.*, 2007). If a patient is dealing with complex emotions that can accompany a diagnosis, e.g. guilt and blame, they may not be able to actively hear, understand and process a great deal of information. The information should be non-directive and non-judgemental. It is important to be sensitive to the emotional impact of the genetic information on the person and their wider family. Simple non-emotive language is preferable, e.g. *altered gene* is preferable to *gene mutation* and *risk* should be replaced by *chance*. Patients may ask to be referred to reliable sources of genetic information, including the internet, support groups and written materials (Burke *et al.*, 2007).

Nutritional genomics

Understanding of human genetics is rapidly increasing, assisted by the use of a range of cutting edge laboratory technologies that enable rapid and accurate determination of gene sequences. This has brought greater understanding of the interaction between genetics and nutrition, and has heralded the advent of nutritional genomics as a scientific discipline.

Nutritional genomics is the investigation or application of the interaction between genetics, genomics, diet, nutrition and other environmental factors specifically in relation to the maintenance of health and prevention or treatment of disease. Some definitions of nutritional genomics are even broader and include the application of genomic technologies to the study of nutritional sciences and food technology (Brown & van der Ouderaa,

2007). In light of this, the importance of nutritional genomics to all aspects of dietetic practice, both now and in the future, is undeniable.

Broadly speaking, nutritional genomics consists of two distinct areas, nutrigenomics and nutrigenetics. Nutrigenomics relates to how diet and nutrients affect gene expression and subsequent protein translation, and therefore metabolism, physiological function and health. In contrast, nutrigenetics relates to how genetic variation within an individual modifies their response to diet and nutrients, and therefore ultimately health or disease. Taken together they can be viewed as two parallel themes that run in opposite directions, one relating to how diet influences gene expression (nutrigenomics) and the other to how genes influence the response to different diets (nutrigenetics) (Brown & van der Ouderaa, 2007).

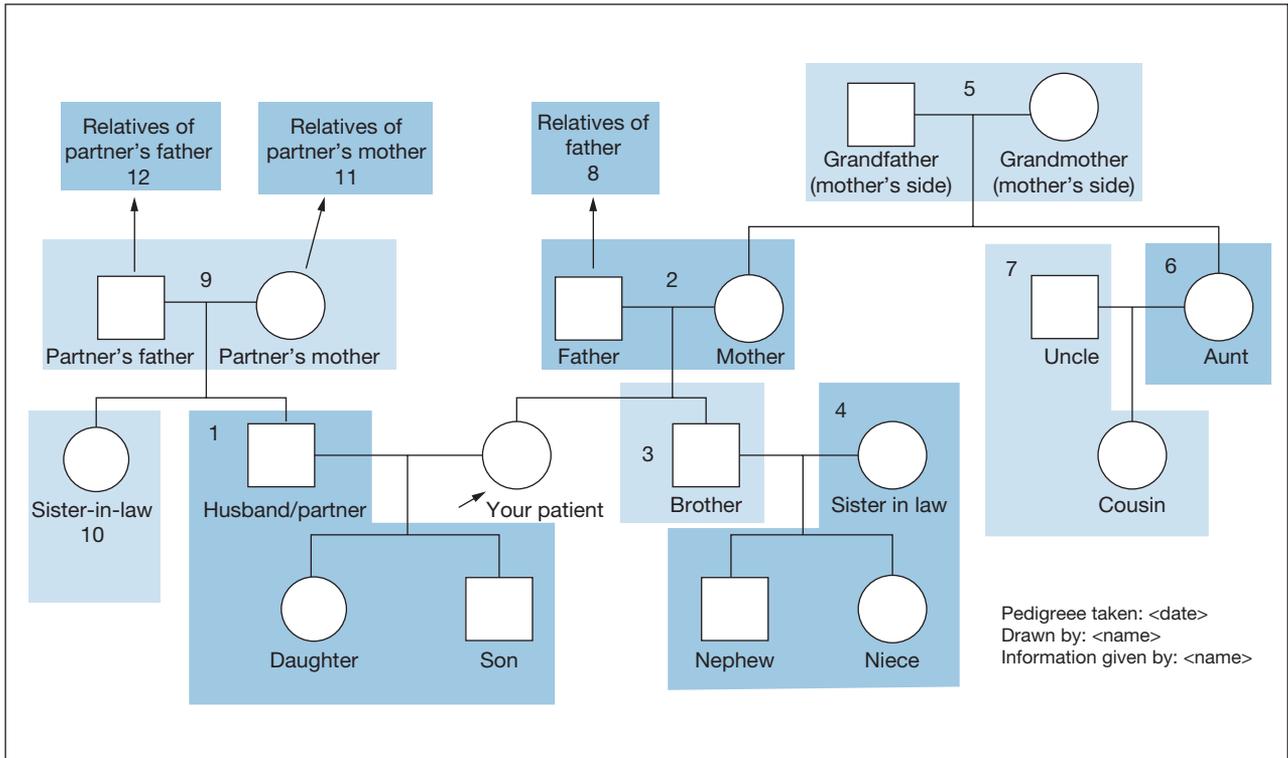

Five tenets of nutritional genomics have been described (Kaput & Rodriguez, 2004):

1. Common dietary chemicals alter gene expression or structure (nutrigenomics).
2. In some people and in some circumstances, diet can be a serious risk factor for disease.
3. Some diet regulated genes are susceptibility genes, and are likely to play a role in chronic diseases.
4. The influence of diet on the balance between health and disease may depend upon genetic make-up (nutrigenetics).
5. Dietary intervention based on personalised nutrition can be used to prevent, mitigate or cure chronic disease.

It is in the last of these areas where the greatest potential for direct application of nutritional genomics to individual dietetic counselling will eventually be realised. In many areas, dietitians already do this by providing evidence based dietary counselling to people with genetic disorders such as PKU and MCADD. However, this advice is largely based upon a cluster of symptoms and a clinical diagnosis rather than on the patient's genetic profile *per se*. In the future it is likely that dietitians will provide targeted dietary advice for individuals with multifactorial chronic diseases, e.g. cardiovascular disease, based upon their genetic profile (Lovegrove & Gitau, 2008). This may eventually allow the transition from generic nutritional recommendations based upon population health, e.g. reducing saturated fat intake, to personalised nutrition based upon an individual's genetic profile, e.g. reducing saturated fat intake only in those with a specific genotype.

Current evidence

There is mounting evidence for the role of nutrigenetics (the influence of genetic variation on response to diet and nutrients) in cardiovascular disease. The effect of dietary fat on cardiovascular risk factors has been extensively studied in large populations. However, there is wide variation in the effectiveness of low fat/low saturated fat dietary interventions, which is often accounted for by variations in dietary compliance between individuals.

Key Information

For each key person, record under the pedigree symbol the following information as appropriate:

- Name
- Date of birth (DOBs are preferable to current ages or estimates)
- Relevant symbols and/or diagnoses and age at diagnoses (if known)
- Cause of death and age at death (if known)

Figure 5.1.1 Stepwise approach to drawing a family pedigree (source: reproduced with permission of the NHS National Genetics Education and Development Centre)

However, genotype is a major predictor of response to a low fat/low saturated fat diet. For example, in a study of middle aged healthy people, there was a significant but weak association between total serum cholesterol and dietary intake of total fat and saturated fat. However, when comparing only those people who carried the apolipoprotein E (*apoE*) $\epsilon 4$ allele, there was a significant and stronger correlation between low density lipoprotein (LDL) cholesterol and saturated fat intake (Loktionov *et al.*, 2000).

ApoE is a protein that facilitates the clearance of chylomicrons and very low density lipoproteins from the bloodstream. The gene encoding apoE can have natural variations (polymorphisms) comprising three common versions ($\epsilon 2$, $\epsilon 3$, $\epsilon 4$). As humans carry two alleles (one from each parent), there are a number of different permutations. Therefore, humans can have one of three possible homozygous genotypes ($\epsilon 2/2$, $\epsilon 3/3$, $\epsilon 4/4$) or three heterozygous genotypes ($\epsilon 2/3$, $\epsilon 2/4$, $\epsilon 3/4$). The most common allele is $\epsilon 3$, followed by $\epsilon 4$ and $\epsilon 2$. A meta analysis has indicated that people with an $\epsilon 2$ allele, e.g. $\epsilon 2/2$, $\epsilon 2/3$, have a reduced risk of coronary heart disease, whereas people with an $\epsilon 4$ allele, e.g. $\epsilon 4/4$, $\epsilon 3/4$, have an increased risk of coronary heart disease (Bennet *et al.*, 2007) (Table 5.1.2).

In a controlled feeding study, a low fat/low saturated fat diet resulted in a larger fall in LDL cholesterol concentrations in males with an $\epsilon 4$ allele (13% decrease in $\epsilon 3/4$; 16% decrease in $\epsilon 4/4$) compared with those who were homozygous for $\epsilon 3$ (5% decrease in $\epsilon 3/3$) (Sarkkinen *et al.*, 1998). Large randomised controlled trials are required before widespread application of this evidence in dietetic practice. However, these data highlight the possibility that patients with hyperlipidaemia might one day be screened for carriage of the $\epsilon 4$ allele on their *apoE* gene, in order that they might be targeted with intensive dietary counselling as they may well show the best response in terms of lowering LDL cholesterol.

Another area for the application of nutrigenetics in cardiovascular disease is in relation to the gene coding for the enzyme methylene tetrahydrofolate reductase (MTHFR). The enzyme is involved in folate metabolism,

and therefore regulates plasma concentrations of homocysteine, which at high levels are a risk factor for cardiovascular disease. A common polymorphism can occur to one specific nucleotide base of the *MTHFR* gene [hence it is called a single nucleotide polymorphism (SNP)]. This SNP occurs at nucleotide position 677 and involves a cytosine (C) base being replaced by a thymine (T) base; hence it is described as MTHFR 677C>T. Most people have both usual alleles (CC), some have one affected allele (CT) and some have both affected alleles (TT).

This small change in nucleotide sequence still allows the MTHFR enzyme to be produced, but the SNP results in an amino acid change and thus the enzyme activity is lower. People with this SNP have less efficient folate metabolism and an approximately 20% higher plasma homocysteine concentration than those who do not (Jacques *et al.*, 1996). This may explain why people who are homozygous for this SNP (TT) have a 16% higher chance of developing coronary heart disease compared with people who are homozygous wild type (CC) (Klerk *et al.*, 2002).

Dietary intervention with folate supplementation reduces homocysteine concentrations, particularly in those with the *MTHFR* TT genotype. For example, a randomised controlled trial showed that folate supplements (1 mg/day) decreased homocysteine in healthy males, but the greatest decrease was seen in those with the homozygous TT genotype ($-6.6\mu\text{mol/L}$) compared to those with the CT or CC genotype (both $-2.6\mu\text{mol/L}$) (Miyaki *et al.*, 2005). Nutrigenetic testing for the MTHFR C677T (TT) polymorphism might enable targeted folate supplementation in those most likely to respond. However, a recent meta analysis indicated that although folate supplementation resulted in a 25% reduction in homocysteine concentrations, this did not have an effect on cardiovascular events, cancer or 5-year mortality (Clarke *et al.*, 2010), raising the possibility that elevated plasma homocysteine is a marker of risk rather than a risk itself.

Barriers to nutritional genomics in practice

In the future nutritional genomics is likely to have a major impact on dietetic practice, offering the potential for targeted dietary interventions based upon an understanding of an individual's genotype (personalised nutrition). However, research to support its application is currently in its infancy, and larger scale trials to demonstrate nutritional, metabolic and clinical benefits are required.

A further concern is the focus of research on the evaluation of dietary interventions on single genes. Using cardiovascular disease as an example, many different genes result in elevated susceptibility (it is a polygenic disease) and there are many environmental risk factors as well, such as diet, smoking and physical activity. Therefore, any single nutrigenetic effect, e.g. reducing saturated fat in *apoE* $\epsilon 4$ carriers, in isolation is likely to be small in comparison with those of the many complex gene environment interactions that subsequently result in cardiovascular disease.

Table 5.1.2 Association between *apoE* polymorphisms, coronary risk and diet

Allele	Allele frequency (Masson <i>et al.</i> , 2003)	Coronary risk* odds ratio (95% CI)	Impact of low fat diet on LDL cholesterol (Sarkkinen <i>et al.</i> , 1998)
$\epsilon 2$	0.08	0.80 (0.70–0.90)	Not measured
$\epsilon 3$	0.77	1.00	5% reduction
$\epsilon 4$	0.15	1.06 (0.99–1.13)	13–16% reduction

*Compared with $\epsilon 3/\epsilon 3$ (Bennet *et al.*, 2007).
LDL, low density lipoprotein.

The potential for ethical, legal and social issues associated with research and practice in genetics and nutritional genomics is emerging. These include how genetic information is analysed, stored and used, particularly in relation to confidentiality, and the avoidance of *genetic discrimination* by those interested in an individual's risk of disease, e.g. health insurers and employers (Reilly & Debusk, 2008).

Finally, studies have shown that dietitians have positive attitudes towards genetics and nutritional genomics, but many have limited knowledge and confidence to enable them to be involved (Whelan *et al.*, 2008). Although there is currently limited evidence to support nutritional genomic interventions, clearly dietitians must be competent and skilled to be able to act upon new research evidence as and when it is published.

5.2

Functional foods

Lisa Ryan

Key points

- Functional foods, when consumed regularly as part of the usual diet, have a specific health beneficial effect beyond their basic nutritional value.
- The beneficial health effects are due to the presence of a variety of bioactive components that elicit their effects via a number of different mechanisms.
- Functional foods encompass a very broad range of products, including infant formulas, medical foods, performance foods, probiotics and foods designed to deliver specialised nutrients and non-nutrients.
- The proposed health effects of functional foods must be substantiated.
- In Europe, the assessment of the scientific evidence to support health claims is the responsibility of the European Food Safety Authority (EFSA).

Food has an important role in major chronic diseases such as cardiovascular disease, diabetes, hypertension, some cancers and obesity. Previously, attention has focused on the harmful effects of major food components, e.g. excess saturated fat, or under consumption, e.g. of fibre, vegetables and fruit. Today, certain foods and food ingredients are being studied for their role in preventing and treating various chronic diseases, and for their far reaching benefits in slowing the ageing process and affecting mood and performance. These foods, known as functional foods, have the potential to promote better health and wellbeing, therefore helping to reduce the risk of chronic disease and to improve specific health functions.

History and development

The concept of functional foods first emerged in Japan as a result of escalating healthcare costs. In 1986, the Ministry of Education, Science, and Culture reported that food has three main functions in the body; nutritive value (primary function); sensory appeal (organoleptic properties) and physiological aspects (including regulation of body functions and physical conditions, preventing disease, promoting recovery and general good health). The concept of functional foods grew out of the third function and the Japanese government promoted the idea of functional foods as a possible way of improving

the health of their ageing population. In 1991, the Japanese renamed functional foods as foods for specified health use (FOSHU) and defined them as '*processed foods containing ingredients that aid specific bodily functions in addition to being nutritious*'. A regulatory system was established to approve such foods and to evaluate the scientific justification of claims. In Japan, FOSHU foods bear a seal of approval from the Ministry of Health and Welfare, making them easily recognisable to the consumer (Arai, 1996). The area of functional foods is expanding and now represents one of the most dynamic growth categories to have emerged from food science and nutrition.

Definition

In contrast to Japan, no legal definitions are available in either the USA or Europe for functional foods; however, they may be broadly defined as '*foods similar in appearance to conventional foods that are consumed as part of a normal diet and have demonstrated physiological benefits and/or reduce the risk of chronic disease beyond basic nutritional functions*' (Clydesdale, 1997). A functional food may be:

- A natural food.
- A food to which a component has been added.
- A food from which a component has been removed.

- A food where one or more components have been modified.
- A food in which the bioavailability has been modified.
- Any combination of the above.

Functional foods may be classified according to the type of food (Table 5.2.1) or according to the type of bioactive ingredient used (Table 5.2.2).

Ingredients

A food is said to be functional if it contains a food component (whether a nutrient or non-nutrient) that affects

one or more targeted functions in the body in a positive way. They are similar in appearance, smell and taste to a conventional food and are consumed as part of the usual diet. Functional foods represent an increasingly diverse collection of foods, e.g. infant formulas, medical foods, performance foods, probiotics and foods designed to deliver specialised nutrients and components (such as fibre, vitamins, minerals, antioxidants, prebiotics, dairy proteins, soya proteins, fats and oils). The beneficial health effects are due to the presence of a variety of bioactive components that elicit their effects via a number of different mechanisms. These substances (bioactives) often originate from plant sources, but some are derived from animals and microorganisms (Table 5.2.2).

Table 5.2.1 Categories of functional foods (source: Arvanitoyannis & Van Houwelingen-Koukaliaroglou 2005. Reproduced with permission of Taylor & Francis)

Category	Example
Basic foods	Tomatoes (rich in natural antioxidant lycopene)
Processed foods	Oat bran cereal
Processed food with added ingredients	Calcium enriched fruit juice
Foods enhanced to have functional component	Oat bran with higher levels of beta-glucan
Isolated, purified preparations of active food ingredients	Soya isoflavones

Examples

Dairy spreads enriched with plant sterols and stanols

Plant sterols are naturally occurring components of plant wall membranes. Over 40 plant sterols have been identified; the three most abundant plant sterols are beta-sitosterol, campesterol and stigmasterol. Stanols are saturated derivatives of sterols and are less abundant in nature than sterols. The term phytosterols is sometimes used as a generic term to encompass both plant sterols and stanols. In the 1950s, it was recognised that phytosterols lower serum concentrations of cholesterol (Best *et al.*, 1954). Phytosterols reduce the absorption of

Table 5.2.2 Examples of bioactive functional food ingredients

Functional ingredient	Food source	Potential effect on health
Beta-glucan	Oats	Lowers blood cholesterol Reduces the postprandial glycaemic response Aids weight control
Conjugated linoleic acid (CLA)	Cheese, meat products	Improves body fat composition Enhances immune system Reduces risk of cancer
Flavonoids, e.g. catechins	Tea, fruit, vegetables	Neutralise free radicals Reduce risk of cancer
Lycopene (carotenoid)	Tomatoes	Reduces risk of prostate cancer
n-3 Fatty acids (ALA/EPA/DHA)	Salmon and fish oils	Reduce risk of cardiovascular disease May improve mental and visual functions
Phytoestrogens, e.g. isoflavones	Soyabeans and soya based foods	Alleviate symptoms associated with the menopause Protect against heart disease and some cancers Lower LDL and total cholesterol Improve bone mineral density
Plant sterols/stanols/stanol esters	Corn, soya, wheat, wood oils	Reduce the absorption of cholesterol in the body Lower blood cholesterol levels (total and LDL cholesterol by ~10%) NB: May interfere with absorption of other fat soluble components from the diet; data on effects of long term consumption at levels >3 g/day are limited
Prebiotics, e.g. inulin, fructo-oligosaccharides	Jerusalem artichokes, shallots, onion powder	Stimulate the growth of certain bacteria in the colon Improve quality of intestinal microflora; gastrointestinal health
Probiotics, e.g. <i>Lactobacillus acidophilus</i>	Yoghurt and other dairy products	Improve quality of intestinal microflora; gastrointestinal health

LDL, low density lipoprotein.

cholesterol by competing for incorporation into mixed micelles (and thus inhibiting cholesterol absorption). Therefore, when phytosterols are part of the regular diet, they have an overall lowering effect on serum cholesterol concentrations. The average daily diet contains approximately 0.25 g of plant sterols, though this may be twice as high in a vegetarian diet. Phytosterols at doses of approximately 2 g/day are required to lower low density lipoprotein (LDL) cholesterol. Dairy spreads fortified with phytosterols (~2 g/daily portion) have been developed as functional foods. The added phytosterols in fortified dairy spreads have been shown to reduce the absorption of cholesterol in the gut (both dietary and endogenous) and to lower blood LDL cholesterol by ~7–10.5% (EFSA, 2009).

Omega-3 enriched eggs and bread

Omega (n)-3 fatty acids are polyunsaturated fatty acids, and longer chain derivatives such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) seem to be consistently associated with health benefits. Plants typically contain the parent n-3 fatty acid, alpha-linolenic acid (ALA), which is essential in humans. Although the longer chain n-3 derivatives can be formed from ALA, research suggests that this is an inefficient process. Furthermore, n-6 fatty acids compete with n-3 fatty acids for metabolising enzymes. Therefore, an excess of n-6 fatty acids in the diet, as is typical of many western diets, will favour the production of longer chain n-6 family derivatives. The main dietary source of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) is oily rich fish. Functional foods containing EPA and DHA, such as enriched eggs and bread, have now been developed as a means of delivering longer chain n-3 fatty acids into the diet.

Oat breakfast cereal rich in beta-glucan

The health importance of dietary fibre has been recognised for decades. However, recently soluble fibres such as beta-glucans have been shown to exert a beneficial effect on health. Beta-glucans are the predominant components of cell walls of cereal grains such as barley and oats. Oat breakfast cereals enriched with oat beta-glucan at doses of at least 3 g/day have shown a statistically significant decrease in LDL cholesterol concentrations (EFSA, 2010). The effect of beta-glucans on other factors and conditions such as the glycaemic response, weight control and certain cancers is also currently under investigation.

Regulation

The effects of functional foods on health must be scientifically proven before claims can be made for a food (see Chapter 4.5). In Europe, the assessment of the scientific evidence to support health claims is the responsibility of the European Food Safety Authority (EFSA). When assessing the evidence, the EFSA considers the extent to which:

- The food/constituent is defined and characterised.
- The claimed effect is defined and is a beneficial physiological effect.
- A cause–effect relationship is established between the consumption of the food/constituent and the claimed effect (for the target group under the proposed conditions of use).

Scientific substantiation requires a favourable outcome to all three statements. If a cause–effect relationship is to be established, the EFSA considers whether:

- The quantity of food and pattern of consumption required to obtain the claimed effect can be consumed within a balanced diet.
- The proposed wording reflects the scientific evidence.
- The proposed wording complies with the criteria for the use of claims specified in the regulation.
- The proposed conditions of use are appropriate.
- Substantiation was dependent on data claimed as proprietary by the applicant.

The process of assessment of claims is continuous and to date positive EFSA opinions on claims have included plant sterols and stanols and cholesterol reduction; xylitol and caries reduction; ALA and brain and nerve tissue development in children; oat beta-glucans and cholesterol reduction, and long chain polyunsaturated fatty acids and visual development in children (Table 5.2.3).

The future

Functional foods constitute a rapidly growing area of product development and research, as well as requiring considerable regulatory efforts. To date, relatively few bioactive ingredients have been substantiated and demonstrated to have a proven beneficial effect on health. Central to the substantiation of functional foods are data from human dietary studies.

An important aspect will also be for functional food manufacturers to communicate health effects reliably to the final consumer. In Europe, the term functional foods is not recognised by the consumer; therefore, approved products may benefit from a specific logo on the label

Table 5.2.3 Examples of positive health claim evaluations from the European Food Safety Authority

Functional food/ingredient	Health effect
Vitamins, minerals	Cardiovascular, brain, gut, immune, bone, dental, antioxidant, metabolism
Protein, carbohydrate	Muscle, bone, energy
Fatty acids	Brain, cardiovascular, vision
Fibre	Gut, cardiovascular
Other substances – phytosterols/stanols, tomato extract, chewing gum	Cardiovascular, dental

LDL, low density lipoprotein.

identifying them as functional foods. If these products are to be consumed as part of the normal diet, they need to be much more visible and recognisable.

The National Diet and Nutrition Survey (NDNS) (Bates *et al.*, 2011) suggested that while there have been some improvements in the UK diet, there are still certain areas where recommendations are not being met, e.g. dietary fibre and n-3 fatty acids. Functional foods have the potential to improve the health of the population and to address some of the issues identified by the NDNS.

5.3

Drug–nutrient interactions

Joan Gandy

Key points

- Nutrition can affect the therapeutic action of many drugs by influences on drug absorption, metabolism and excretion.
- The action and/or side effects of drugs may result in marked changes in food intake. Drugs can also impair nutrient absorption or metabolism, or increase nutrient excretion.
- Prolonged therapeutic drug use may have adverse effects on nutritional status, especially in older people.
- Information about therapeutic drug use, including over the counter medicines, herbs, alcohol consumption and tobacco use, should be obtained during a nutritional assessment.

There are many interactions between drugs and both macro- and micro-nutrients. Drugs and nutrients are absorbed from similar sites and metabolised and excreted in similar ways. Therefore, just as a drug can interfere with the action of another, some drugs may interfere with the action of a nutrient or *vice versa*. It is essential that dietitians have knowledge of these interactions and alert medical personnel to possible problems they may not be aware of. Boullata & Hudson (2012) recently reviewed the implications for dietetic practice of drug–nutrient interactions.

Prescribed drugs are likely to have the greatest nutritional implications since they are the most powerful or high dose forms of medication. However, it is important to consider that people often self administer other types of preparations with pharmacological effects and nutritional implications. These include:

- Over the counter drugs, e.g. analgesics, indigestion remedies, laxatives.
- Herbal remedies, including Chinese herbal remedies (see Chapter 5.4).
- Nutritional supplements, e.g. fish oil capsules, large doses of vitamins.
- Alcohol.
- Tobacco.
- Illegal substances.

Drug abuse can cause many nutritional problems, both directly from the effects of the drug itself and indirectly from the poor dietary habits and living conditions often associated with it.

Drug–nutrient interactions can be broadly categorised into:

- *Effect of nutrition on drugs* – the influence of nutritional factors on drug absorption, action and effectiveness.
- *Effect of drugs on nutrition* – the influence of drugs on nutritional intake, metabolism, excretion and requirements.

Classes of drugs that are most likely to have nutritional implications are shown in Table 5.3.1. Many drugs used in the treatment of mental illness have drug–nutrient interactions and these are summarised in detail in Table 7.10.6. Cytotoxic chemotherapy drugs are also known to have effects on nutritional status and these are discussed further in Chapter 7.15. This chapter gives an overview of the subject with examples; it is not definitive and the titles listed in the resources section of this chapter should be consulted for further detail.

Effects of nutrition on drugs

The metabolism of a drug may involve the following stages, any of which can be influenced by nutrition:

- Transport from the gut lumen to intestinal enterocytes (if the drug is taken orally), sometimes followed by presystemic metabolism prior to absorption into the blood.
- Transport in the blood, usually bound to plasma proteins.

Table 5.3.1 Classes of drugs that are most likely to have nutritional implications

Class of drug	Possible nutritional implications
Amphetamines	Increased appetite
Antacids	Can bind with minerals such as phosphorus, magnesium, iron and zinc, and reduce their absorption Antacids raise gastric pH and this may also impair the absorption of some trace elements, especially vitamin B ₁₂ , which requires acid conditions for its release from dietary protein
Antibiotics	Anorexia Altered gut flora and diarrhoea Tetracycline forms complexes with calcium (in foods or mineral supplements), reducing the absorption of both
Anticoagulants	Warfarin action is impaired by vitamin K
Anticonvulsants	Interfere with folate metabolism Interfere with vitamin D metabolism
Antidepressants	Anorexia MAOI type A usage necessitates avoidance of tyramine*
Antihyperlipidaemics	Clofibrate and cholestyramine can result in malabsorption, especially of minerals and fat soluble vitamins
Antipsychotics	Some types markedly increase appetite*
Antirheumatics	Methotrexate inhibits folate metabolism Penicillamine reduces absorption of iron and zinc
Corticosteroids	Anabolic effects and weight gain Glucose intolerance
Cytotoxic (anticancer) drugs	Anorexia Taste changes Sore and painful mouth and tongue Nausea, vomiting and diarrhoea Damage to intestinal villi Interfere with folate metabolism (especially methotrexate) Reduce thiamine status
Dopaminergic drugs (used in parkinsonism)	Levodopa causes nausea and vomiting if taken on an empty stomach Levodopa absorption is inhibited by iron supplements Levodopa can be inhibited by B ₆ supplements
Diuretics	Thiazide and loop diuretics can cause excessive urinary loss of potassium, calcium, zinc and water soluble vitamins Dehydration
Hypoglycaemics	Action has to be balanced against carbohydrate intake Alcohol can potentiate their action Chlorpropamide can react with alcohol and cause facial flushing
Laxatives	Reduced absorption of nutrients (liquid paraffin)
Mood stabilisers	Lithium action is affected by dietary sodium*
Non-steroidal anti-inflammatory drugs (NSAIDs)	Gastric irritation and risk of bleeding if taken on an empty stomach Aspirin increases vitamin C excretion
Oral contraceptives	Affect glucose and lipid metabolism Can cause weight gain

*See Chapter 7.10.3.

MAOI, – monoamine oxidase inhibitors.

- Deactivation by a two stage metabolic process:
 - Oxidation by microsomal enzyme systems involving reduced nicotinamide adenine dinucleotide (NADPH) and cytochrome P450, predominantly in the liver but also in other organs including the lungs and small intestine.
 - Conjugation with glucuronic acid, sulphate or glycine.
- Excretion of the conjugate in urine or bile.

Table 5.3.2 gives examples of drug–nutrient interactions that affect drug absorption, metabolism or excre-

tion. NB: This list is not exhaustive; *Stockley's Drug Interactions* or the *British National Formulary* should be consulted for further information.

Drug absorption

The pharmacological effect of an orally administered drug depends on the rate and extent to which it is absorbed from the gastrointestinal tract. This can be either delayed or enhanced by the presence or absence of food. The pres-

Table 5.3.2 Examples of drug–nutrient interactions affecting absorption, metabolism and excretion of drugs (adapted from Webster-Gandy *et al.*, 2011, tables 38.1–38.3, pp. 738–40. Reproduced with permission of Oxford University Press)

Drug or class of drug*	Food and/or nutrient	Effect of interaction and advice
Absorption		
Bismuth Flucloxacillin Phenoxymethylpenicillin Rifampicin	Presence of food in the stomach	Absorption delayed and reduced Advise to take on an empty stomach or 1 hour before food
Ciprofloxacin Norfloxacin Tetracyclines	Milk and dairy products	Absorption reduced Advise to leave 2-hour gap between drug and dairy consumption
Theophylline	High protein diet High carbohydrate diet	Bioavailability reduced by high protein diets Bioavailability increased by high carbohydrate diets
Ciprofloxacin Digoxin Phenytoin Rifampicin Tetracycline Theophylline	Enteral feeds	Absorption reduced Leave time gap between giving medication and enteral feed
Metabolism		
Amiodarone Buspirone Calcium channel blockers Carbamazepine Ciclosporin Colchicine Corticosteroids Coumarins Digoxin Fexofenadine Simvastatin	Grapefruit juice	Metabolism of drug altered due to liver enzyme, cytochrome P450, stimulation Advise to follow manufacturer's instructions
Warfarin	Large amounts of Brussel sprouts, green vegetables, cabbage, lettuce, green tea, excess quantities of ice cream, avocado, mango Cranberry juice	Drug metabolism increased and anticoagulant effect of warfarin decreased Anticoagulant effect of warfarin increased NB: A fatal incident reported
Levodopa Phenobarbital, phenytoin	High doses of vitamin E Vitamin B ₆ (pyridoxine)	Anticoagulant effect of warfarin increased Effects of levodopa reduced by concurrent supplementation of pyridoxine Advise to avoid vitamin B ₆
Excretion		
Lithium	Salt (sodium)	Excretion affected by increased and decreased salt intake Advise to keep sodium intake constant once stabilised on lithium

*This list is not exhaustive. *Stockley's Drug Interactions* or *British National Formulary* should be consulted for further details.

ence of food in the stomach and proximal intestine may reduce drug absorption as a result of the following:

- Delayed gastric emptying.
- Altered gastrointestinal pH.
- Competition for binding sites with nutrients.
- Chelation of drugs by food cations, e.g. tetracyclines chelate with calcium ions present in milk and dairy products, resulting in reduced absorption of both calcium and antibiotic.

- Dietary fats impeding the absorption of hydrophilic drugs.

Some drugs must therefore be taken on an empty stomach in order to maximise their rate of absorption and therapeutic effect. Conversely, others must be taken with food to achieve a slower, more sustained rate of absorption or to minimise side effects such as gastric irritation, e.g. aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs). Medicines should be taken with water as

drinks such as fruit juice, tea and coffee can alter the drug's pH balance and therefore its properties.

Drug transport

Many drugs are transported in blood bound to plasma proteins. Severe malnutrition, or diseases such as liver disease affecting the synthesis of plasma proteins, may reduce the body's ability to transport drugs and hence impair their effectiveness.

Drug metabolism

Factors that affect the deactivation or conjugation of a drug can alter its pharmacological or toxic effects. Periods of short term starvation or prolonged periods of nutritional inadequacy can influence the effectiveness or safety of drugs. The amount of a drug required to produce a certain pharmacological effect is determined by body weight. Sudden reduction in weight or dehydration may therefore result in over dosage. Undernutrition also reduces the activity of microsomal drug metabolising enzymes and this can either diminish a drug's effectiveness (by reducing the rate of synthesis of an active metabolite) or enhance its toxicity (by reducing the rate of its excretion) (Dickerson, 1988). In addition, the metabolism of drugs is affected by the amount of water in the body and this can be perturbed by dehydration or oedema, including that associated with kwashiorkor (protein energy malnutrition) (Oshikoya & Senbanjo, 2009). Some drugs are fat soluble, e.g. barbiturates; therefore, their metabolism will be affected by both decreased and increased levels of adipose tissue associated fat. The effects of obesity on drug metabolism vary depending on the pathway by which they are metabolised (Brill *et al.*, 2012). Obviously, decreased or increased clearance rates may lead to potentially impaired drug action or increased possibility of side effects. Doses may need to be adjusted as some are based on ideal body weight rather than actual body weight, e.g. anaesthesia.

It is important to consider that drug–nutrient interactions may be variable, with some individuals being more susceptible than others. An example of this is the interaction between grapefruit juice and simvastatin that results in increased levels of the circulating drug, which has the potential to increase side effects. However, there is debate as to whether or not this potential effect outweighs the potential beneficial effect of simvastatin on cholesterol levels (Pirmohamed, 2013; Backman & Bakhai, 2013).

Drug excretion

Urinary acidity affects drug reabsorption from the renal tubules. Supplemental intakes of nutrients that increase urinary acidity, e.g. large amounts of vitamin C, can decrease the excretion of salicylate drugs such as aspirin.

Potentially serious interactions

The following interactions have the potential to lead to serious events:

- Warfarin and vitamin K containing foods.
- Warfarin and cranberry juice.
- Grapefruit juice and fexofenadine or ciclosporin.
- Angiotensin converting enzyme (ACE) inhibitors or angiotensin II receptor antagonists and potassium supplements or salt substitutes – these drugs may cause potassium retention, which may be exacerbated by potassium supplements and potassium containing salt substitutes, resulting in hyperkalaemia.
- Monoamine oxidase inhibitors (MAOIs) and tyramine – patients taking a MAOI, e.g. phenelzine and moclobemide, should avoid tyramine containing foods, e.g. mature cheese, yeast extracts, soyabean products, pickled herring, red wine, as these may cause a dramatic increase in blood pressure and palpitations.
- Isotretinoin and vitamin A – isotretinoin is a retinoid used for the treatment of acne. Due to the risk of vitamin A toxicity it should not be used with vitamin A supplements.

Effects of drugs on nutrition

Drugs may affect food intake or the absorption, metabolism or excretion of nutrients. This may have implications in terms of food choice and/or nutritional requirements.

Food intake

Food intake may be reduced as a result of drugs that have the following effects:

- Anorexia – either as a direct effect of the drug on appetite, e.g. cytotoxic chemotherapy drugs, or as a result of side effects such as drowsiness or lethargy, e.g. tranquillisers.
- Cause nausea and vomiting – this is a common side effect of many drugs.
- Gastrointestinal tract effects – e.g. NSAIDs often cause gastric irritation and should be taken with, or after, food. Other drugs may cause bloating or early satiety. Chronic abdominal pain or diarrhoea may reduce the desire to eat.
- Taste changes – many drugs, e.g. cytotoxic chemotherapy, make food taste bland (ageusia) or change taste perception (dysgeusia). Many patients receiving some cytotoxic drugs report a metallic taste, often associated with protein consumption.
- Dry mouth (xerostomia) – lack of saliva makes it difficult to masticate and swallow food, especially those of a dry or fibrous consistency.
- Sore or painful mouth (mucositis) or tongue (glossitis) – a common side effect of chemotherapy that can significantly impair food intake.
- Impaired memory or confusion – people may forget to eat.

Drugs may also increase food intake and weight gain if they stimulate appetite or induce cravings. Corticosteroids, insulin and some psychotropic drugs are known to have either or both these effects (see Chapter 7.10.3).

Nutrient absorption

Absorption can be impaired as a result of:

- *Formation of insoluble complexes* – many drugs can chelate with minerals and trace elements, e.g. penicillamine (sometimes used in the treatment of rheumatoid arthritis) chelates zinc; cholestyramine binds with iron; and antacids may bind with phosphorus.
- *Competition for binding sites*, e.g. salicylates (aspirin) compete with vitamin C; and sulphasalazine, used in the treatment of arthritis, impairs folate absorption.
- *Damage to the absorptive surface of the intestinal mucosa* – cytotoxic chemotherapy can cause villous atrophy, resulting in malabsorption.
- *Binding of bile acids* – fat soluble vitamin absorption will be impaired by bile salt binding drugs such as cholestyramine.
- *Lipase inhibitors* that reduce fat absorption and are used to aid weight loss, e.g. orlistat, may impair absorption of fat soluble vitamins.
- *Increased intestinal motility* – drugs that cause diarrhoea or stimulate peristaltic activity, e.g. senna or phenolphthalein laxatives, may result in nutrient losses.

Nutrient metabolism

Some drugs may affect lipid or glucose metabolism. The following drugs may result in dyslipidaemia:

- Beta blockers.
- Corticosteroids.
- Thiazide diuretics.
- Anabolic steroids.
- Some anti-HIV drugs.
- Retinoids.
- Combined oral contraceptives.

Drugs that may affect glucose tolerance, apart from those used to manage diabetes, include thiazide diuretics and corticosteroids.

Micronutrient metabolism

Micronutrients are cofactors and coenzymes in many metabolic pathways, including those that metabolise drugs. Increased activity of these pathways as a result of drug metabolism may increase micronutrient requirements. Drugs can also compete with, or inhibit, the metabolic conversion of some micronutrients to their active metabolites, particularly folate. Some medicines may require nutritional supplements to prevent detrimental effects. These include:

- *Corticosteroids* – long term oral use or high inhaled doses is a risk factor for osteoporosis; therefore, calcium supplements are needed.
- *Methotrexate* – a folate antagonist, so a folate supplement (5 mg/day) is needed to prevent deficiency. It is used in rheumatoid arthritis and in cancer chemotherapy.
- *Isoniazid* – an antibiotic used in the treatment of tuberculosis and may have an antipyridoxine effect; a 10 mg/day supplement of pyridoxine is recommended.

- *Antiepileptic drugs in pregnancy* – many are associated with birth defects; 5 mg/day of folate should be prescribed as women with epilepsy are more likely to have low folate levels.
- *Some cytotoxic antibiotics, imidazole, antifungal agents and anticonvulsants*, e.g. phenytoin, phenobarbitone and primidone, impair vitamin D metabolism by inhibiting the conversion of 25-hydroxyvitamin D to the active form 1,25-dihydroxyvitamin D, with consequent disturbances in calcium metabolism and adverse effects on bone (Expert Group on Vitamins and Minerals, 2003).

Drugs may also affect the metabolism of dietary components. Type A monoamine oxidase inhibitors (MAOI A) exert their antidepressant effect by inhibiting the breakdown of endogenously produced amine neurotransmitters. However, they also inhibit the breakdown of dietary amines such as tyramine, which, if allowed to accumulate, can produce a dangerous rise in blood pressure. Patients on these drugs therefore have to avoid dietary sources of tyramine and other vasoactive amines (see Chapter 7.10.3).

Nutrient excretion

As well as their intended increase in sodium excretion, diuretic drugs can also result in enhanced losses of other elements such as potassium, calcium, magnesium and zinc. Tetracycline increases the urinary excretion of vitamin C.

Clinical significance of drug–nutrient interactions

It is important to remember that poor nutritional status can impair drug metabolism and that drug treatment can have a detrimental effect on nutritional status. However, not all drug–nutrient interactions are clinically significant. In many instances, any losses in nutrient availability or drug action will be small and may be of short duration. Drugs that are most likely to have dietetic implications are those that:

- Have a narrow range between therapeutic effect and toxicity, e.g. lithium and anticoagulants.
- Need to be taken for a prolonged period of time.
- Have implications in terms of the timing of food intake (habitual meal pattern may need to be adjusted).
- Necessitate dietary restrictions or regulation (food choice may need to be altered).
- Have side effects that impact on appetite or gastrointestinal function.
- Directly compete with a nutrient, e.g. vitamin K and warfarin.

Factors that increase the risk from drug–nutrient interactions include:

- Presence of gastrointestinal, liver and/or renal function.
- A nutritionally compromised state due to poor diet, alcoholism or disease.

- Recent weight loss.
- Dehydration.
- Multiple drug therapy.
- Prolonged drug therapy.

Many of these factors are likely to coexist in elderly people. In addition, the physiological changes that occur with age such as a decrease in fat free mass and body water, decreased plasma protein concentration and general decline in renal and liver function mean that the risk of adverse drug reactions is much higher (Klotz, 2009). For this reason, it is a requirement that drug data sheets provide details of suitable dosages for elderly people.

Elderly people are also more likely to be given the types of drugs that have powerful effects and are most likely to impact on nutrition, e.g. anti Parkinson's drugs. Diminished salivation in the elderly may make it more difficult to swallow tablets, and oesophageal motility disorders lead to bulky drugs sticking in the oesophageal mucosa. Other problems such as failing memory, poor hearing and vision, and difficulty with opening containers may mean that drug regimens are not followed correctly, particularly if they are complex. Drug usage is therefore an important consideration in the dietary assessment of elderly people.

Due to the nature of nutrients in enteral tube feeds, drug–nutrient interaction potential is increased. Drugs in liquid form may interact with constituents of the feed preparation, so altering their bioavailability and requiring dose adjustment, e.g. digoxin. There are clinically significant interactions between enteral feeds and phenytoin, theophylline, digoxin, ciprofloxacin, tetracyclines and rifampicin.

Alcohol and drugs

It is important to always assess alcohol intake as part of a nutritional assessment, in part because it can affect drug–nutrient interactions. It may enhance the action of many drugs acting on the brain, e.g. antidepressants, benzodiazepines and antiepileptic drugs, leading to impaired mental ability and increased sedation. It is a misconception that all antibiotics interact with alcohol; however, there are significant interactions with metronidazole and tinidazole, leading to nausea, vomiting and flushing. Even small amounts of alcohol consumed with disulfiram (used to treat alcohol dependence), causing facial flushing, tachycardia, giddiness, hypotension and potentially collapse. Large changes in alcohol consumption will affect the anticoagulant effect of warfarin. NB: Some mouth-washes bought over the counter contain sufficient alcohol to cause this reaction.

Specific drug–nutrient interactions are discussed in chapters in Section 7 as appropriate.

5.4

Alternative and complementary therapies

Joan Gandy

Key points

- Use of complementary and alternative medicine (CAM) therapies is increasing.
- Complementary therapies are used alongside conventional treatment. Alternative therapies are used instead of conventional treatment or advice.
- Dietary supplements are also commonly complementary therapies. Their use should be based on clinical need and underpinned by evidence of efficacy and safety.
- Herbal remedies have potent effects and many interact with conventional drugs.
- Dietitians should ask about the use of CAM, especially dietary supplements, during a nutritional assessment to assess the likely impact on nutrient intake and conventional treatments.

The use of complementary medicine therapies (which includes the use of supplements) and alternative therapies (CAM) is increasing. Therefore, it is essential that dietitians are aware of CAM's efficacy, potential and risks benefits. Dietitians should enquire about their use in every nutritional assessment and are able to advise on their efficacy and safety to enable clients to make informed choices. The Cochrane collaboration (Mannheimer & Berman, 2008) describe CAM as '*a broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period. . . . Boundaries within CAM and between the CAM domain and that of the dominant system are not always sharp or fixed*'.

There is a fundamental difference between complementary and alternative therapies, which are defined by the USA National Center for Complementary and Alternative Medicine (NCCAM) (2012) as:

- *Complementary therapies* are used together with conventional treatment, e.g. acupuncture in addition to analgesics to treat pain.
- *Alternative therapies* are used instead of conventional treatment.

In addition, NCCAM defines integrative (integrated) medicine as the combination of conventional medicine and CAM whose safety and effectiveness are supported by some high quality evidence.

There are many forms of CAM and it is not possible to provide a definitive list. However, the Cochrane Collaboration has reviewed this field and considers the following categories:

- Treatments that someone usually self medicates with, e.g. botanicals, nutritional supplements, health food, meditation and magnetic therapy.
- Treatments that are provided by others, e.g. acupuncture, massage therapy, reflexology, laser therapy, balneotherapy, chiropractic and osteopathic manipulations, certain types of psychological counselling, naprapathy and acupressure herbalism.
- Treatments that are self administered under periodic supervision of a therapist, e.g. yoga, biofeedback, Tai Chi, homeopathy, hydrotherapy, Alexander therapy, nutritional therapy and Ayurveda.
- Other interventions including Qi Gong, Doman Delcato patterning, anthroposophical medicine, Unani medicine, traditional African medicine, Bach flower remedies, clinical ecology, colon cleansing or irrigation, and music or sound therapy.
- Diagnostic techniques, e.g. iridology, kinesiology, Vega testing, biofunctional diagnostic testing, electroacupuncture by Voll and hair analysis.

In the UK most CAM practitioners work in private practice; however, some CAM therapies are offered in the NHS (NHS Choices www.nhs.uk/Livewell/complementary-alternative-medicine/Pages/complementary-alternative-medicines.aspx; Wye *et al.*, 2009). This is a controversial area and is often hotly debated in the medical press.

When enquiring about the use of CAM, it is important that the dietitian is respectful of the reasons for their use as these may be cultural or religious, e.g. Ayurveda is commonly used in India. The reasons people use CAM therapies are complex and include the following (Hollander & Mechanick, 2008):

- People feel that symptoms, especially fatigue and chronic pain, are not adequately addressed by conventional practitioners.
- Some prefer to use natural products, as they believe these are safer than man made products such as medicines.
- Some are misled by claims of dramatic improvements in health and cures.
- Many consumers are confused by the often spurious scientific claims of some treatments.
- Terminally ill people and carers who have exhausted conventional treatment may seek further treatments outside conventional medicine.

Dietitians must be aware of the significance of the use of CAM, as while some are innocuous, there are potential problems with some treatments. These therapies are particularly popular in some clinical areas, e.g. multiple sclerosis and cancer, and dietitians specialising in these areas must be conversant with them and any potential problems (see Chapter 7.6.4 and Chapter 7.15.1). These problems include:

- *Lack of nutritional expertise of the practitioner*, including ignorance of biochemistry and physiology (see Professional regulation later in this chapter).
- *Diagnosis of a non-existent nutritional problem*, especially deficiencies. Such deficiencies may be misdiagnosed by the use of tests that have little validity, e.g. hair analysis (Ernst, 2001). Other methods are used that have no credibility or scientific basis, e.g. kinesiology and Vega (electrodermal) testing. Laboratory tests for micronutrients are reviewed by Bender (2003).
- *Lack of informed guidance* – people may obtain information from less reliable resources such as some Internet sites. Schmidt & Ernst (2004) found that many websites endorsed unproven therapies and that a significant proportion of them were giving advice that could be detrimental. They consider that some raised serious concern as they overtly discouraged patients from using conventional therapy.
- *Some therapies may do harm* – elimination diets may be recommended without an in depth understanding of nutrition, resulting in deficiencies (see Chapter 7.11.2). Some alternative therapists advocate stopping conventional treatments, which can have potentially harmful consequences, e.g. advising a type 1 diabetic to stop insulin treatment. Other therapies such as Chinese herbs may cause serious drug interactions.

Some patients, their family or carers may have particularly strong beliefs about the use of CAM therapies and these require careful consideration. This is exemplified by a recent high profile court cases in the UK. Dietitians

should explore with clients the reasons for CAM use offering appropriate advice and presenting the evidence base as appropriate.

Professional regulation

Unlike medicine, nursing and the allied health professions, CAM practitioners are poorly, if at all, regulated and there is usually no minimum level of knowledge of expertise. While there are professional bodies for some CAM therapies, e.g. the British Acupuncture Council, these are often self regulatory and the titles are unprotected. In addition, unregulated practitioners will not necessarily be covered by professional indemnity insurance and therefore practice without this protection for themselves and their patients (consumers).

Within the field of nutrition, only the title dietitian (dietician) is protected by law; anyone using the title of dietitian must be registered with the Health and Care Professions Council (HCPC) (Chapter 1.1). Someone using this title without registration is liable to persecution. The titles nutritionist and nutrition therapist are not protected; therefore, these can be used without formal qualifications [British Dietetic Association (BDA), 2012]. However, many nutritionists are registered with the Association for Nutrition (AfN), which has proficiency and competency criteria, and promotes continuing professional development (CPD) and safe conduct. Like the HCPC, the AfN requires registrants to maintain their knowledge and expertise through CPD. Only nutritionists registered with the AfN can use the title Registered Nutritionist. The AfN is working towards making the title nutritionist protected, possibly with the HCPC. Nutrition therapists are not required to be registered, although they do have a professional body (the British Association for Applied Nutrition and Nutritional Therapy). Appropriately trained or qualified nutritional therapists can apply to join the voluntary register held by the Complementary and Natural Healthcare Council (CNHC).

Differences between dietitians, nutritionists and nutrition therapist are discussed further by the BDA (2012).

Nutritional supplements

Nutritional supplements are taken orally as capsules, pills, liquids or powders and in addition to food (Webb, 2006). Supplements may include essential nutrients, e.g. minerals, vitamins and fatty acids, may usually be in the diet and/or have well established functions in the body, e.g. creatine. Alternatively, they may be plant extracts, e.g. garlic. In 2008 a third of adults in the UK reported taking supplement on most days [Food Standards Agency (FSA), 2008]. The three most popular supplements were multivitamins (36%), cod liver oil (35%) and vitamin C (35%). The use of dietary supplements is increasing in many developed countries, including the UK (NHS & BAZIAN, 2011) and the USA (Gahche *et al.*, 2011); over 50% of people surveyed in the USA reported using dietary supplements.

Supplement usage is not necessarily undesirable; fish oils are beneficial for cardiovascular health and people who do not eat oily fish may benefit from taking them as supplements. Folic acid supplementation is recommended for women for the first 12 weeks of pregnancy. There are many circumstances in which vitamin and mineral supplementation may be either necessary or a sensible precaution including:

- People with an identified vitamin or mineral deficiency, e.g. iron.
- People with increased physiological needs, e.g. pregnant women, infants and children.
- People with increased nutrient losses as a result of gastrointestinal disease or resection, other disorders or side effects of drug treatment.
- People with poor appetite, eating or swallowing difficulties due to illness.
- Elderly people, especially those in residential care or with poor wound healing.
- People on either prescribed or self imposed restrictive diets.
- People at high risk of disorders such as osteoporosis or rickets.

There is evidence to suggest that many of those who take vitamin and or mineral supplements are the least likely to need them (Cade *et al.*, 2004). The National Diet and Nutrition survey showed that supplement users often had a higher micronutrient intake from food sources alone than non-supplement users (Henderson *et al.*, 2003). Conversely, people who might benefit from certain supplements may not be taking them. The majority of women of child bearing age do not consume sufficient folate to provide protection against neural tube defects in the event of planned or unplanned pregnancy (Henderson *et al.*, 2003).

The reasons given for supplement usage vary. In general, people choose to take multivitamin and mineral products in the belief that they will boost energy, reduce the effects of ageing, cut the risk of disease such as cancer, extend life or treat specific conditions, e.g. arthritis (FSA, 2008). The marketing of dietary supplements will undoubtedly affect the decision to take dietary supplements, especially for those aimed at particular groups of people, e.g. the elderly. Supplements of single nutrients tend to be chosen for more specific reasons and to prevent or treat a particular condition or symptom (Neuhouser *et al.*, 1999).

Problems associated with their use

While use of some supplements is based on sound evidence of efficacy, e.g. folate in pregnancy to prevent neural tube defects, use of others is based on more dubious claims or misinformation (Satia-Abouta *et al.*, 2003). For example, enzymes present in some supplements cannot be of any benefit as they will be denatured as soon as they come into contact with stomach acid and are rendered ineffective. Some trace elements available in

supplements are not essential for human nutrition [Expert Group on Vitamins and Minerals (EVM), 2003].

Safety

The report by the EVM (2003) highlighted the fact that remarkably little is known about the requirements, mode of action, bioavailability and toxicity of many micronutrients. It attempted to determine safe upper levels, but in many cases there was insufficient data to assess the nutritional and toxicological implications. There was a lack of well designed, large comparative human studies of significant duration at different levels of intake and with adequate assessment of possible adverse effects. There was even less information on potentially vulnerable groups, e.g. children or the elderly. The toxicity of some nutrients has only been evaluated in animals and the relevance to humans is uncertain. The EVM set safe upper levels for eight vitamins and minerals; for another 22 the data were limited and only possible guidance levels were set. Neither safe nor guidance levels could be set for three others.

The EVM report concluded that, while current intakes of most vitamins and minerals are not harmful, several may have temporary side effects if taken in high doses. Others may have irreversible adverse effects if taken in large amounts over long periods of time (Table 5.4.1). Concerns over possible risks from prolonged high intakes of vitamin A were also highlighted and, following further review, the Scientific Advisory Committee Nutrition (2005) recommended that people who consume liver (the main dietary source of vitamin A) more than once a week, or older adults who are at risk of osteoporosis, should be cautious about taking retinol containing supplements. Women who are, or may become, pregnant are advised to avoid vitamin A supplements.

Overdosage

Overdosage with vitamins and minerals can occur as a result of taking a preparation that provides many times the reference nutrient intake (RNI) for a nutrient in the belief that it will have more therapeutic benefits. However, inadvertent overdosing may occur as a result of:

- Taking inappropriate combinations of supplements. For example, people may take a multivitamin preparation for bone and joint along with a healthy heart supplement, unaware that each contains more than the RNI for vitamins A and D.
- The vitamin content of some supplements may be significantly higher than the amount stated to be present to allow for natural deterioration during the shelf life of the product (EVM, 2003). This is particularly likely to be the case with supplements containing vitamins A, D and E, which are prone to oxidation.

Fat soluble vitamins are stored in the body and the risks associated with prolonged high intakes, particularly from vitamins A and D, are well documented. The risk of overdosage from water soluble vitamins is much less as excessive intakes are usually excreted in the urine. However,

Table 5.4.1 Possible adverse effects of vitamin and mineral supplements (EVM, 2003; FSA, 2008)

Nutrient	Possible adverse effects
Beta-carotene	Long term intake of >7 mg/day may increase the risk of lung cancer Supplements should not be taken by people who smoke
Nicotinic acid	50-mg doses can cause skin flushing and other reversible side effects such as gastrointestinal disturbances Prolonged intake of higher doses may cause liver dysfunction It is recommended that supplemental intakes do not exceed 17 mg/day
Vitamin A	An excessive intake is teratogenic and may also cause irreversible bone and liver damage Retinol containing supplements should be avoided by people who consume liver more than once a week, or older adults at risk of osteoporosis Pregnant women should avoid taking supplements
Vitamin C	>1000 mg/day may cause abdominal pain and/or diarrhoea
Vitamin B ₆	>200 mg/day may cause irreversible neurological damage It is recommended that supplementary intakes do not exceed 10 mg/day
Calcium	>1500 mg/day may cause abdominal pain and/or diarrhoea
Iron	>17 mg/day may cause constipation, nausea and abdominal pain
Magnesium	>400 mg/day may cause osmotic diarrhoea
Manganese	Neurotoxic at high levels of intake It is recommended that supplemental intakes do not exceed 4 mg/day, and in older adults should not exceed 0.5 mg/day
Nickel	Nickel containing products may cause a skin rash in sensitive individuals
Phosphorus	>250 mg/day may cause mild stomach upset in sensitive individuals Long term excessive intake may be detrimental to bone health
Zinc	High intakes impair absorption of iron and copper and may also have gastrointestinal side effects It is recommended that supplemental intakes do not exceed 25 mg/day

the risks are not negligible; irreversible neurological damage can occur following excessive intakes of vitamin B₆. Excessive intakes of some minerals and trace elements (especially iron, copper, fluorine and sodium) can be directly toxic. The threshold between safe upper limits and toxicity may be small in some cases.

Interactions

Although overt toxicity is rare, the long term consequences of excessive high intakes of some vitamins and minerals may be significant. High intake of one, e.g. iron, can impair absorption of another, e.g. zinc, and cause a deficiency. Interactions are particularly likely between elements that are close to each other in the periodic table, e.g. iron, copper, manganese, zinc and chromium (EVM, 2003). Antioxidants also function as part of a coordinated biochemical chain of defence against free radicals; high doses of a single antioxidant supplement such as vitamin E could disturb the antioxidant–pro-oxidant balance and lead to potential risks (Opara, 2002).

Supplemental intakes of some micronutrients can also interact with medicinal drugs, e.g. vitamin B₆ can reduce the therapeutic effect of levodopa used to treat Parkinson's disease and interact with other drugs such as isoniazid, theophylline and phenobarbitone (see Chapter 5.3). It is easy to cause nutritional imbalances by the use of supplements, whereas it is very difficult to do so by consuming food. In order to avoid the potential risks, the use of isolated supplements, particularly in high doses,

should therefore be avoided other than in cases of clear clinical need.

Of more concern are the findings that some of these supplements may be associated with long term risks. A meta analysis of seven large randomised trials showed a small but significant increase in all cause mortality and cardiovascular death with beta-carotene therapy (Vivekananthan *et al.*, 2003). Supplemental intakes of beta-carotene may increase the risk of lung cancer in people with a history of smoking (EVM, 2003; Omenn *et al.*, 1996; Albanes *et al.*, 1996). Supplemental intakes of vitamin E in excess of 400 IU/day (268 mg/day) be associated with premature mortality (Miller *et al.*, 2005). Many consumers of megadoses of micronutrients are aware of the potential of overdose but continue to take large doses of supplements (FSA, 2008).

Regulation of supplements

The EU Food Supplements Directive (EC 46/2002) outlines a framework for certain classes of food supplements. It regulates and guarantees legal status of these classes of supplements within the UK and throughout Europe. Vitamin and mineral supplements must be safe and appropriately labelled to enable consumers to make informed choices (see Chapter 4.5). More information on the classification of supplements as food or medicine can be found at the Government Chemist website (www.governmentchemist.org.uk).

Table 5.4.2 Most common herb–drug interactions (source: Webster-Gandy 2001, table 385, p. 744. Reproduced with permission of Oxford University Press)*

Herb	Interacts with	Comment
St John's wort	Antidepressants	Drug plasma concentration reduced, leading to reduced therapeutic effect
	Antivirals: HIV protease inhibitors (atazanavir, indinavir, nelfinavir, ritonavir, saquinavir)	Reduced therapeutic effect
	HIV non-nucleoside reverse transcriptase inhibitors (efavirenz, nevirapine)	Reduced therapeutic effect
	Anticonvulsants (carbamazepine, phenobarbital, phenytoin)	Reduced control of seizures
	Ciclosporin, tacrolimus	Increased risk of transplant rejection
	Digoxin	Reduced therapeutic effect
	Oral combined contraceptives, oestrogen containing patches and vaginal rings	Reduced therapeutic effect
	Voriconazole	Reduced therapeutic effect
	Theophylline	Reduced asthma control
	Warfarin	Reduced anticoagulant effect
	SSRIs (fluoxetine, paroxetine, sertraline)	Increased serotonergic effects
	Triptans (sumatriptan, naratriptan, rizatriptan, zolmitriptan)	Reduced therapeutic effect
Ginkgo biloba	Anticoagulant (warfarin)	Increased risk of bleeding
	Antiplatelet (aspirin)	
Ginseng	Anticoagulant (warfarin)	Increased risk of bleeding
Dong quai	Anticoagulant (warfarin)	Increased risk of bleeding
Echinacea	Immunosuppressant	Possible immune stimulation
Saw palmetto	Anticoagulant (warfarin)	Altered anticoagulation

*This list is not exhaustive. *Stockley's Drug Interactions* or *British National Formulary* should be consulted for further details. SSRI, selective serotonin reuptake inhibitor.

Herbal medicine

Herbal medicine is based on the use of plants or plant extracts to treat disease. Herbal remedies are one of the most powerful forms of complementary therapies and there are considerable risks from their inappropriate use. In the UK, the main systems of herbal medicine practised are western and Chinese. Western herbal medicine is largely, although not exclusively, based on the use of plants native to Britain, Europe and North America. Chinese herbal medicine is part of traditional Chinese medicine (TCM), which may include other CAM therapies, e.g. acupuncture. Other forms of herbal medicine include Ayurveda and Tibetan. Practitioners prescribe herb mixtures based on an individual's symptoms and condition. People can also purchase over the counter herbal remedies from retail outlets or via the Internet.

Problems associated with their use

Herbal medicines are often assumed to be safe as they are natural products. However, herbal remedies can be associated with problems including:

- **Potency** – herbal remedies contain potent pharmacological ingredients that can have similar effects to many conventional drugs. Many conventional drugs were developed following observations of the effects of

certain plants, e.g. salicylic acid is found in willow bark and its salts (salicylates) are manufactured as analgesics, e.g. aspirin.

- **Interactions** – herbal ingredients can interact with other herbs, conventional drugs and nutrients in foods (Table 5.4.2).
- **Purity** – herbal medicines made to poor standards may be a health risk. Poor manufacturing practices in some countries have resulted in contamination with heavy metals or toxic herbs, posing a significant risk to health (Goudie & Kaye, 2001). Inadequate labelling or batch to batch variation in ingredient types, levels of active substance and proportions can lead to herbal medicines being used incorrectly (Dunning, 2004).

Some herbal products sold in the UK have to be licensed like other medicines, but many over the counter products are exempt. The Medicines and Healthcare Products Regulatory Agency (MHRA) has a traditional herbal medicines registration scheme to ensure that unlicensed over the counter traditional herbal medicines meet assured standards of safety, quality and patient information. In the UK, suspected adverse reactions to both licensed and unlicensed herbal preparations can be reported using the yellow card system. The MHRA also issues alerts about cases of poisoning and adverse reactions, e.g. as it did for Herbal Flos Lonicerae (Herbal Xenicol) Natural Weight Loss Formula (MHRA, 2013).

Herbal remedies such as feverfew, golden seal, juniper, mistletoe, nutmeg, rosemary and sage are contraindicated in pregnancy due to the increased risk of miscarriage. No herbal preparation should be taken during the first 3 months of pregnancy.

Common herb–drug interactions

The number and availability of herbs as supplements and as complementary therapy are increasing, leading to increased potential for herb–drug interactions. It is important to assess herb intake during a nutritional assessment as, like conventional drugs, they have the potential to enhance or reduce drug action. Examples of common herb–drug interactions are shown in Table 5.4.2. St John's wort (*Hypericum perforatum*) is commonly used as an antidepressant. However, it induces liver enzymes and reduces the effect of several drugs; a physician or pharmacist should be consulted before concomitant use.

Evidence base for CAM therapies

Dietetics is an evidence based practice and dietitians, like other regulated healthcare professionals, have a responsibility to use the best possible practice (see Chapter 1.1). It is therefore reasonable to expect the same level of rigour for all therapies, including CAM (Lewith *et al.*, 2000). There are innate difficulties in conducting this research as funding and support may not be available, and there is resistance from some CAM therapists who question the salience of conventional methods of assessment (Jackson & Scambler, 2007). Perhaps for these reasons, the available evidence is often from studies conducted in small groups of subjects. In addition, studies may not be well constructed. This limits the ability to produce high level evidence such as systematic reviews and meta analyses. However, some high level evidence for the efficacy and safety of CAM is available. For example, Posadzki *et al.* (2012) recently published a systematic review of published case reports and case series on the adverse effects of homeopathy.

As the result of increasing use of CAM in the USA, the National Institute of Health has established the National Center for Complementary and Alternative Medicine (NCCAM) with the mission '... to define, through rigorous scientific investigation, the usefulness and safety of complementary and alternative medicine interventions and their roles in improving health and health care'. It funds research and produces publications and guidelines on CAM for healthcare professionals and the public.

Dietitians should look for and critically appraise the evidence for CAM as they would conventional medicine (see Evidence based practice in Chapter 1.1 and Appendix A1). The Cochrane Collaboration has a section on CAM and reviews are available on many topics, e.g. aromatherapy for dementia.

While it is understandable that people with incurable or chronic conditions may use CAM, its use should be underpinned by evidence of efficacy and safety. However,

when there is no risk to the client, the potential placebo effect should be considered, although vulnerable patients must not be given false hope or have necessary treatments delayed. Ultimately, the patient is responsible for making the decision to follow a complementary or alternative dietary regimen. However, it is the responsibility of the dietitian to ensure that the patient has been given sufficient scientifically based information on which to base that decision.

PART 2

Clinical dietetic practice

SECTION 6

Nutrition support

6.1

Nutritional requirements in clinical practice

C Elizabeth Weekes

Key points

- The lack of robust evidence for all prediction methods means that the determination of nutritional requirements requires a significant element of clinical judgement.
- Irrespective of the method used, requirement calculations should be interpreted with care and only used as a starting point.
- Practitioners should regularly review the patient and reassess requirements to take account of any significant changes in clinical condition, nutritional status, physical activity level and goals of treatment.
- The nutritional requirements for a number of clinical conditions have yet to be established.
- The requirements for a number of nutrients in illness and injury have yet to be established.

The aim of devising a nutritional prescription is to provide a patient with their complete requirements either via a single route or any combination of oral, enteral or parenteral nutrition, while avoiding the known complications associated with both under- and over-feeding (ASPEN, 2002; NICE, 2006). The estimation of nutritional requirements is an important part of the patient assessment, yet no single, validated method for estimating requirements exists, and the evidence base for all prediction methods currently in use is poor (Reeves & Capra, 2003). Therefore, practitioners need to exercise a considerable degree of clinical judgement when determining the nutritional requirements of an individual.

All prescriptions for nutritional support should take account of the patient's needs for energy, protein, fluid, electrolytes, micronutrients and fibre (NICE, 2006). However, a number of factors complicate the determination of nutritional requirements in clinical practice (Table 6.1.1) and should be considered prior to estimating the requirements of an individual. Even within a single disease, individual variation, e.g. age, comorbidities, nutritional status, response to surgery or treatment, may make prognosis unpredictable. Furthermore, illness or injury does not have a consistent effect on energy expenditure and this is also likely to be the case for other nutrients. Different treatment modalities, e.g. surgery, chemotherapy or pharmacological agents, may influence requirements in different ways and the same treatment may have very different effects in individuals with the same disease. These differences in response to treatment

may be due, at least in part, to genetic predispositions and environmental influences. The measurement and assay techniques used to assess nutrient status and determine nutritional requirements are not always fully described in the literature and may differ between studies (equipment, timing, protocols, etc.), thus making comparisons difficult. Furthermore, older studies may not be relevant to current practice due to advances in diagnostic procedures and management strategies. Irrespective of the route and likely duration, the aims and objectives of nutritional support should be clearly defined and documented at baseline, reviewed at each stage of the patient's illness and amended accordingly, e.g. minimising losses in acute illness and nutritional repletion in the recovery phase (NICE, 2006).

Energy

Basal metabolic rate and total energy expenditure

In healthy individuals total energy expenditure (TEE) comprises basal metabolic rate (BMR), dietary induced thermogenesis (DIT), i.e. energy expended in the digestion, absorption and transport of nutrients, and physical activity (Figure 6.1.1). Basal metabolic rate, i.e. the metabolic activity required to maintain life, comprises approximately 60% of TEE in any individual; measured BMR is highly reproducible.

The conditions essential for the measurement of BMR are:

Table 6.1.1 Factors affecting nutritional requirements in illness and injury

Basal requirements	Age Sex Body weight Body composition (proportions of fat and muscle mass) Previous and current nutritional intake Ambient temperature
Goals of treatment	Diagnosis Prognosis Likely duration of nutritional support
Disease effects	Metabolic state, e.g. catabolic, normobolic or anabolic Severity of illness Inflammatory response Gastrointestinal function Medical interventions, e.g. mechanical ventilation, radiotherapy, chemotherapy, hormone treatment or transplantation Surgery Pharmacological interventions, e.g. sedation, oral steroid therapy Pain Psychological state
Activity	Mobility status, e.g. bed bound, mobile on ward Level of consciousness Neuromuscular function

- Postabsorptive (12-hour fast).
- Lying still at physical and mental rest (but not asleep).
- Thermoneutral environment (27–29°C).
- No stimulants such as tea, coffee or nicotine in the previous 12 hours.
- No heavy physical activity during the previous day.
- Validation gases must be calibrated to ensure measurements are accurate and reliable.
- Steady state must be established, i.e. <10% difference in minute to minute oxygen (VO₂) and carbon dioxide (VCO₂) volume measurements over 5 minutes.

If any of these criteria are not met, then the measurement is defined as resting energy expenditure (REE) or resting metabolic rate (RMR). In the clinical situation it is rarely possible to measure BMR due to the exacting requirements listed above. In sick or injured subjects, REE will comprise BMR plus the effect of any metabolic response to injury or disease. If the patient is not fasted, the REE measurement may also include some proportion of DIT. In some patients, such as those with involuntary movements due to neuromuscular dysfunction, an element of physical activity may also be included during measurements of REE. Conversely, if measurement conditions are strictly controlled, REE may not equate to total energy requirements since neither activity nor DIT will be accounted for.

There are a large number of BMR prediction equations, although the most commonly cited are Harris Benedict (Harris & Benedict, 1919) and Schofield (1985). More

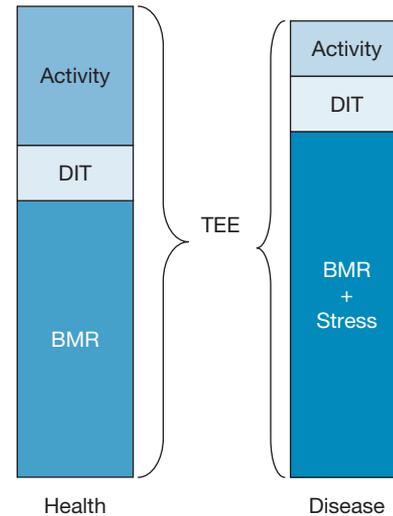

Figure 6.1.1 Energy expenditure in health and disease [source: The British Dietetic Association 2013. Reproduced with permission of The British Dietetic Association (www.bda.uk.com)]

recently, the Henry equations (Henry, 2005) have been evaluated (Ramirez-Zea, 2005; SACN, 2011) and recommended as the most rigorously tested and applicable to modern healthy populations. The Henry equations were derived from a database of 10 552 BMR values in studies conducted from 1914 to 2005, including a larger cohort of elderly subjects than in previous databases. Only studies where conditions met strict criteria for BMR measurements were included.

Inflammatory state

In sick or injured individuals, TEE is influenced by many factors and in any individual patient may be lower, similar to or, in rare cases, higher than requirements in healthy populations (Figure 6.1.1). In the majority of chronic conditions, BMR is usually normal or may be slightly increased. Since any metabolic stress induced increase in BMR is often accompanied by a decrease in physical activity, TEE in chronically ill individuals is usually normal or decreased (Kulstad & Schoeller, 2007; SACN, 2011).

Acute illness increases in BMR above that predicted for healthy individuals of the same age and weight are usually 0–40%, and very rarely, up to 100%. Both the magnitude and duration of the increase are dependent on the presence of an inflammatory response; therefore, an assessment of the patient's inflammatory state is important in the determination of their energy requirements. To avoid the risk of overfeeding in acutely ill individuals, it might be prudent to include a stress factor in any estimate of energy requirements only while there is biochemical and clinical evidence of an inflammatory response, e.g. elevated C-reactive protein or white cell count, low serum albumin, poor appetite or oedema.

In the presence of an inflammatory response, weight gain and other clinical benefits are unlikely to be achieved with nutritional support alone (Streat *et al.*, 1987) and the goal of nutritional support is usually to minimise

losses while the patient is in this state. Aggressive nutritional support should only be considered when the patient is more able to utilise the nutrients provided, i.e. during recovery (anabolic phase). A patient is likely to be moving into the recovery phase as oedema resolves and the parameters listed earlier return to the normal range.

Physical activity

Individuals requiring nutritional support range from paralysed and sedated, critically ill patients to fully mobile patients on the ward or in the community. To date however, there is a relative lack of research on the effects of illness and injury on physical activity levels (Elia, 2005), although a recent report concluded that acute illness is usually accompanied by a decrease in physical activity that compensates for any increase in BMR (SACN, 2011). The energy expended in physical activity is lowest in the sickest patients, with sedated, ventilated patients usually expending <10% above BMR on physical activity. This can be highly variable however, especially in agitated patients (Frankenfield, 2006). In hospitalised individuals it is reasonable to assume that physical activity will be lower than habitual levels. For example, in preoperative patients activity accounts for 20% above BMR, while postoperatively physical activity may decrease to 5% BMR in the first few days, increasing to 15% BMR by days 9–12 (Kinney *et al.*, 1968).

While it might be expected that physical activity will be increased in patients receiving active physiotherapy, moving painful or damaged limbs, or in those with abnormal neuromuscular function, this may not result in increased TEE as the patient compensates by resting or sleeping. For example, in patients with involuntary movement due to Parkinson's disease, TEE was not increased due to a reduction in the energy expended in voluntary physical activity (Toth *et al.*, 1997).

As an individual recovers from illness, or once they are discharged from hospital, the component of TEE that is most likely to change is physical activity, assuming there have been no effects on neurological or muscular function. In the community some patients receiving nutritional support, irrespective of feeding route, may have similar activity levels to healthy individuals, whereas house bound or nursing home patients are likely to have physical activity levels similar to those of hospital patients. In the determination of energy requirements, regular assessment of habitual activity is important. However, the best method for assessing physical activity level objectively in clinical practice has yet to be determined (Frankenfield & Ashcraft, 2011). Multiplication factors for physical activity do exist (Taylor, 2007) but are as variable and open to misinterpretation as are stress factors, and thus a considerable degree of clinical judgement is required in their use.

Dietary induced thermogenesis

Dietary induced thermogenesis (DIT) usually accounts for 8–10% of TEE. In healthy individuals the main deter-

minant of DIT is the energy content of the food, followed by the protein fraction (Benedict & Carpenter, 1918). The effects of injury and sepsis on DIT are unclear, although evidence suggests the effects are similar to those in healthy individuals (Westerterp 2004). While differences in DIT might be expected when comparing the parenteral with the enteral route, studies have so far failed to show a significant difference (Stokes & Hill, 1993). When enteral feed is given as a bolus, the effect on DIT is similar to that observed with food, i.e. an increase in total energy expenditure of 8–10%. In contrast, the continuous infusion of nutrients does not significantly increase resting energy expenditure over fasting level (Heymsfield *et al.*, 1987). In the determination of energy requirements, there is rarely a need to make a separate adjustment for DIT as most prediction equations were derived from data collected from subjects who were receiving nutritional support during metabolic measurements. The effects of DIT are therefore already included in the equation.

Prediction methods

The most accurate methods for determining energy requirements are calorimetry and the doubly labelled water technique; however, these methods are generally too expensive and impractical for routine clinical use (Branson & Johannigman, 2004). In clinical practice therefore, energy requirements are usually estimated using published prediction methods. Three main methods for estimating energy requirements exist, all of which use some combination of body weight, age or sex. First, the factorial method involves estimating BMR from prediction equations and then adding factors for metabolic stress, physical activity and DIT (e.g. Taylor, 2007; Todorovic & Micklewright, 2011). Second, a method has been proposed by other organisations (ASPEN, 2002; NICE, 2006) where requirements are based on energy values per kilogram of body weight, adjusted for particular purposes, e.g. 25–30 kcal/kg body weight for bedridden patients (Table 6.1.2). Third, a number of disease specific regression equations have been derived, in particular for intensive care unit (ICU) patients (Frankenfield *et al.*, 2005) and burns (Ireton-Jones *et al.*, 1992).

All three methods are open to criticism, e.g. the Parenteral and Enteral Nutrition Group of the British Dietetic Association (PENG) (Todorovic & Micklewright, 2011) guidelines involve calculating BMR using the Henry equations (Henry, 2005) and adding one factor (0–60%) to take account of metabolic stress and another (10–25%) for activity and DIT. All these steps have the potential to introduce error. All BMR prediction equations were derived for use in healthy populations and therefore, their use in sick individuals is open to criticism. Furthermore, the data used to derive the stress factors are unclear and there is considerable scope for misinterpretation by inexperienced practitioners. While there is a lack of evidence to support this method, the approach is easy and takes account of the main factors that impact on an individual's energy requirements, i.e. weight, age, gender, physical activity level and DIT.

Table 6.1.2 Guidelines for estimating nutritional requirements in stable patients

Energy (/kg/day)	Protein (/kg/day)	Micronutrients
25–35 kcal (105–147 kJ) (NICE, 2006)*	0.8–1.5 g (NICE, 2006)*	Provision of adequate electrolytes, minerals, micronutrients (allowing for any pre-existing deficits, excessive losses or increased demands) and fibre if appropriate (NICE, 2006)*
20–35 kcal (84–147 kJ) (ASPEN, 2002) [†]	0.8–2.0 g (ASPEN, 2002) [†]	Recommendations are made for specific nutrients based on route of administration For enteral nutrition, recommendations are based on the RDA/AI levels and for parenteral nutrition, recommendations were made on the assumption that patients had increased requirements (ASPEN, 2002) [†]

*For patients who are not severely ill or injured, nor at risk of refeeding syndrome.

[†]For unstressed adult patients with adequate organ function.
RDA, recommended daily allowance; AI, adequate intake.

While easy to use and based on the parameter with the greatest influence on BMR, the second method (kcal/kg body weight) does not account for changes in energy expenditure with age, gender or metabolic state, and it is unclear for people who are obese whether requirements should be calculated using actual or ideal body weight. Its applicability for depleted individuals has also been questioned. Similarly, there are no defined criteria for when to use 20, 25, 30 or 35 kcal/kg/day.

Disease specific equations are based on physiological variables that may change considerably over a short period of time, e.g. body temperature, heart rate and minute ventilation. While they may be more accurate in the specific population for which they were derived, these equations are also open to similar criticisms regarding validity, and currently there are no indications on how frequently requirements should be reviewed and amended in the light of any changes in these variables. Furthermore, it is yet to be determined if amending feeding regimens in response to changes in physiological variables results in beneficial outcomes.

The data used to derive all prediction methods are difficult to locate and none of the methods described above has been fully validated (Reeves & Capra, 2003). Furthermore, while prediction methods may provide adequate estimates of requirements for groups of patients, they all have a poor predictive value for individuals. Regardless of the method used, all estimates of energy requirements should be interpreted with care and used as a starting point only. Since any one of a number of factors might vary during a patient's illness and recovery, requirements should be reviewed and recalculated regularly to avoid either under- or over-feeding (NICE, 2006).

Protein (nitrogen)

In clinical practice the determination of protein (nitrogen) requirements is complicated by the fact that protein homeostasis is in a state of constant flux. In the healthy individual, protein requirements are dependent to a varying degree on a number of factors, including recent and long term protein and energy intakes, physical activity and the quality of the protein consumed (Calloway & Spector, 1955). A chronic lack of protein (and energy)

results in the body adapting to starvation in order to preserve body protein stores. In illness or injury, determination of protein requirements is further complicated by the metabolic state of the patient and the presence or absence of an inflammatory response. The maintenance of nitrogen balance depends on long term and recent nitrogen and energy intakes and clinical state in injury or illness. As a result, it is very difficult to predict requirements in any one individual at any particular time.

In severe chronic illness, such as cancer, chronic respiratory or cardiac failure, the presence of cachexia may further complicate the picture (see Chapter 7.15.9). Cachexia results in severe and specific loss of skeletal muscle mass, with relative preservation of visceral protein, as the body reprioritises protein metabolism away from the peripheral tissues and towards the liver. This preferential loss of skeletal muscle mass occurs even in the presence of poor dietary intake. In the short term this response may be beneficial as protein stores are liberated to mount the immune response and promote healing. However, in the longer term, or if the loss of muscle mass is excessive, this is detrimental to the patient (WHO/FAO/UNU, 2007).

In clinical practice a prescription consisting of 0.8–1.0 g of protein/kg/day is likely to provide sufficient protein for the majority of patients. In those who are metabolically stressed however, requirements may be higher, although current recommendations suggest that provision of more than 1.5–2.0 g of protein/kg/day is unlikely to be beneficial in terms of clinical outcome and may indeed be detrimental, particularly in patients who have had a prolonged period of poor intake and are therefore at risk of refeeding syndrome (NICE, 2006).

The largest nitrogen losses have been documented in sepsis, major trauma and burns. In these conditions nitrogen balance is almost impossible to achieve in the early catabolic phase post injury and currently there appears to be little to gain from providing nitrogen in excess of 1.5 g of protein/kg body weight in the critically ill (NICE, 2006), although this is open to debate (Frankenfield, 2006). The repletion of protein stores is most likely to be effective once a patient is in the recovery (anabolic) phase, is able to mobilise and when adequate amounts of energy are also provided (WHO/FAO/UNU, 2007).

Fluid

In health, fluid requirements are 25–35 mL/kg body weight. This is approximately 2–3 L for individuals within the normal range for body mass index (BMI). The metabolic response to acute illness and injury results in changes in fluid and electrolyte balance such that water and sodium are retained avidly. This often results in oedema in the early days of illness that may take up to 10 days to return to normal, or longer in the presence of sepsis or other complications. Recovery is accompanied by a return of the capacity to excrete any excess salt and water acquired during the acute phase.

In postsurgical patients there is evidence that poor fluid management (usually administration of excess fluid sodium and chloride) is a common cause of oedema, prolonged ileus and other complications, and has an adverse effect on patient outcome (Lobo *et al.*, 2006). Patients are, therefore, extremely susceptible to errors in fluid prescription early after injury or surgery. The British Consensus Guidelines on Intravenous Fluid Therapy for Adult Surgical Patients (GIFTASUP) (Powell-Tuck *et al.*, 2011) provide evidence based guidelines on the clinical management of fluid balance in surgical patients, those requiring nutritional support and patients with acute kidney injury (see Chapter 7.17.5). The guidelines recommend that food and fluids should be provided orally or enterally and intravenous infusions should be discontinued as soon as possible. In disease or following surgery, estimates of fluid requirements should take into account any losses resulting from pyrexia, drains, diarrhoea, burns, stomas and fistulae, and all sources of fluid should be considered (including fluids given with some intravenous drugs) to minimise the risks of overhydration, especially in patients receiving enteral or parenteral nutrition (see Chapter 6.6).

Currently there is insufficient evidence to provide guidelines on sodium and fluid requirements in very thin or obese individuals; therefore, patients at the extremes of BMI should be monitored closely for signs of over- or under-hydration, and fluid prescriptions adjusted accordingly.

Micronutrients

In the presence of illness or injury, micronutrient deficiencies may occur for a variety of reasons, although blood measurements may not be reliable markers of micronutrient status (Shenkin, 2000):

- Inadequate (or imbalanced) intake.
- Increased metabolic rate and increased number of biochemical reactions.
- Adverse effects of treatment.
- Increased oxidative stress.
- Losses from fistulae, burns, diarrhoea, dialysis.

The effects of micronutrient deficiency are non-specific and insidious, e.g. muscle weakness, anorexia and depression, and are commonly associated with acute and chronic illness. Suboptimal levels may impair function before

signs of deficiency become evident and micronutrient deficiencies may therefore go undiagnosed in the presence of illness or injury (see Appendix A2).

In the absence of an adequate evidence base, guidelines for the provision of micronutrients to patients with acute or chronic illness (Arends *et al.*, 2006) are non-specific in that they state that provision should be based on recommended daily amounts (RDAs) or adequate intakes (AIs) (Table 6.1.2). While recognising that these intakes are recommended for healthy populations rather than sick individuals, in the absence of evidence this pragmatic approach appears to be justified. In some patients with long term chronic conditions, e.g. cancer, multiple sclerosis and rheumatoid arthritis, excess micronutrient intake may be of concern, particularly in those taking a number of non-prescription supplements. During assessment the potential adverse effects of self dosing of alternative medicines and/or micronutrient supplements should always be considered.

With regard to nutritional support, most standard oral nutritional supplements and enteral feeds contain sufficient minerals and electrolytes to meet daily requirements for sodium, potassium, magnesium and phosphate (NICE, 2006), but only if the patient is receiving enough of the feed to meet all their energy needs. Since many patients are either receiving less than full nutrition from these products or have pre-existing deficits, high losses or increased demands, additional provision may be required. However, care is needed to avoid excessive provision in some patients, e.g. those with renal or liver impairment. Some specialised feeds are designed specifically to provide adequate electrolytes, vitamins and minerals in lower energy provision for patients with low total energy needs.

Premixed parenteral nutrition (PN) bags contain very variable amounts of electrolytes and minerals, and care is needed to avoid giving PN with either inadequate or excessive electrolyte and/or mineral content (NICE, 2006). As with electrolytes and minerals, most standard oral and enteral feeds contain enough vitamins and trace elements to ensure that needs are met if the patient is taking enough feed to meet their daily energy needs. However, when this is not the case, further balanced micronutrient supplementation may be required, especially in those with pre-existing deficits, poor absorption, increased demands or high losses (NICE, 2006). Premixed PN bags invariably contain inadequate levels of some micronutrients and therefore additions need to be made prior to administration. The provision of PN without adequate micronutrient content must be avoided.

Special considerations

Estimating energy and protein requirements in obese patients

Energy

The factor that has the greatest influence on BMR is actual body weight (Horgan & Stubbs, 2003); however, some clinicians have recommended the use of adjusted weights

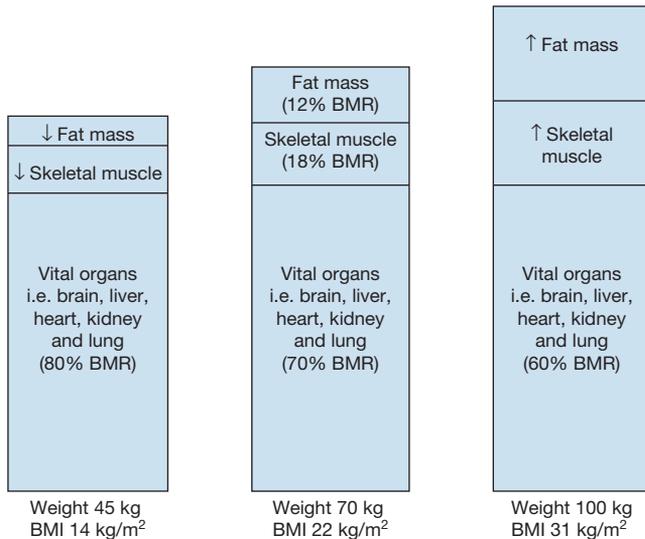

Figure 6.1.2 Effects of changes in body composition on basal metabolic rate

to calculate BMR from prediction equations in subjects at the extremes for BMI. Regardless of BMI, rapid weight loss is associated with increased complications and poor outcome in hospitalised patients (NICE, 2006); therefore, weight loss should not be a nutritional goal during acute illness or following injury, even in the obese. Figure 6.1.2 shows how changes in weight and body composition affect BMR. The excess body weight in obese individuals largely comprises tissue with a low metabolic rate and some clinicians have therefore recommended adjusting weight downwards to calculate BMR, e.g. 25% adjusted weight = (actual body weight × 0.25) + ideal body weight (Ireton-Jones, 2005). Other authors however, recommend the use of actual body weight (Krenitsky, 2005) since BMR prediction equations were derived from data on individuals across the range for BMI and actual rather than adjusted body weight was used to develop the equations. As there is no good evidence to support the use of adjusted body weight or specific cut-offs, clinical judgement is required to minimise the risks of over- or underestimating energy requirements in obese individuals (BMI >30 kg/m²). In clinical practice, actual body weight should be used to estimate BMR in obese individuals (Frankenfield & Ashcraft, 2011), but the assignment of stress factors should be undertaken with caution (Todorovic & Micklewright, 2011). Alternatively, energy requirements can be calculated using 19–21 kcal/kg actual body weight (Glynn *et al.*, 1999). However, it may be beneficial in some conditions, e.g. cancer of the breast and prostate, to aim for weight loss once a full recovery has been made in order to aid mobility and reduce the risk of recurrence (World Cancer Research Fund, 2007).

Protein

Since protein requirements are to a large extent determined by lean body mass, in obese patients there is an argument for using an adjustment to actual body weight

to calculate protein requirements, or to use ideal rather than actual body weight, although original work relating to this suggestion is difficult to locate.

Refeeding syndrome

There are several published regimens for managing patients at risk of refeeding syndrome. The lack of randomised controlled trials in this area however, means that management is based on consensus and expert opinion rather than evidence (Khan *et al.*, 2011). Irrespective of which regimen is employed, the common principles are to prevent refeeding syndrome by cautious reintroduction of energy and correction of biochemical abnormalities. While some authors recommend correction of biochemical abnormalities prior to introduction of energy and other macronutrients (Crook *et al.*, 2001), others recommend that both can occur in tandem without deleterious effects to the patient (NICE, 2006). There are currently no published randomised trial data to support either view. It is likely that the problems associated with refeeding are less likely to arise with oral nutritional support since starvation is usually accompanied by a loss of appetite; however, care should be taken in the prescription of oral nutritional supplements, particularly in the area of eating disorders (NICE, 2006). Underweight individuals tend to lose muscle and fat stores while preserving tissues with a high metabolic rate, i.e. brain, liver, heart and kidney. On a body weight basis, their metabolic rate is about 25% higher than that of normal weight individuals and some clinicians have used this as a rationale to use ideal or usual body weight instead of actual body weight when calculating BMR. For a full discussion of the management of severely depleted individuals, see the report (MARSIPAN) by the Royal College of Psychiatrists and the Royal college of Physicians (2010) (see Chapter 6.4).

Estimating requirements for patients with abnormal fluid status

Oedema and ascites increase body weight without increasing metabolically active tissue. In the presence of overhydration therefore, dry weight should be measured after paracentesis, drainage of ascites or post dialysis, and used to calculate BMR. In those patients where excess fluid cannot be removed, consider using the last recorded weight prior to developing ascites or oedema or estimating dry weight using the equation:

$$\text{Estimated dry weight} = \text{Actual body weight} \\ - (\text{Weight of ascites} + \text{Weight of oedema})$$

Estimating energy requirements for critically ill patients

In comparison with other clinical populations, there are considerably more studies measuring the energy expenditure of critically ill patients. The evidence base for protein provision in critically ill patients is more limited however, and for micronutrient provision there is even less evi-

dence. Reported energy requirements for ICU patients vary considerably, in part due to the heterogeneity of the different ICU populations studied and in part due to differences in definitions of critical illness and/or the presence of sepsis. In addition to the factors that affect energy expenditure in general, e.g. age, gender and weight, the determination of energy requirements in ICU patients is complicated by a number of additional metabolic and management factors, such as hyperglycaemia, the presence or absence of sedation, ventilation mode or the fraction of inspired oxygen. In the ICU setting, the estimation of an individual patient's energy requirements can be particularly challenging.

In bed bound artificially ventilated patients, BMR is frequently increased; however, TEE is not usually elevated, mainly because of minimal physical activity and/or sedation (SACN, 2011). In the most acutely ill patients however, e.g. severe burns, TEE may be transiently elevated above normal (Bessey & Wilmore, 1988). For a full discussion of nutritional requirements in critically ill patients, see Chapter 7.17.1.

6.2

Malnutrition

Rebecca Stratton and Marinos Elia

Key points

- Malnutrition adversely affects physical and psychological health, and impairs recovery from disease, increasing mortality, complications, hospital stay and use of other healthcare resources.
- Malnutrition is common and costly but is often unrecognised and untreated.
- Routine and regular screening is recommended to improve the detection and treatment of malnutrition.
- Screening should be undertaken using a quick and simple to use, valid, evidence based tool with a care plan attached.
- Treatment of malnutrition should be undertaken promptly with appropriate nutritional support; energy, protein and other nutrients, including micronutrients, should be considered.

Malnutrition can be defined as '*a state of nutrition in which a deficiency or excess (or imbalance) of energy, protein and other nutrients causes measurable adverse effects on tissue/body form (body shape, size, composition), body function and clinical outcome*' (Elia, 2000, p. 2).

Malnutrition is a broad term that includes not only protein energy malnutrition (both over- and under-nutrition), but malnutrition of other nutrients, such as micronutrients. The adverse effects of malnutrition will mostly respond to nutritional treatment. This chapter concentrates on protein energy undernutrition (described here as malnutrition).

Prevalence of malnutrition and at risk groups

Malnutrition is common and is a major clinical and public health problem in the UK (Elia, 2000; Elia & Russell, 2009). At any given point in time, >3 million people in the UK are malnourished with most (~93%) living in the community (Elia & Russell, 2009). Although malnutrition among people in hospitals was identified over three decades ago (Bistrain *et al.*, 1974; Hill *et al.*, 1977), it remains a common and often unrecognised problem (Elia, 2003; Stratton *et al.*, 2003). The British Association for Parenteral and Enteral Nutrition (BAPEN) national screening weeks have shown that approximately one-third of hospital admissions are at risk of malnutrition (Russell & Elia, 2010). Similar estimates of the prevalence

of malnutrition in hospitalised infants and children exist (Stratton *et al.*, 2003; Gerasimidis *et al.*, 2011; Joosten *et al.*, 2011).

The prevalence of malnutrition depends on the criteria used to define it and varies with age, the associated clinical condition and the type of treatments (including surgery) being undertaken. The frequency of malnutrition, and the risk of developing malnutrition, is typically highest in:

- Infants, young children and the elderly.
- Patients with malignancy, gastrointestinal, respiratory or renal disease.
- Those with multiple comorbidities, including the critically ill.
- Individuals undergoing complex surgery, transplantation or treatment for burns.

Once in hospital, deterioration in nutritional status often occurs unless action is taken to prevent it. Studies show that between 30% and 90% of adults and children lose weight whilst in hospital (Stratton *et al.*, 2003). This is partly because malnutrition is often unrecognised and untreated, frequently going undetected. Measurement and documentation of important nutritional information, including body mass index (BMI), unintentional weight loss and recent food intake, in hospital inpatients, outpatients and in many other care settings is often lacking (Elia, 2000; Cawood *et al.*, 2008; Volkert *et al.*, 2010). This is partly due to the absence of formal screening

programmes that link the recognition of malnutrition with treatment plans.

At any point in time, only about 2% of over 3 million adults at risk of malnutrition are in hospital, with 5% in care homes and the remainder in the community (2–3% in sheltered housing) (Elia *et al.*, 2010). National and local surveys suggest 15–30% of outpatients, 5–23% of patients visiting a general practitioner (GP), 25% patients receiving district nursing care, 30–40% of care home residents and 10–14% of individuals in sheltered housing are at risk of malnutrition (Russell & Elia, 2010; Stratton & Elia, 2010). The elderly are a group at particular risk, as suggested by a secondary analysis of a national survey which found that 12% of free living and 21% of institutionalised elderly are at risk of malnutrition and that geographical inequalities exist (higher rates of malnutrition in the North than the South of England) (Elia & Stratton, 2005). In addition, malnutrition is more common in those from more deprived areas (Stratton & Elia, 2006). In community settings, as in hospitals, malnutrition is often undetected and untreated (Cawood *et al.*, 2008; Volkert *et al.*, 2010). An increasingly ageing population, the pressure on healthcare resources (NHS QIPP challenge) (Department of Health, 2010c) and the new community led NHS structure (Department of Health, 2010a) mean a greater proportion of sick and debilitated individuals will be cared for outside hospital, and services for managing malnutrition will be commissioned by community based Clinical Commissioning Groups.

Causes of malnutrition

In the UK, the primary cause of malnutrition is disease, hence the term disease related malnutrition. Other causes for malnutrition include poverty and deprivation, and behavioural problems in children. Disease related malnutrition arises when nutritional intake does not meet nutritional needs because of decreased dietary intake, increased nutritional requirements or an impaired ability to absorb or utilise nutrients.

Insufficient dietary intake is the main reason for malnutrition developing and progressing, and there are many factors that limit nutritional intake (Figure 6.2.1). Broadly these factors can be divided into two types:

- Disease related factors that reduce intake despite availability of food.
- Other factors such as inadequate availability, quality or presentation of foods that reduce intake.

Numerous studies across many different diagnostic groups have documented energy, protein and micronutrient intakes to be insufficient to meet nutritional requirements, particularly in institutionalised patients. Also, studies have shown that food in institutions (hospitals, care homes) is often not consumed and therefore wasted, sometimes because catering practices do not meet the needs of the sick (see Chapter 4.4.1). Nutritional support (oral nutritional supplements, enteral tube feeding, parenteral nutrition) is often not used early enough or

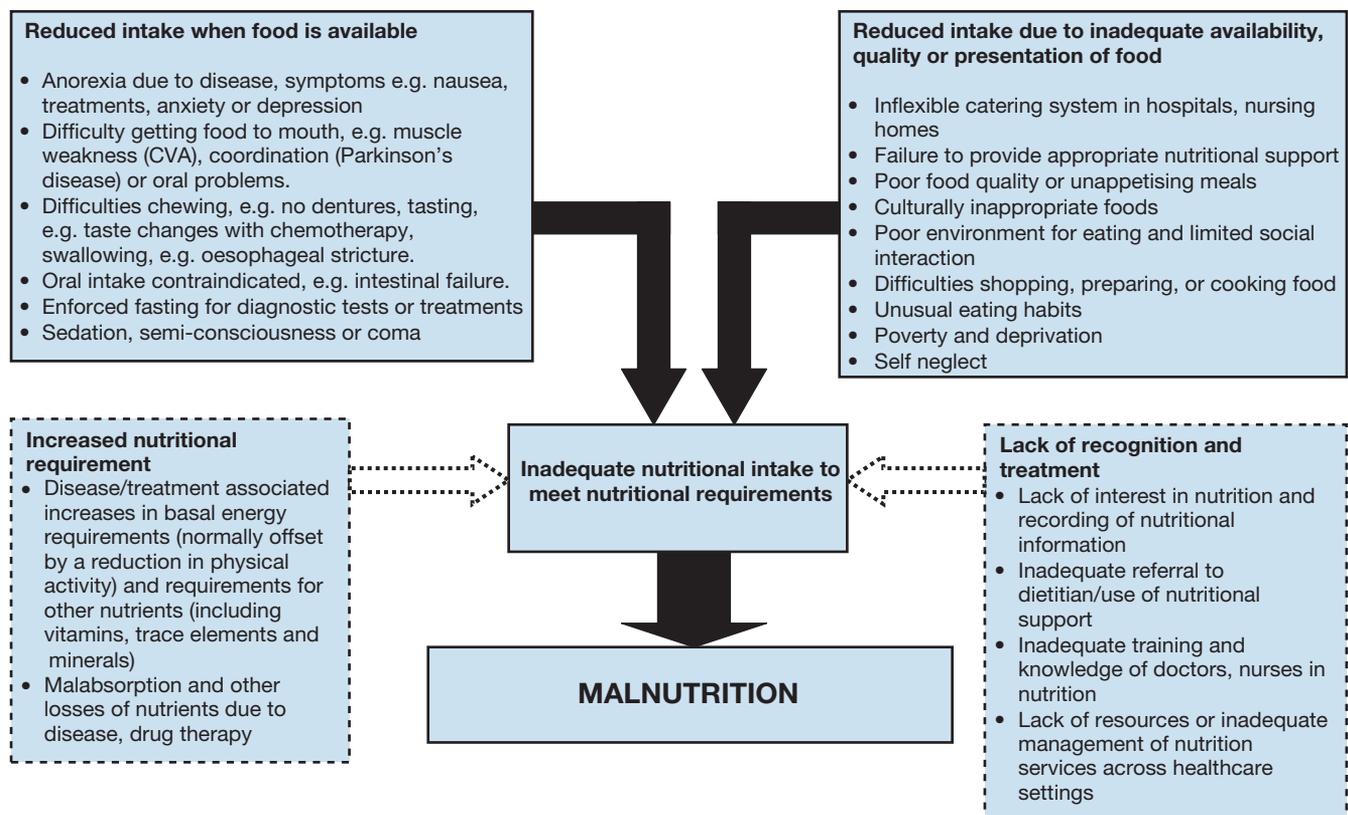

Figure 6.2.1 Causes of malnutrition

frequently enough to prevent or treat malnutrition, despite a large and growing evidence base that suggests benefits when nutritional support is used appropriately. This is increasingly an issue as current economic constraints mean budget holders may choose to withhold prescribed nutritional care, failing to recognise that greater costs result when leaving malnutrition untreated (increased costly hospital admissions and complications such as infections and pressure ulcers).

Malnutrition may also arise if total requirements for energy and nutrients (protein, vitamins, minerals and trace elements) are increased with disease, after trauma and surgery, and with some treatments, e.g. drug therapy and chemotherapy. Increments in basal energy metabolism occur in a number of disease states, postoperatively and in sepsis and burns patients. However, in many cases this is offset by reductions in physical activity (Gibney *et al.*, 1997; Jebb, 1997) so that total energy expenditure is not substantially increased (See Chapter 6.1). Increased nutrient losses and inability to absorb nutrients also elevate requirements, increasing the risk of malnutrition developing.

Consequences of malnutrition

Malnutrition has a diversity of effects, influencing every system of the body. It has many adverse consequences on body structure and function, physical and psychological health, and on recovery and outcome after disease and injury, including surgery (Stratton *et al.*, 2003). Malnutrition results in loss of body structure with weight loss due to loss of fat and lean tissue, including organ mass. In children, malnutrition will also impair growth and development, leading to stunting and/or wasting. However, malnutrition is more than a reduction in nutritional status as there are impairments in physical and psychological health and function that include the following:

- Impaired immune function increasing susceptibility to infection and sepsis.
- Delayed wound healing and increased risk of pressure ulcers.
- Muscle wasting and weakness that may affect:
 - Respiratory function – weakened respiratory muscles may make it difficult for a patient to cough and expectorate effectively, increasing the risk of chest infection. This may also make it harder to wean a patient from artificial ventilation.
 - Cardiac function – this may be impaired, resulting in reduced cardiac output and liability to heart failure.
 - Mobility – weakness of skeletal muscles delays a return to full mobility. Reduced mobility increases the risk of thromboembolism and pressure ulcers.
- Altered gastrointestinal structure and function, impairing digestion, absorption and the gut barrier.
- Apathy and depression, leading to loss of morale and reduced will to recover.
- General sense of weakness and illness, which impairs appetite and physical ability to eat, and hence tends to perpetuate and worsen the state of malnutrition.

- Adverse effects on learning and behaviour in children, with potential long term deficits in cognition.
- Poor libido, fertility, pregnancy outcome and mother-child interactions.

These physical and psychological consequences of malnutrition increase susceptibility to disease, impair clinical outcome and increase healthcare use and costs. Individuals identified as being at risk of malnutrition have:

- Increased risk of mortality and complications during and after hospitalisation.
- Longer hospital stays and greater hospital costs.
- Greater requirement for healthcare post discharge.
- Increased risk of admission to hospital and more visits to the GP.

Consequently, increased use of healthcare resources means malnutrition is very expensive. It is estimated that in 2007 the annual expenditure on disease related malnutrition in the UK exceeded £13 billion, which when extrapolated to the European Union, approximates to €120 billion (Elia & Stratton, 2009; Ljungqvist *et al.*, 2010).

Detection of malnutrition

The rationale for establishing a policy to routinely detect malnutrition is that it:

- Is a common and costly problem.
- Has many adverse short and long term effects on health, function and recovery.
- Is treatable in most cases.

For many years, malnutrition has been under detected and under treated, and for this reason, many national organisations recommend that malnutrition be routinely identified using screening. These include the British Dietetic Association (BDA, 2009), Royal College of Physicians (2002), BAPEN (Elia, 2003), NHS Quality Improvement Scotland (2003), National Institute for Health and Care Excellence (NICE, 2006) and the Department of Health (2008; 2010a; 2010b) Legislation in England [Regulation 14 of the Health and Social Care Act 2008 (Department of Health, 2008)] states that registered organisations have a duty to safeguard service users from malnutrition and dehydration, to identify poor nutrition and dehydration with nutritional screening and to take action to treat it. The Care Quality Commission (CQC) is the regulator in England that continuously monitors registered care providing organisations and their compliance with this aspect of the law.

It has also been suggested that obesity should be routinely identified, ideally using the same screening procedure (Elia, 2003). Obesity has many health risks (see Chapter 7.13.1), but treatment of obesity should not generally be undertaken in those who are acutely unwell. Such patients may still be at risk of malnutrition due to weight loss or limited dietary intake, e.g. nil by mouth post stroke, and should be treated accordingly.

Table 6.2.1 Important characteristics of a screening tool for malnutrition

Practical	Quick and easy to complete and to understand Has a range of alternative measures for when weight or height cannot be measured
Universal	Can be used in all adults of all ages (including the elderly), including the sick and healthy Is applicable across different care settings (hospital, GP practice, nursing home, free living) Allows continuity of care Can be used for public health purposes
Reliable	Good reproducibility between users Good internal reliability
Valid	Content, face, internal, concurrent and predictive validity
Evidence based and independently peer reviewed	
Linked to a care plan for treatment	Facilitates nursing and other staff initiating appropriate monitoring or treatment and referral to the dietitian or nutrition support team
Developed by a multidisciplinary group for use by all healthcare professionals	
Acceptable to patients and healthcare professionals	

Screening

Screening is a rapid, simple and general procedure, often carried out at first contact with an individual, to detect those with significant risk of malnutrition, so that action plans for monitoring and/or treatment can be implemented. Some individuals may need help or advice with eating and drinking; others may need special diets and a referral to a dietitian for expert advice. Screening should be routinely and regularly undertaken in hospitals, nursing and residential care and in other primary care settings, e.g. patients seen by district nurses, at risk groups or newly registered patients in GP practices. The frequency of screening and any associated monitoring and treatment will depend on the patient group, the healthcare setting and the resources available.

Screening is a multidisciplinary responsibility and can be undertaken by nurses, doctors, dietitians or other healthcare professionals. Screening, using a test or tool, should be part of a screening programme that includes a full range of activities from identification of risk with the tool, to diagnosis and treatments. Screening can precede nutritional assessment, which is a more in depth and specific evaluation of those individuals at risk and typically undertaken by a dietitian (see Chapter 2.2). Nutritional assessment may be required in the case of serious nutritional problems, to identify micronutrient status or to undertake other detailed dietary investigations. Although dietitians have the expertise, it is neither practical nor cost effective for them to assess the nutritional status of every patient admitted to hospital and they are unlikely to come into direct contact with many of those at risk in the community (often only after problems have arisen). Therefore, identification of people with, or at risk of, malnutrition requires a locally agreed policy and the assistance of other health professionals.

There are many screening tools in use in clinical practice, but it is important to use a tool that meets the important characteristics listed in Table 6.2.1. A screening tool for malnutrition should attempt to establish the following in the most objective way possible:

- Chronic protein energy status, e.g. body mass index (BMI), weight for height, weight and height for age.
- Any recent changes in protein energy status, e.g. weight loss, inadequate dietary intake.
- Any likely future changes in protein energy status, e.g. likelihood of inadequate dietary intake and weight loss.

When objective measures are not feasible, e.g. in an acutely unwell, bed bound individual, or there is concern about their interpretation, e.g. oedema, alternative measures should be considered. As part of the screening programme, the underlying cause of changes in nutritional status, e.g. disease or condition, psychosocial issues and behavioural problems, should also be established and treated if appropriate, e.g. for those who are terminally ill, active treatment may not be undertaken. Although there are many factors that increase an individual's risk of malnutrition, e.g. gastrointestinal symptoms, metabolic stress and pressure ulcers, they do so by affecting the adequacy of nutritional intake relative to an individual's nutritional needs. In most cases, nutritional intake is reduced, nutritional needs are not met and the result is that weight is lost. Therefore, a screening tool is able to assess risk of malnutrition simply by identifying chronic protein energy status, e.g. BMI in adults, and previous and predicted recent changes in status, e.g. weight loss and reduced dietary intake. Thus, screening can reflect aspects of an individual's nutritional status encompassing:

- Past, e.g. unintentional weight loss and lack of nutritional intake.
- Present, e.g. BMI.
- Future, e.g. potential for lack of nutritional intake and weight loss.

The past can be most easily assessed using unintended weight loss over a defined time scale, e.g. 3 months. This is assessed in terms of the extent of unintentional body weight loss, ideally as a percentage of usual body weight, e.g. >10% of weight lost in 3 months. Three to 6 months is the most common time period over which to assess weight loss, although it can be a shorter, e.g. 1 week, or longer, e.g. 1 year, time interval. Weight loss is also a marker for inadequacy of nutritional intake. No nutritional intake for >5 days (without disease) equates to a weight loss of 5–10% (Elia, 2003). Detailed dietary history is not taken as part of screening as it is time consuming and requires a nutritional expert, e.g. dietitian, to undertake (screening is not usually undertaken by dietitians). Detailed dietary information may be obtained as part of nutritional assessment.

The present or current status of an individual can be objectively identified using BMI. This is a simple and reproducible index that reflects body composition and function. A BMI of <20 kg/m² is considered to be underweight and a BMI of <18.5 kg/m² as severely underweight. Individuals with a BMI of >30 kg/m² are considered obese. These are nationally recognised and accepted cut-offs for BMI and are based on the loss of physiological function and wellbeing, and increased clinical risk as BMI decreases. These cut-offs are consistently recommended for all adults, including elderly people. However, these cut-offs denote only risk of malnutrition, as some individuals may be constitutionally thin, fit and well despite having a low BMI.

When screening for risk of malnutrition, particularly in the acute setting, consideration of the future likelihood of deterioration in nutritional status (poor, inadequate nutritional intake leading to weight loss) is needed. For example, a free living individual suffers a stroke and is admitted to hospital, unable to swallow and eat. Despite having a desirable BMI and no history of weight loss, they are at risk of malnutrition as they will be unable to eat for >5 days. During this timeframe, even an individual without disease or injury would lose 5–10% of body weight, feel unwell and lose muscle mass (Elia, 2003). Similarly, those who suffer severe injury are unconscious and have intestinal failure, and many others with severe, acute illness are at risk of malnutrition due to a prolonged inability to eat or drink. These individuals will usually require nutritional assessment by a dietitian or nutrition support team and the provision of artificial nutritional support.

Similar principles apply to screening for malnutrition in paediatrics, although there is more complexity as consideration of growth and development is required. Anthropometric measurements have been widely used to screen for malnutrition in children. These include weight for age, height for age, BMI for age, weight for height and

mid upper arm circumference (see Chapter 3.8.2). The new WHO charts for children (aged 0–4 years) are purported to reflect optimal growth in children of all ethnic groups because of the striking similarities in results obtained from the countries that contributed data (the USA, Norway, Oman, Brazil, India and Ghana) (Wright *et al.*, 2010). The charts are based on anthropometric measurements obtained from children who were breast-fed for about 6 months by relatively affluent, non-smoking mothers who experienced a healthy pregnancy. The charts, which have separate sections for preterm babies, infants aged 0–1 years and older children, have been widely adopted in the UK and other countries. Establishing the most appropriate cut-off points for unintentional weight change in children of different ages can be difficult because growth rates vary considerably with age. In contrast to adults, where weight maintenance is considered to be normal, failure to increase weight over even a short period of time, e.g. 1 month, in a rapidly growing child may represent substantial growth failure, and a 5% weight loss over the same period can be of serious concern. In clinical practice, rapid changes in weight, dietary intake and disease related factors might all need to be taken into account. A variety of screening tools have been developed for use in children (mostly in hospital settings), (e.g. Sermet-Gaudelus *et al.*, 2000; Gerasimidis *et al.*, 2010; Hulst *et al.*, 2010), although a universally accepted tool is lacking. Discrepancies between the currently available tools are expected because they incorporate different criteria to detect malnutrition (see Chapter 3.8.2).

Individuals with other nutritional concerns or problems may need to be referred to a dietitian for more detailed evaluation of the extent or risk of nutritional depletion (Chapter 2.2). Particular attention should be paid to the aspects shown in Table 6.2.2. The nature and extent of these problems will determine the way malnutrition is managed or averted. All individuals requiring detailed nutritional assessment and artificial nutritional support need to be referred to a dietitian or nutrition support team (see Chapter 6.3 and Chapter 6.4).

Setting up a screening programme

To facilitate a screening programme, which includes routine screening, monitoring, assessment and treatment plans, and may include referral to the dietitian, the following are suggested:

- Establish a policy locally that ensures that screening is undertaken and repeated as appropriate (and specifies areas, if any, that are exempt from routine screening).
- Agree on the screening tool to be used locally and the resources available for a screening programme across healthcare settings.
- Devise locally agreed care plans for monitoring and treating those identified by screening.
- Ensure equipment required for screening, e.g. weighing scales, stadiometers, tape measure and callipers, is available and regularly calibrated where appropriate.

Table 6.2.2 Aspects relating to malnutrition to be considered in nutrition assessment

Dietary aspects	Adequacy of current intake Recent changes in food intake Appetite Existence of factors likely to impair food intake
Clinical aspects	Presence of factors likely to increase nutrient requirements Presence of factors likely to increase nutrient losses Acute or chronic disease affecting the gastrointestinal tract Use of drugs and other treatments affecting food intake or nutrient utilisation
Physical aspects	Signs of muscle wasting, emaciation or oedema Presence of pressure ulcers (stages I–IV) or other wounds (see Chapter 7.17.5)
Anthropometric aspects	Degree and rapidity of any unintended weight loss BMI, growth (in infants and children) Evidence of muscle wasting, e.g. reduced mid arm muscle circumference or grip strength
Psychosocial aspects	Depression, anxiety or apathy Social isolation Poverty

BMI, body mass index.

- Establish the criteria for those requiring more detailed nutritional assessment and dietetic referral (this will vary locally depending on the resources available).
- Set up systems for the documentation of the results of screening, monitoring and treatment.
- Regularly audit the efficacy of the screening programme.

Malnutrition universal screening tool ('MUST')

Although there are several screening tools available for adults, the Malnutrition Universal Screening Tool ('MUST') is mentioned here as an example because it meets all the key characteristics for a screening tool outlined in Table 6.2.1. 'MUST' was developed by the Malnutrition Advisory Group, a multidisciplinary group of the BAPEN and is supported by the BDA, the Royal College of Nursing, the Registered Nursing Homes Association and the Royal College of Physicians (England). In Scotland, screening of hospital patients is a standard and 'MUST' is the tool suggested for use (NHS Quality Improvement Scotland, 2003). NICE (2006) also recommends the use of 'MUST'. The tool has been extensively peer reviewed by many national organisations and independent healthcare practitioners for use in clinical settings and for public health.

'MUST' (Figure 6.2.2) is an evidence based tool (Elia, 2003) that has been designed to help identify adults who are at risk of malnutrition, as well as those who are obese. It has not been designed to detect poor vitamin and mineral status. 'MUST' involves identification of chronic protein energy status (BMI), change in status (unintentional weight loss) and the presence of an acute disease resulting, or likely to result, in no dietary intake for >5 days. It has been developed for use in all adults, including the elderly, the sick and healthy, free living individuals and those in healthcare, i.e.:

- Hospital wards.
- Outpatient clinics.

- General practice.
- Community settings, e.g. patients receiving care at home and in nursing or other care homes.
- Public health.

'MUST' can be applied to all types of patient groups, is easy and rapid to use and can be used by the multidisciplinary team; it is reproducible, internally consistent and valid. It can be used in situations where weight or height cannot be measured, providing a range of alternatives, including reported or documented measurements, other surrogate measures, subjective criteria and clinical judgement. The tool categorises individuals into low, medium and high risk of malnutrition, and identifies the obese. 'MUST' provides guidelines for care plans, which should be modified to suit local policy and resources.

Practicalities

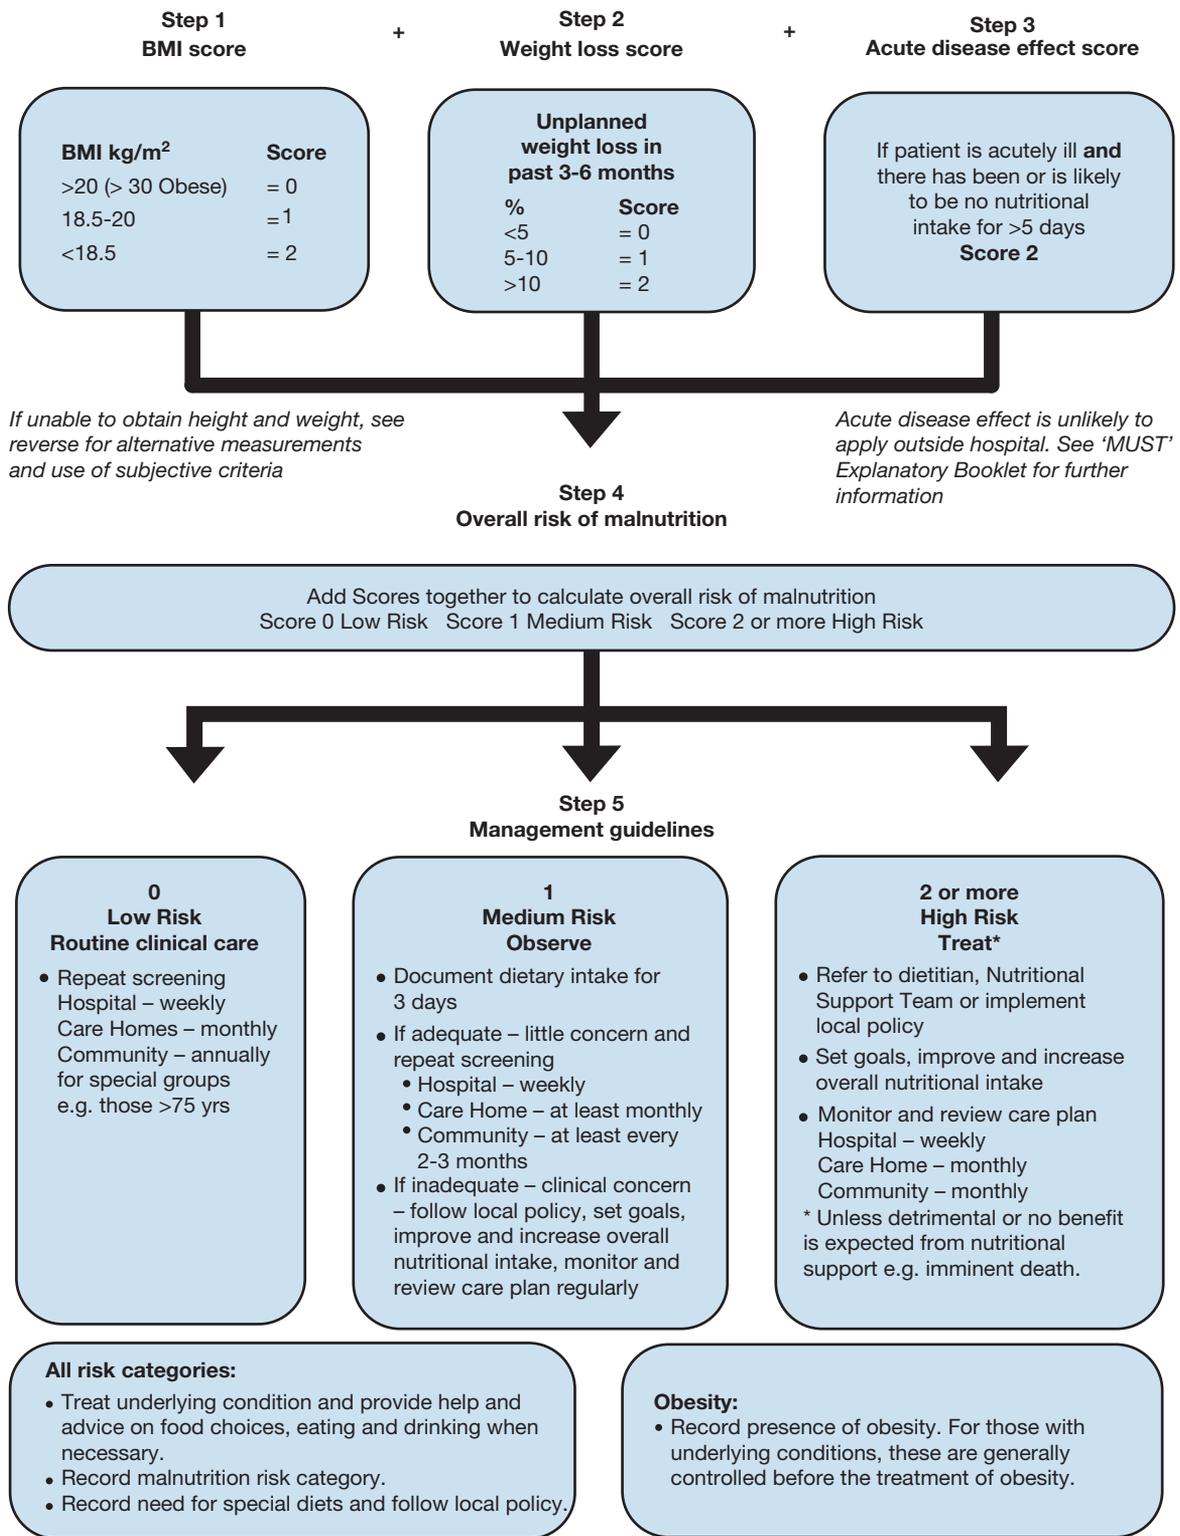

'MUST' is a five step screening tool to identify adults who are malnourished or at risk of malnutrition, and it includes simple management guidelines that can be used to develop a care plan. The five steps are shown in Figure 6.2.2 and are as follows:

Step 1

Measure height and weight to calculate BMI and a BMI score. If unable to measure weight and/or height, use alternative procedures:

- Recently documented or self reported height and weight (if reliable and realistic).
- If the individual is unable to report their height, a surrogate measure to estimate height, e.g. ulna length (see Appendix A7) or knee height.

if weight and height cannot be obtained, use mid upper arm circumference (MUAC) to estimate BMI. If MUAC is <23.5 cm, BMI is likely to be <20 kg/m². If MUAC is >32.0 cm, BMI is likely to be >30 kg/m².

Re-assess subjects identified at risk as they move through care settings

See The 'MUST' Explanatory Booklet for further details and The 'MUST' Report for supporting evidence.

Figure 6.2.2 The Malnutrition Universal Screening Tool ('MUST') [source: BAPEN (British Association for Parenteral and Enteral Nutrition) 2013. Reproduced with permission of the British Association for Parenteral and Enteral Nutrition (www.bapen.org.uk)]

Step 2

Note percentage unplanned weight loss and give a weight loss score. If recent weight loss cannot be calculated:

- Use self reported weight loss (if reliable and realistic).
- Changes in MUAC can also be used as an approximate indication of weight loss, e.g. a 10% reduction in MUAC suggests a weight loss of 10%.

Step 3

Establish if there is an acute disease effect and score (for patients who are acutely ill and for whom there has been or is likely to be no nutritional intake for >5 days – unlikely to apply outside of hospital).

Step 4

Add scores from Steps 1–3 to obtain the overall risk of malnutrition.

Step 5

Use management guidelines and local policy to develop appropriate care plans.

If BMI or weight loss (Steps 1 and 2) cannot be obtained, the following criteria can assist professional judgement of whether an individual is at risk of malnutrition (medium and high risk) or not (low risk):

- *BMI* – obtain a clinical impression of whether the individual is very thin (obvious wasting)/thin, or is of acceptable weight, overweight or obese.
- *Unplanned weight loss* – obtain a clinical impression of whether the individual has lost weight. Have clothes and/or jewellery become loose fitting? Is there a history of decreased food intake, reduced appetite or swallowing problems over the past 3–6 months? Is there evidence of underlying disease, psychosocial problems or physical disabilities that are likely to cause weight loss?

Care should be taken when interpreting BMI or percentage weight loss in individuals with fluid disturbances, plaster casts, amputations and critical illness, and in pregnant or lactating women (Elia, 2003). For more information on undertaking 'MUST', charts to calculate BMI and weight loss scores, electronic applications, use of alternative measures and screening individuals in whom extra care in interpretation is needed, see www.bapen.org.uk and Elia (2003).

Self screening with 'MUST'

A patient friendly version of 'MUST' has been developed for adults to screen themselves for malnutrition. Self screening in outpatients has been shown to be reproducible, have good concurrent validity with healthcare professional screening and to be easy for a wide variety of individuals to complete (Stratton *et al.*, 2011). Self screening with 'MUST' has also been shown to predict patient outcome (Cawood *et al.*, 2011). Further work is ongoing to understand how best to implement self screening within different care settings as part of the overall management of malnutrition.

Benefits of implementing a screening programme

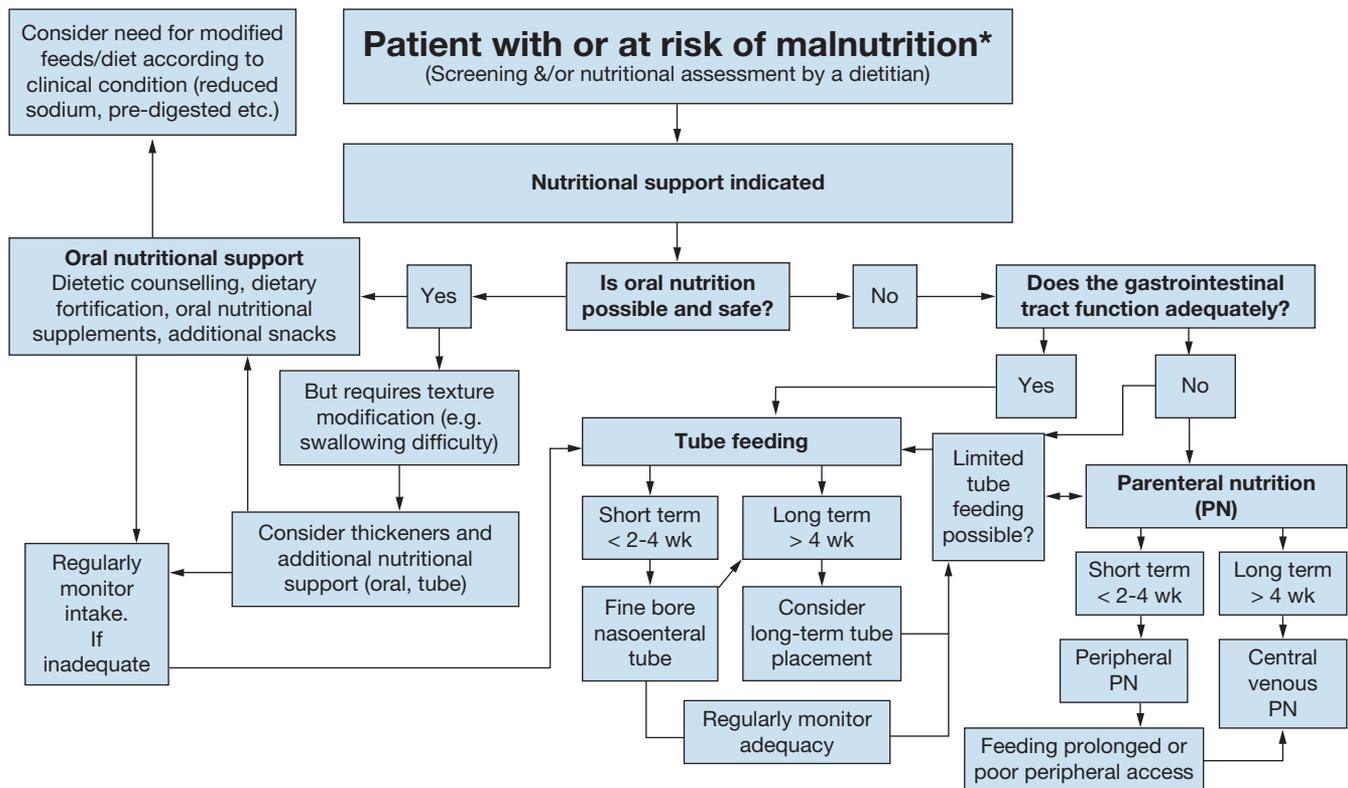

Considering the enormous costs of disease related malnutrition, a condition that is largely treatable, prompt identification with screening, followed by the most appropriate, effective, evidence based treatment is recommended (Elia, 2003; Elia *et al.*, 2005; NICE, 2006). NICE recently released cost saving guidance, within the top four of which was nutritional support (in the form of oral nutritional support, tube feeding and parenteral nutrition). Specifically, NICE suggested that improving systematic screening, assessment and treatment of malnourished patients (NICE CG32 guideline) could lead to an estimated cost saving of £28 472 per 100 000. NICE suggests that if this guidance [CG32] were fully implemented and resulted in better nourished patients, then this would lead to reduced complications such as secondary chest infections, pressure ulcers, wound abscesses and cardiac failure. Conservative estimates of reduced admissions and reduced length of stay for admitted patients, as well as reduced demand for GP and outpatient appointments, indicate that significant savings are possible (NICE, 2009).

A pragmatic programme of screening implementation (using 'MUST') in care homes in Peterborough Primary Care Trust highlighted some such benefits (Cawood *et al.*, 2009). A programme involving education and training on malnutrition, screening and treatment using the framework of 'MUST', locally agreed care plans and monitoring, improved the documentation of nutritional status, the proportion of residents screened and the use of appropriate care plans. After the implementation of the screening programme, reduction in the number and duration of hospital admissions was observed, associated with a significant cost saving. Similar improvements of nutritional care and outcome have been observed in other settings, e.g. hospital wards, where screening has been implemented (Rypkema *et al.*, 2003; Kruijenga *et al.*, 2005).

Treatment of malnutrition

Following the identification of patients at risk of malnutrition with screening, there is a need to implement evidence based treatments. Nutritional treatment of malnutrition (often termed nutritional support) can encompass modification of the diet (dietary fortification), dietetic counselling, use of oral nutritional supplements (single and multinutrient supplements), enteral tube feeding, parenteral nutrition and combinations of these therapies (Figure 6.2.3). The nutritional treatment of malnutrition should be undertaken alongside management of the underlying causes of malnutrition, e.g. disease, symptoms associated with disease and its treatment, and psychosocial problems.

The best strategy for treating malnutrition should be devised for the individual patient, whilst considering a number of factors. First, the type of nutritional treatment chosen will depend on whether the individual is safely and physically able to eat and drink. If they are, consideration is needed of the likely adequacy of intake, which may

* For all patients, treat underlying conditions, ensure help with feeding and help/advice on special diets as required (gluten free, low sodium, diabetic, texture modification)

Figure 6.2.3 Algorithm for the treatment of malnutrition

be severely compromised by anorexia, other side effects of disease and any modifications required, e.g. texture, composition (see later). In addition to the diet, oral nutritional supplements and feeding via tube may be required. If the individual is not safely able to eat and drink and oral intake is contraindicated, non-oral means of feeding are required (enteral tube feeding). If feeding into the gastrointestinal tract is contraindicated, then intravenous feeding (parenteral nutrition) is considered (see Chapter 6.3, Chapter 6.4 and Chapter 6.5). For some patients, combinations of treatments will be required.

Second, the method of nutritional support chosen may vary depending on whether an individual will require short or long term support, if they are acutely or chronically ill, in hospital or in the community. In the community, the ability of individuals and their carers/parents to manage nutritional support, e.g. for the very young and old, and their preferences regarding feeding methods need to be considered.

Nutritional treatments may need to be modified (in texture, composition, consistency and quantity) if there are symptoms, e.g. nausea, swallowing problems, severe anorexia, electrolyte disturbances, etc., associated with the disease or its treatment (see Chapter 7.3).

Deficiencies of micronutrients, e.g. vitamins, minerals and trace elements, frequently coexist (Finch *et al.*, 1998; Elia & Stratton, 2005). Nutritional treatment of malnutrition should consider the provision of micronutrients in

addition to energy and protein. All micronutrient deficiencies should be corrected.

Active nutritional treatment may not be considered appropriate in the terminally ill or dying patient. For more information on the ethics of withholding or withdrawing feeding, refer to Lennard-Jones (1998) and Chapter 7.16.

Once the extent of the shortfall between an individual's nutritional requirements and their current or anticipated dietary intake (which could be from food and drink, or may be nothing if intake is contraindicated) has been estimated, the types and quantities of nutritional support can be chosen. Most individuals with malnutrition, both in hospital and in the community, can be managed orally with diet and supplementation. The choice about which form of treatment to use will largely depend on the needs of the individual patient, although local policy and resources need also to be considered. These needs may change during the course of treatment, and so regular monitoring and changes to the types of nutritional support used are required.

Monitoring progress

With any nutritionally compromised individual, it is essential that their condition and the effectiveness of the nutritional support strategy are reviewed at regular intervals. Nutritional support should not be prescribed or

provided indefinitely, and goals for treatment should be set and monitored. As a result of monitoring, the type or level of nutritional support may need to be adjusted, dietary guidance amended or reinforced, and new goals set. Monitoring may include assessments of:

- Weight loss, stabilisation or gain (may repeat screening) and growth.
- Body composition, e.g. muscle mass, and function, e.g. strength, ability to walk and quality of life.
- Changes in nutritional (and fluid) intake – quantity, type, variety. Weight change can be a marker of the adequacy of nutritional intake.
- Effectiveness of remedial suggestions, e.g. change in drug therapy or texture of foods, for alleviating problems with food intake.
- Bowel function, fluid and electrolyte balance, swallowing function, skin condition or other symptoms indicative of malnutrition and micronutrient status.
- Compliance with nutritional support.

The frequency of monitoring will depend on the:

- Severity of malnutrition.
- Clinical condition of the individual (stable, deteriorating, improving) and their age.
- Type of nutritional support being used, e.g. patients receiving artificial nutrition may need daily monitoring.
- Setting of an individual (hospital, nursing home, home).
- Resources available for follow-up and monitoring.

6.3

Oral nutritional support

Abbie Cawood

Additional contributor: Rebecca Stratton

Key points

- The role of the dietitian is to provide evidence based advice on the most appropriate oral nutritional support for the patient, and tailor dietary advice to the patient's needs.
- Oral nutritional support aims to improve nutritional intake of macro- and micro-nutrients; approaches include fortified food, snacks, nourishing drinks and oral nutritional supplements.
- Dietary strategies improve intake, weight and body composition, but the effect on clinical outcomes and healthcare use has not been fully addressed.
- Oral nutritional supplements have consistently been shown to improve intake, weight, and body composition, with other clinical and economic benefits, e.g. improved function, reduced complications and readmissions to hospital.
- All patients receiving ONS should be monitored regularly against the goals of the intervention.

Oral nutritional support is a collective term used to describe the nutritional options available via the oral route, to manage people who have been identified as malnourished or at risk of malnutrition (see Chapter 6.2). Oral nutritional support should consider macronutrients (energy, carbohydrate protein, fat) and micronutrients (NICE, 2006a). Oral nutritional support options include any of the following methods to improve nutritional intake, as defined by NICE (2006a):

- Fortified food with protein, carbohydrate and/or fat plus vitamins and minerals.
- Snacks.
- Altered meal patterns, practical help with eating.
- Oral nutritional supplements (ONS).
- Provision of dietary advice – including on all of the above and tailoring counselling to the patient's clinical, nutritional, social and psychological needs.

Who should receive oral nutritional support?

Oral nutritional support should be considered for any patient with inadequate food and fluid intakes to meet requirements, unless they cannot swallow safely, have inadequate gastrointestinal function or if no benefit is anticipated, e.g. end of life care (NICE, 2006a) (see Chapter 7.16). For other nutritional support options, see Chapter 6.4 and Chapter 6.5. Healthcare professionals should consider oral nutritional support to improve

nutritional intake for people who can swallow safely and are malnourished or at risk of malnutrition (NICE, 2006a) (see Chapter 6.2). This is an A grade recommendation in the National Institute of Health and Care Excellence (NICE) CG32 Nutritional Support in Adults (NICE, 2006a), which is the highest classification of recommendation based on the highest level of evidence. More recently, the Care Quality Commission (2010), as part of the Health and Social Care Act, has highlighted that action should be taken where any risk of poor nutrition or dehydration is identified, and the Department of Health (2010) Essence of Care Framework similarly highlighted that nutritional support be considered for those people who are identified at risk of malnutrition or who are malnourished.

Role of the dietitian in oral nutritional support

The role of the dietitian is to provide evidence based advice on the most appropriate oral nutritional support option for the patient. The dietitian provides tailored dietary advice according to the patient's disease, symptoms and treatment regimen, whilst considering the patient's social, physical, psychological, clinical and nutritional needs. Advice may be given on dietary fortification (in addition to encouragement to eat), food choice and preparation, and how to overcome anorexia or specific difficulties with eating, perhaps due to side effects or symptoms associated with a disease or its treatment.

Dietary strategies encompass food fortification, extra snacks and nourishing drinks that can be used on their own or in combination with other nutritional support strategies such as ONS and artificial nutrition. Individual patient needs should always be taken into consideration; dietary strategies alone may be adequate for some patients, whereas for others ONS may be the most clinically effective option and should not be delayed.

The effectiveness of dietary advice will depend on many factors, including the method of counselling used, the content and form of the advice given and the patient themselves. The efficacy of dietary advice may be limited in the very sick those with poor consciousness or limited comprehension, and when there are possible time constraints in acute settings. In all settings, dietitians can provide invaluable encouragement and advice (both verbal and written) in the treatment of malnutrition and in the nutritional management of many complex disease states. However, dietetic services can sometimes be thinly spread, which means dietitians are unable to oversee the management of every individual in need of oral nutri-

tional support. Therefore, dietitians have an important role as educators of medical, social care and nursing staff, particularly in the primary and social care sectors, regarding measures that can be taken to improve oral intake. Dietitians can put in place evidence based pathways for oral nutritional support for other healthcare professionals to follow. These pathways should clearly indicate those patients who need more expert dietetic advice or input from a dietitian (BDA, 2009).

Oral nutritional support strategies to improve nutritional intake

There are several oral nutritional support strategies available (Figure 6.3.1).

Fortified food

The aim of food fortification should be to increase the nutrient density of the diet, not the actual amount of food consumed. In practice, food fortification, primarily with

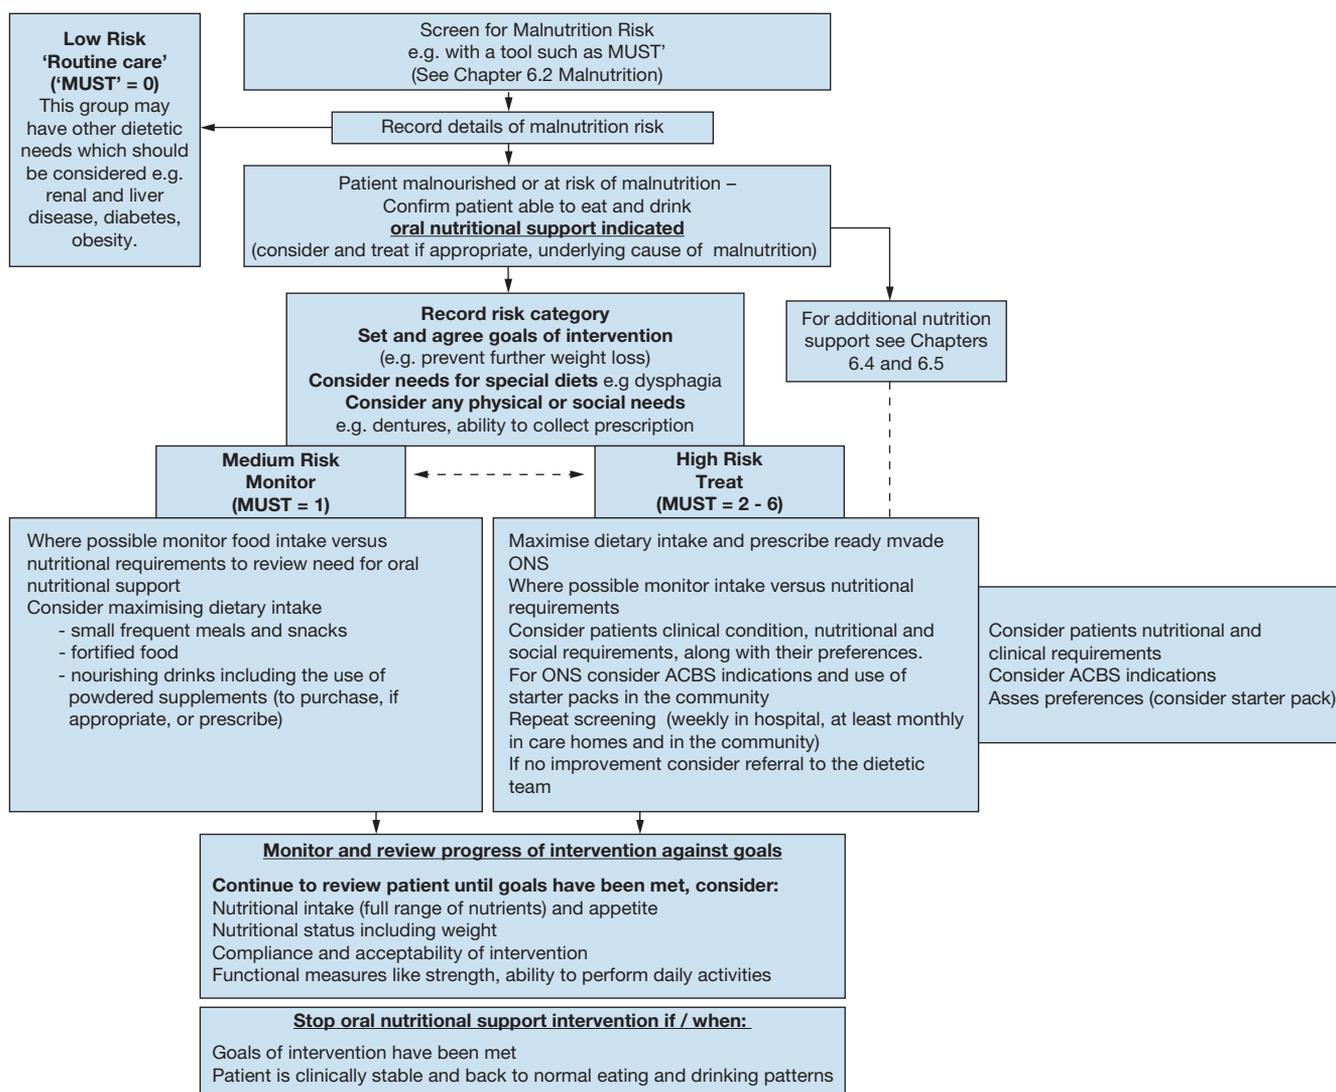

Figure 6.3.1 Algorithm for oral nutritional support in the management of malnutrition

the addition of energy rich foods, mostly results in increasing energy intakes. Food fortification practices include:

- Fortifying milk by adding four tablespoons of skimmed milk powder to 1 pint of milk. This fortified milk can then be used throughout the day in drinks, on cereals or to make custard, milk puddings, etc.
- Adding grated cheese to soup, savoury dishes and mashed potato.
- Adding double cream to soup, mashed potato, sauces or desserts.
- Adding butter to vegetables, pasta and scrambled egg, and during cooking.
- Adding jam, syrup or honey to breakfast cereals, milk puddings or other desserts.
- Adding sugar to foods or drinks.
- Avoidance of low fat, low sugar and diet foods and drinks.

However, NICE (2006) stated that care should be taken when using dietary fortification in isolation as this approach tends to supplement energy but not other nutrients. Ideally, patients should be encouraged to fortify their diet with foods that are energy and nutrient dense (and not just energy dense).

The use of food fortification may be an attractive option for the patient with anorexia, as the quantity and volume of food consumed does not increase and familiar food ingredients are used. However, dietary fortification may alter the sensory properties of foods, which may or may not be desirable for individual patients. Fortification using high fat foods (especially those with a high saturated fat content like butter, cream and hard cheese) may not be desirable for some patients, e.g. those with high cholesterol levels. There may also be practical difficulties on busy hospital wards or if patients are physically, e.g. disability or fatigue, or mentally unable or unwilling to modify their diet at home without help, so reducing compliance. For all patients the costs of this approach need to be considered, along with issues for purchase, preparation and storage. Thought should also be given to dietary recommendations that other family members may be following and that may conflict with the strategies for managing malnutrition, e.g. weight reducing advice for the management of obesity.

Snacks

Additional food items in the form of snacks can be used in the treatment of malnutrition with the aim of increasing nutritional intake. As with food fortification, consideration should be given to improving energy, protein and micronutrient intakes with the right type of snacks. Compliance with such a strategy may be good, as snacks are familiar and generally well liked. Examples can include cake or malt loaf, yoghurt, custard, toasted crumpets or teacakes with butter, cheese and crackers. It may also be helpful to recommend eating small amounts of food as snacks throughout the day. Snacks may not be effective in patients with anorexia who may be unable to eat more

food, or in patients with physical difficulties with eating (chewing, swallowing). For free living patients, there are also cost considerations and issues of purchase, preparation and storage.

Nourishing drinks

As far as possible, patients should be encouraged to consume drinks that are better sources of nourishment than just tea, coffee or water. Liquids tend to be less satiating than solid foods so can be a good option in patients with very poor appetites. Depending on individual patients and their clinical conditions, suitable suggestions include:

- Milky drinks, e.g. cocoa, drinking chocolate, malted milk drinks, milkshakes, coffee made with full fat milk or fortified milk.
- Soup (especially condensed or *cream of* varieties).
- Fruit juices (or drinks enriched with micronutrients).
- Powdered supplements that can be made up with water or milk, e.g. Complan and Build Up; these can be purchased in pharmacies or supermarkets, although some are available on prescription.

Oral nutritional supplements

Oral nutritional supplements, sometimes referred to as sip feeds, typically contain a mix of macronutrients (protein, carbohydrate and fat) and micronutrients (vitamins, minerals and trace elements). Like tube feeds, ONS are foods for special medical purposes (FSMPs) and as such are regulated under the Commission Directive 1999/21/EC (European Commission, 1999). This directive defines and categorises the products, gives compositional guidelines and sets out labelling requirements. These products are specially formulated, intended for the dietary management of patients and should be used under medical supervision. Oral nutritional supplements can be prescribed in the community (BMJ Group and Royal Pharmaceutical Society of Great Britain, 2011) for the management of disease related malnutrition. Prescribing details can be found in the *British National Formulary (BNF)* section 9.4.2 (www.bnf.org). Other prescribable indications include short bowel syndrome, intractable malabsorption, preoperative preparation of undernourished patients, inflammatory bowel disease, total gastrectomy, bowel fistulae and dysphagia. The cost of ONS is often a consideration. However, despite the enormous public expenditure on malnutrition (see Chapter 6.2), that on treatments including ONS is low (~1% of the overall prescribing budget) (Stratton & Elia, 2010). Nevertheless, ONS, like all forms of oral nutritional support, should be used appropriately.

Most ONS are liquid feeds, but puddings and powders are also available (see Appendix A10). There are a range of types (high protein, fibre containing), styles (juice, milk, yoghurt, savoury, prethickened), energy densities [1–2.4 kcal/mL (4.18–10.0 kJ/mL)] and flavours available to suit a wide range of patient needs. Most provide around 300 kcal (1.25 MJ), 12 g of protein and a full range of vita-

mins and minerals per serving. Oral nutritional supplement type, dose and duration are used according to clinical judgement. However, most prescriptions range from one to three supplements/day, with clinical benefits typically seen with >300 kcal/day (1.25 MJ/day). Supplementation periods range from weeks in elderly patients who are acutely ill or post surgical, to months for chronically ill patients in the community. Many ONS are nutritionally complete when consumed in a certain volume (range from two to seven servings/day depending on the type of supplement); this means the supplement contains sufficient micronutrients to meet the daily requirements.

Liquid ONS tend not to suppress intake from normal food and in some groups, may help to stimulate appetite (NICE, 2006a; Stratton & Elia, 2007). Oral nutritional supplements should not replace the provision of good food or nutritional care (help with feeding and meal provision) in institutions (hospital and care homes) or in a person's own home. Patients likely to benefit from ONS across both hospital and community settings include acutely ill hospitalised patients (especially the elderly, and hip fracture and gastrointestinal surgical patients), malnourished patients recently discharged from hospital, and those with chronic conditions such as cancer, chronic obstructive pulmonary disease (COPD), neurological conditions, renal and liver disease (NICE, 2006a, Stratton & Elia, 2007). Oral nutritional supplements are also used before and after surgery; perioperatively as part of the nationally recognised ERAS (Enhanced Recovery After Surgery) programme, to improve outcomes after surgery, reduce complications and promote early discharge of patients (Yuill *et al.*, 2005) (see Chapter 7.17.5). Suitability of ONS for specific ethnic groups, people with allergies, vegans and those with other special requirements should always be checked.

Patients find ONS an acceptable form of nutritional support (NICE, 2006a), and compliance with ready made ONS has been shown to be good (78% of prescribed volume consumed), although is variable across settings (Hubbard *et al.*, 2012). It should however be remembered that the efficacy of ONS may be limited if compliance is poor. Optimising compliance with ONS will prevent waste and maximise clinical benefits. Practical tips to aid compliance could include:

- Testing the patient's preferences by offering a variety to try. In the community you may want to try a prescribable starter pack of a range of types and flavours.
- Consider using varied flavours and a choice of different types and consistencies. NB: Some patients are also happy to use only one type and flavour.
- Encouraging ONS to be taken in small doses at intervals throughout the day or as a medication as opposed to a food.
- Using a more energy and nutrient dense ONS (Nieuwenhuizen *et al.*, 2010).
- Consider offering practical advice to patients, e.g. serving ONS chilled or warmed, or using ONS within everyday recipes.

- In some patient groups, e.g. the elderly or those with COPD, the combination of ONS with physical activity programmes (resistance training) may facilitate improvements in intake (Anker *et al.*, 2006; Volkert *et al.*, 2006).

Other strategies

Other strategies that may help to increase dietary intake in the treatment of malnutrition include dining room ambience, sensory enhancement of foods (flavour and odour enhancement), use of music and resistance training or exercise, particularly in the elderly living in long term care settings. In children, behavioural therapy may be useful.

Tailoring dietary advice for oral nutritional support (including practical considerations)

Many factors can impair nutritional intake, with the main factors being disease and its treatment (Stratton *et al.*, 2003). Whenever possible, the underlying cause impairing intake should be identified and addressed. In addition to disease, other factors are social, functional, physical, mechanical and environmental, and may differ depending on where the patient resides (own home, care home, hospital, living alone). Considerations when tailoring dietary advice for oral nutritional support may include:

- Effect of the disease or its management (treatment, surgery), e.g. side effects such as nausea and vomiting, taste changes, dry or painful mouth and the need for modified texture.
- Ability to shop (physical, financial) or collect prescriptions.
- Ability to prepare food or the need for assistance with eating.
- Dentition, loss of appetite, fatigue, early satiety, e.g. stomach resection, abdominal tumours or ascites often result in people feeling full when consuming a small quantity of food.

In addition to advising on the most suitable form of oral nutritional support, dietary advice can also be tailored and personalised for each individual patient. Some of the following practical suggestions may be of help.

Social and functional considerations

These will include factors such as the ability to shop, collect prescriptions or prepare food. Useful strategies include:

- Encourage patients to ask for and accept help from neighbours and friends.
- Encourage patients to make full use of local support services, e.g. social services, home help, meals on wheels and day care facilities, which can provide practical help in terms of shopping, cooking or meal provision and perhaps lessen the social isolation of those who live alone.

- If the patient has limited functional ability and/or no carer or home support, consider ready made meals, snacks, drinks and ONS as appropriate.
- Encourage the use of a pharmacy delivery service if ONS are prescribed.

Physical considerations

Physical considerations include poor appetite, tiredness and early satiety, which may be addressed by considering the following:

- Increase energy and nutrient density and/or decrease amount or volume of food or supplement.
- Offer a smaller portion size and avoid overwhelming platefuls of food (little and often).
- Advise light physical exercise which may improve appetite, e.g. a short walk.
- A small amount of alcohol before or with a meal (if allowed) can stimulate appetite.
- Try spreading meals and snacks throughout the day or try nourishing drinks.
- Consider eating when appetite is best.
- Make use of convenient, simple to prepare foods or meals.
- Choose foods that are particularly fancied, regardless of the time of day.
- Avoid strong cooking smells that could be off putting.
- Take time to eat and relax after meals or between courses.
- Avoid filling up with large volumes of liquid before, during or after meals.
- Some patients (particularly those with early satiety) may find fatty, greasy or rich foods exacerbate their feelings of fullness and would benefit from avoiding these.
- If appetite is poor, e.g. in acute illness or the postoperative period, patients may find nourishing drinks and ONS less satiating than additional food stuffs.

Specific symptoms related to illness or treatment side effects

Nausea and vomiting

Nausea and vomiting can occur for a number of reasons; they are a consequence of many disease states and a common side effect of treatments, e.g. chemotherapy. If nausea and vomiting are severe and food cannot be taken at all, hydration is the first priority. Antiemetics and additional nutritional support can be considered.

Useful strategies include:

- Make use of times when the feeling of nausea is less to eat or prepare foods. Eat anything that is fancied when it is wanted.
- Avoid cooking smells or letting smells linger in the house. Ask someone else to cook or make use of convenience foods, e.g. ready made foods, drinks, snacks and supplements, that create little smell.
- Avoid fatty and fried foods.
- Avoid drinks with meals and serve food relatively dry (unless on a modified consistency diet).
- Sipping drinks and ONS through a straw may be helpful (less likely to detect odour of fluid, resulting in lower taste sensitivity).
- Cold foods, e.g. cold meat, cheese and sandwiches, may be better tolerated than hot foods as they have less smell.
- Savoury foods and drinks may be more acceptable than sweet tasting items.
- Ginger flavoured drinks and foods may be helpful, e.g. ginger ale, ginger beer, ginger biscuits and ginger tea.
- Early morning nausea may be alleviated by dry carbohydrate based foods such as unbuttered toast, cream crackers and plain biscuits.
- Eating or drinking something as soon after vomiting as possible. Ice lollies/ice cubes can clear the mouth.
- Avoid lying down after eating.

Taste problems

Some people are born with taste disorders, but most develop after an illness or injury. People may experience a reduced ability to taste (hypogeusia), an inability to taste (agueusia) or a distorted or altered ability to taste (dysgeusia); many taste disorders are linked to smell disorders. Causes of taste problems include:

- Upper respiratory and middle ear infections.
- Radiation therapy for cancers of the head and neck.
- Medications, including some antibiotics and antihistamines.
- Head injury.
- Some ear, nose and throat surgeries.
- Poor oral hygiene and dental problems.

Useful strategies include:

- Prepare foods with a variety of colours and textures.
- Use aromatic herbs and spices to add more flavour.
- Avoid combination dishes such as casseroles that can hide individual flavours and dilute taste.
- Allow hot food to cool a little before being eaten; high temperatures can accentuate an unpleasant taste sensation.
- If meat tastes unpleasant, try alternatives such as fish, eggs, cheese and dairy products. Cold meats may taste better than hot meats. Marinades can also be helpful.
- Use sharp tasting foods and drinks that are refreshing, e.g. fresh fruit, boiled sweets, mints, lemonade, fruit juice and tonic water.
- If using ONS, consider more tart flavours or a different style, e.g. juice and yoghurt.
- Specific taste problems:
 - Bitterness – avoid foods sweetened with saccharine which can exacerbate this sensation.
 - Metallic – gargle with lemon juice in water before eating.
 - Sweetness – can be offset by adding lemon juice or diluting drinks with soda or mineral water. Adding spices such as ginger, nutmeg or cinnamon to des-

serts and puddings may reduce the sensation of sweetness.

- Saltiness – avoid salt and salty foods or accompaniments, e.g. salted nuts or crisps, packet soups, gravy, sauces, bacon, ham and other types of preserved or canned meat. Adding a pinch of sugar to some foods before serving may be useful.

Dry mouth (xerostomia)

This is a common consequence of damage to the salivary glands, usually as a result of surgery or radiotherapy to the head and neck region. The resulting lack, or even absence, of saliva makes mastication (moving food around the mouth) and swallowing difficult. Lack of saliva can predispose to tooth decay and hence good oral hygiene should be encouraged in all patients. Artificial saliva sprays, gels or salivary stimulant pastilles are prescribable for dry mouth associated with radiotherapy or other conditions.

Useful strategies include:

- Moisten meals with the use of gravy, sauces, butter, cream or evaporated milk.
- Avoid very dry hard foods, e.g. biscuits, crackers or toast.
- Sip drinks frequently, particularly with meals.
- Suck items that help stimulate saliva flow, e.g. boiled sweets, fruit pastilles, pineapple chunks, grapefruit segments and ice cubes (perhaps flavoured with lemon juice or made from fruit juice) – avoid in patients who have a sore mouth (see next section).
- Choose sharp tasting foods, e.g. lemon flavoured food, grapefruit, gooseberry or rhubarb – avoid for patients with sore mouths (see next section).

Sore or painful mouth

This may result from infection, inflammation or ulceration of the oral areas, making eating painful and difficult. Stomatitis (inflammation of the mucous lining of the mouth, e.g. cheeks, gums, tongue, roof or floor of mouth) and mucositis (painful inflammation and ulceration of the gastrointestinal tract, including the mouth) may follow radiotherapy in the head and neck area or as a side effect of some cytotoxic (chemotherapy) drugs. It is important to ensure that these patients are receiving effective pain control at appropriate times to avoid compromising food intake more than is necessary. Appropriate mouth care should be undertaken.

Useful strategies include:

- Eat soft, moist foods by adding sauces, gravy, custard, etc. Some foods may be easier to eat if they are mashed or liquidised.
- Avoid very dry or rough textured foods, e.g. toast, raw vegetables, cereal bars or crisps.
- Avoid foods and drinks at extremes of temperature that can exacerbate pain.
- Avoid salty or highly spiced foods, e.g. salted crackers, salted nuts, crisps, pepper, chilli, curry powder and soya sauce.

- Avoid tart beverages, e.g. pure orange juice and grapefruit juice.
- Use ice lollies, ice cubes or frozen ONS for a soothing effect.

Swallowing difficulties (dysphagia)

Swallowing difficulties may seriously compromise nutritional intake and it is important that dysphagia is properly assessed and managed. Improving nutritional intake in patients with dysphagia can be achieved with oral nutritional support. Dysphagia is a prescribable indication for ONS; a variety of thickeners and prethickened ONS are available. Tube feeds may be necessary if the swallowing difficulty severely limits oral intake (see Chapter 7.3).

Summary of the evidence for oral nutritional support strategies

Dietary fortification

Trials in institutions (including hospitals) have indicated the ability of dietary fortification, using food items, e.g. cream, and glucose polymers, to significantly increase energy intakes (e.g. Gall *et al.*, 1998; Odlund-Olin *et al.*, 2003; Barton *et al.*, 2000). These trials do not assess patient outcomes or the cost effectiveness of this approach. The addition of food snacks can increase energy (Turic *et al.*, 1999, Simmons *et al.*, 2010) and protein intakes (Smoliner *et al.*, 2008) in nursing home residents and children with cystic fibrosis (Hanning *et al.*, 1993). There is a scarcity of data on outcomes (functional or clinical) or the cost effectiveness of these strategies. One trial that assessed functional outcomes found no improvement (Smoliner *et al.*, 2008). For some patient groups, food snacks may be less effective at improving nutritional intakes than liquid ONS, (e.g. Turic *et al.*, 1999; Stratton *et al.*, 2006). Dietary advice (tailored advice from a dietitian) may lead to improvements in weight, body composition and quality of life in some patient groups (COPD, cancer) (Weekes *et al.*, 2009; Ravasco *et al.*, 2005, Baldwin & Weekes, 2011); however, the impact of dietary strategies on clinical outcome and healthcare costs in most patient groups and settings has not been fully addressed in well designed randomised controlled trials and is a research priority.

Oral nutritional supplements

There is a large evidence base for ONS in different patient groups, in both hospital and community settings. Current evidence from systematic reviews and meta analyses (Avenell & Handol, 2010; Baldwin & Weekes, 2011; Cawood *et al.*, 2012; Collins *et al.*, 2012; Elia *et al.*, 2005; 2006; Koretz *et al.*, 2007; Milne *et al.*, 2006; 2009; NICE, 2006a, Potter *et al.*, 1998; Stratton *et al.*, 2003; 2005; Stratton & Elia, 2007) suggest that total nutritional intake is significantly improved by ONS in most patient groups in hospital and community settings. In the community, improvements in intake are more likely in those who are

underweight [body mass index (BMI) <20 kg/m²]. Food intake tends not to be reduced.

Improvements in body weight and composition (and growth in children) occur with supplementation. Oral nutritional supplements tend to attenuate weight loss in the acutely ill hospitalised patient, and significantly increase weight gain in chronically ill community patients, with weight gain being more likely in those who are underweight (BMI <20 kg/m²) (and most likely to have recently lost weight). Improvements in weight in the acutely ill are related to improvements in physical function observed with consuming ONS.

Functional improvements, which vary according to the patient group, can occur with supplementation. These include increased muscle strength, quality of life, walking distances, activities of daily living, immunological benefits, reduced fatigue and improved wound healing. In those with chronic disease, improvements in function are more likely in those who are underweight (BMI <20 kg/m²) and gain weight with supplementation.

Systematic reviews and meta analyses indicate fewer complications such as infections and pressure ulcers with ONS. These can also prevent pressure ulcers in at risk groups. Reductions in mortality have been consistently shown with ONS versus routine care in acutely ill, hospitalised and elderly patients with a range of conditions.

Oral nutrient supplementation can reduce hospital length of stay and the number of admissions and readmissions to hospital, with potential cost savings. Cost analysis shows intervention with ONS can reduce healthcare costs and be cost effective in those at risk of malnutrition (NICE, 2006b; Cawood *et al.*, 2010). Cost effectiveness analyses take into account the benefits of the intervention balanced against the costs of the intervention, including the use of healthcare professional resources, e.g. for review and monitoring.

Monitoring of all oral nutritional support strategies

Specific targets or goals of oral nutritional support that are appropriate for the individual patient should be recorded. These could include:

- Measures of energy and nutritional intake.
- Appetite.
- Nutritional status.
- Anthropometric measurements (weight, BMI, mid arm muscle circumference, triceps skinfold thickness).
- Functional measures, e.g. strength using hand grip dynamometry.
- Clinically relevant outcomes (pressure ulcer size, infection, quality of life, daily activities).

Regular monitoring of patients receiving oral nutritional support should be undertaken to:

- Assess compliance and acceptability.
- Monitor effectiveness against goals.
- Encourage compliance where appropriate.

- Assess whether current strategy is still required or if other forms of nutritional support, e.g. tube feeding, are warranted.
- Monitor changes in clinical and nutritional status.

Patients receiving oral nutritional support in the community should be monitored every 3–6 months or more frequently if there is any change in clinical condition (NICE, 2006a). Patients receiving oral nutritional support in the hospital setting should be monitored daily initially, reducing to twice weekly when stable (NICE, 2006a).

Discontinuation strategy

Oral nutritional support should be stopped when the patient is established on adequate oral intake from normal food or fed via another route, e.g. enteral or parenteral nutrition.

6.4

Enteral nutrition

Sarah Armer and Rhys White

Key points

- The decision to start feeding should consider the ethics of individual patient circumstances, the requirement to do no harm and the potential improvement in quality of life.
- The route of feeding, feeding regimen, including timing and type of feed, should be decided on an individual basis, taking into account clinical indications, treatment plan and nutritional status.
- A specific monitoring plan should be put in place for each patient.
- Effective monitoring will help to ensure that nutritional support is provided safely, complications are detected early and treated effectively, and nutritional objectives are met and/or reviewed to ensure the effectiveness of the nutritional intervention.
- All patients going home on enteral feeding should have an individual discharge plan.

Enteral tube feeding has become a widely used method of ensuring adequate nutrition in patients who have a functioning gastrointestinal tract but are unable to maintain an adequate or safe oral intake. Enteral feeding in both the hospital and community setting is becoming increasingly common, as a range of access and delivery methods have been successfully established. Prior to initiating enteral tube feeding, broader matters such as ethics and consent should be considered (British Gastroenterology Association, 1999), in addition to practical issues such as discharge planning, training and support in the community. Dietitians are uniquely placed to provide guidance and recommendations regarding nutritional support and play a key role within the multidisciplinary team in the treatment of patients requiring enteral nutrition (American Dietetic Association, 1997).

Indications for enteral nutrition

Enteral feeding is indicated when oral intake is insufficient or unsafe (NICE, 2006) and is most commonly used in patients with the following features or disorders (NICE, 2006):

- Unconscious patients.
- Neuromuscular swallowing disorders, e.g. stroke.
- Physiological anorexia.
- Upper gastrointestinal obstruction, e.g. head and neck tumours.
- Gastrointestinal dysfunction or malabsorption, e.g. pancreatitis, gastrointestinal dysmotility.

- Increased nutritional requirements.
- Psychological problems.
- Specific treatment, e.g. Crohn's disease.

Several factors need to be considered when deciding to initiate enteral tube feeding. These include the risks and benefits of enteral tube placement, the most appropriate method of tube placement and selection of the most suitable feeding tube. The decision should be made following a multidisciplinary discussion and the views and wishes of the patient and/or their family or carers should be considered. A decision to enterally feed a patient may also be influenced by the future treatments required, e.g. surgery or radiotherapy. Nutritional support should be tailored to the clinical state and the perceived best outcome for the patient (see Chapter 2.2 and Chapter 6.1).

Ethics of withholding or withdrawing nutrition

Ethical issues should always be considered before initiating enteral tube feeding and consent must be obtained if a patient has the mental capacity. Often consent and ethics are considered before gastrostomy tube placement, but invariably nasogastric tubes are placed without similar discussions and considerations. Even when only short term nutritional support is thought to be necessary, informed consent should be obtained (if possible) and ethical issues should be considered (RCP, 2010). A multidisciplinary nutrition support team should be available to assess patients and is ideally placed to communicate with

patients, carers and the referring team regarding appropriate feeding options. A well functioning nutrition support team can reduce the number of inappropriate gastrostomy placements (Abuksis *et al.*, 2004; Sanders, 2002).

When making a decision regarding enteral feeding, it is essential to first establish what the healthcare professionals are trying to be achieved (RCP, 2010). Whilst offering adequate food and water to patients is a basic duty of care, artificial nutritional support (both enteral and parenteral) is regarded as a medical treatment. In cases where the benefits of nutritional support are uncertain, a time limited trial can be undertaken with clearly agreed objectives. Good open communication with family members and carers and the multidisciplinary team is essential at all times.

The issue of whether to continue feeding severely ill patients who have a poor but not hopeless prognosis is less clear. Where the patient themselves is unable to consent, the consultant (senior medical practitioner) responsible for care has a duty to act in their best interests. Any previous relevant opinions of the patient in the form of an advanced directive must be taken into account. Under the Mental Capacity Act (2005) the medical team is required to obtain the view of family and carers. The patient may have conferred a Lasting Power of Attorney (LPA), giving someone else the authority to make decisions about health and personal welfare. The Royal College of Physicians and the General Medical Council (RCP, 2010) have provided a comprehensive overview of the legal position in the UK regarding the withholding and withdrawing of life prolonging medical treatment, including nutritional support (see Chapter 1.1 and Chapter 7.16).

Routes of enteral feeding

Enteral feeding is preferable to parenteral feeding when the gut is accessible and has adequate, absorptive capacity, as it is more physiological and cheaper (Stroud *et al.*, 2003). Few patients cannot receive some form of enteral nutrition (EN) through the various routes available. The route of enteral feeding is decided on an individual basis according to the clinical indications, treatment plan and nutritional state of the individual patient. Enteral feed may be delivered:

- Directly into the stomach (gastric feeding) via orogastric, nasogastric, gastrostomy or oesophagostomy tube.
- After the stomach (post pyloric feeding) via nasoduodenal or nasojejunal tube, gastrojejunostomy or jejunostomy.

Gastric feeding routes

Nasogastric feeding

This is usually used for short term nutritional support (<4 weeks) or in the longer term when other options such as gastrostomy feeding are contraindicated or inappropriate (McAtear, 1999). All patients should have an individual

nutritional risk assessment carried out prior to passing a nasogastric tube [National Patients Safety Agency (NPSA), 2005)].

A fine bore nasogastric tube, usually made from polyvinyl chloride (PVC) or polyurethane, is inserted through the nose and into the stomach. Polyvinyl chloride tubes are suitable for short term feeding (<10 days) and are usually a rigid wide bore (10–18 FG; French gauge – the external circumference of the tube in millimetres; Ryles or Levin's tube). Complications associated with wide bore tubes are well known (nasal erosion, oesophageal ulceration) but, despite this, they should be considered an initial feeding route in patients at high risk of pulmonary aspiration (most commonly critically ill patients), with conversion to a fine bore tube once successful gastric emptying is established. More expensive and durable polyurethane tubes are more suitable for longer term use. In practice, both tubes become dislodged with similar frequency. Some polyurethane tubes can be repassed (marked single patient use); however, most can only be used once only (marked single use). Fine bore feeding tubes are usually of 6–9 FG. Tubes must be radio-opaque throughout their length and have visible markings to ensure accurate identification and documentation of position (NPSA, 2011).

Other methods of gastric placement are:

- Orogastric – used in head injury patients or those with facial trauma.
- Cervical pharyngostomy, oesphagostomy and stomagostric tubes – can be placed in head and neck cancer patients.

Confirmation of gastric tube placement

It is vital to establish that the tube tip is positioned in the stomach and not the lungs before each feeding episode, before flushing with water or medication and if there is any doubt about the position of the tube. Deaths resulting from the misplacement of nasogastric tubes have been reported NPSA (2005; 2011). The following methods for confirming nasogastric tube placement are recommended (NPSA, 2005):

- *Stomach aspirate pH* – aspirate stomach contents and check that the contents are acidic, pH ≤ 5.5 (≤ 5 on paper that does not have $\frac{1}{2}$ markings) using CE marked pH indicator strips or paper. If the patient is on continuous feeding or receiving drugs such as antacids (including proton pump inhibitors), the pH may be > 5.5 . If the problem is due to the presence of feed, the pH should be rechecked 1 hour after feeding. If due to antacids, the timing of this medication may need to be reviewed.
- *X ray confirmation* – this should only be carried out if there is any doubt about the position of the tube or difficulty in obtaining aspirate. An X ray only confirms the position of the nasogastric tube tip at the time of the X ray, and as the tip may become dislodged following the X ray, further confirmation of gastric pH will be required.

Alternative methods for placing and confirming position of nasogastric tubes

Electromagnetic sensing devices permit real time tracking of feeding tube position during placement, e.g. Cortrak Enteral Access System™ (Corpak Medsystems). This has been demonstrated to show good reliability in ascertaining gastric and post pyloric tube placement (Rao *et al.*, 2009; Taylor *et al.*, 2010). The guide wire containing the electromagnetic transmitter (stylet) can be reintroduced to confirm tube tip position even after initial placement.

Gastrostomy feeding

A gastrostomy is the creation of an artificial tract between the stomach and the abdominal surface, and is commonly used for long term enteral support. A gastrostomy can be placed endoscopically [percutaneous endoscopic gastrostomy (PEG)], surgically or radiologically [radiologically inserted gastrostomy (RIG)]. The terms PEG and RIG describe the actual procedure; however, they are also commonly used to describe the type of tube placed and are most often used to describe a gastrostomy tube with a fixed internal retention device (a disc like bumper). There is often confusion over the definition and terminology used to describe gastrostomy tubes. It is important that dietitians understand the differences between the types of tubes and the correct terminology to describe them.

In order to provide appropriate and safe management of a gastrostomy tube, information regarding when the tube was inserted and how it is retained can be important and help to reduce the risk of complications. Often, how the tube was inserted, e.g. endoscopically or radiologically, is of least importance to the dietitian. Prior to the placement of a gastrostomy tube, a full assessment of the patient, including clinical presentation/medical history, social circumstances and ability to manage the tube, should be carried out. Placement of a gastrostomy is a consented procedure; patients should have the full risks and benefits of placing the tube explained prior to consent being obtained (Westaby *et al.*, 2010). Tubes specifically designed for gastrostomy use should be used; Foley catheters are not designed, or licensed, as enteral feeding devices and may cause duodenal obstruction (Tibbitts & Sorrell, 1999).

Percutaneous endoscopic placement

A PEG is placed under direct visualisation using an endoscope (a camera which is passed down through the mouth and into the gastrointestinal tract). Transillumination of the abdominal wall with the endoscope identifies the appropriate site for insertion. An incision is made into the stomach and a loop of thread introduced. The thread is grasped internally and pulled up to the mouth using the endoscope. A gastrostomy tube is attached to the thread, pulled down through the oesophagus, into the stomach and out through the abdominal wall to lie with its internal bumper against the gastric mucosa. A flange and clamp are then fitted externally. Endoscopic tubes can also be placed using gastropexy and a direct puncture tube inser-

tion. The tube is inserted directly into the stomach through an external puncture and the stomach is sutured to the abdominal wall until the stoma tract matures. This negates the need for a tube to be pulled through the mouth and oesophagus if there is an obstruction. The advantages of using a PEG include:

- Performed as a day care procedure, reducing costs compared with other placement methods.
- High success rate (Wollman *et al.*, 1995).
- Quick – taking <20 minutes.
- General anaesthetic not required.
- Low incidence of complications.

The contraindications and other considerations with PEG placement include:

- Severe obesity.
- Portal hypertension or gastric varices.
- Coagulation abnormalities.
- Active gastric ulceration or malignancy.
- Total or partial gastrectomy.
- Ascites.
- Peritoneal dialysis.
- Oesophageal or gastric tumours that prevent passage of an endoscope.
- Oropharyngeal or oesophageal carcinoma – placement of a PEG tube using the standard pull through technique is associated with a small risk of tumour implantation at the skin site (Cappell, 2007). To reduce this risk, particularly in patients for whom cancer therapy is of curative intent, gastrostomy placement should be achieved by a direct gastric puncture technique (Foster *et al.*, 2007).
- Chronic progressive neurological and neuromuscular disorders, e.g. motor neurone disease. There may be an increased risk associated due to the use of sedation as patients generally have a degree of respiratory compromise. There is some limited evidence to suggest that radiologically placed tubes may confer a survival benefit in these patients because this method avoids the risk of sedation (Shaw *et al.*, 2006).

Removal and replacement of a percutaneous endoscopic gastrostomy tube

Tubes with compressible or deflatable internal bumpers are traction removable and therefore avoid the need for a further endoscopy. Non-traction removable tubes will require endoscopic removal or the tube can be cut and the internal bumper allowed to pass through the gastrointestinal tract naturally. This approach has been widely used and is considered a safe option (Merrick *et al.*, 2008). However, there is an associated, small but recognised risk of bowel obstruction (Coventry *et al.*, 1994) so a risk assessment should be carried out and the patient consented for the procedure.

There are two types of bedside replacement gastrostomy tubes:

- *A balloon retained gastrostomy device* – a balloon is inflated internally with sterile water or saline to hold the tip of the feeding tube against the gastric wall fol-

lowing percutaneous insertion. These gastrostomy tubes usually have a length of tube externally but low profile tubes, or 'buttons', are also available which are flush to the skin and therefore more discreet.

- A *flexible bumper retained gastrostomy device* – held in place by either a flexible internal cage like bumper or an internal bolster that is deployed by cutting an external suture.

Radiological placement

Radiologically inserted gastrostomies are becoming increasingly common. A naso- or oro-gastric tube is required to dilate the stomach with air and, under X ray guidance, gastropexy sutures are inserted to anchor the stomach to the anterior abdominal wall. A gastrostomy is inserted and its position confirmed in the stomach using X ray. Balloon gastrostomies or 'pig tail' tubes are most commonly used. Disc or bumper retained gastrostomies can also be placed radiologically using the pull through technique, where the tube is inserted via a guide wire into the mouth and pulled down through the oesophagus into the stomach and out through the abdominal wall. Tubes inserted using this technique are sometimes referred to as a PIG (per oral image guided gastrostomy) and have the advantage of not requiring gastropexy and allowing insertion of a lower maintenance tube, i.e. bumper/disc retained; however, they are technically more difficult to insert radiologically than endoscopically.

The advantages of RIG placement include:

- Very low risk of tumour seeding from head and neck tumours with direct puncture method as no endoscope required.
- Sedation not required.
- Clear picture of anatomy allowing tube placement in difficult patients where endoscopic placement may have been unsuccessful.

Surgical placement

Surgically inserted gastrostomies are becoming less common with the increasing use of PEGs and RIGs. Surgically placed gastrostomies require a mini laparotomy and general anaesthetic. When a gastrostomy is inserted surgically, it requires a purse string suture around the gastrostomy tube in the stomach wall to keep it in place.

Post insertion instructions

It is safe to commence feeding 4 hours after PEG insertion (NICE, 2006) although local policy may vary. There is no clear consensus on when it is safe to first use a newly inserted RIG for feeding, with some centres feeding after 4 hours and others waiting 24 hours. Like for any interventional procedure, there is potential for complications (including peritonitis, infection, bowel perforation, haemorrhage and aspiration pneumonia), but prompt recognition of these complications with early action reduces the risk of serious harm or death. The NPSA (2010) recommends that all NHS organisations with departments that insert gastrostomy tubes should ensure that:

- Local protocols specify the observations to be taken in the immediate recovery period.
- Medical notes are marked with a high visibility sticker warning of the possible complications that could occur and necessary action.
- Where patients are discharged within 72 hours, equivalent warnings should be communicated to the GP, community nurses, care home nurses, as well as to the patient and/or carers.

Post pyloric feeding routes

Nasoduodenal or nasojejunal feeding

A feeding route bypassing the stomach overcomes the problem of gastroparesis and subsequent aspiration risk. In patients with high gastric aspirates, the small bowel may be working normally. Tubes are most commonly placed endoscopically but can also be placed under X ray guidance or at the bedside. The risk of aspiration is reduced most significantly when the feeding tube is inserted beyond the ligament of Treitz, i.e. intrajejunal placement (Heyland *et al.*, 2001). These tubes often incorporate a lumen for gastric aspiration in these patients (Silk, 2011).

The techniques for bedside placement of nasojejunal tube using different patient positions and prokinetic agents have varying rates of success. Self advancing polyurethane tubes, e.g. Tiger 2™ Tube (Cook Medical, USA), have unique alternating cilia like flaps that allow peristalsis to pull the tube into the small bowel more effectively than standard bedside placements. Endoscopic placement is time consuming and costly, and may not be easily accessible to intensive care patients. A newer bedside technique using a transnasal endoscope for placing nasojejunal tubes has shown promising results, but requires further evaluation (O'Keefe *et al.*, 2003; Zick *et al.*, 2011). Several researchers suggest that at present the X ray guided technique of tube placement is the most successful (Thurley *et al.*, 2008). As with gastric placement, Cortrak® has also been demonstrated to be reliable in ascertaining postpyloric tube placement (Rao *et al.*, 2009). However, it is unknown whether tubes inserted by this method can be positioned beyond the ligament of Treitz.

Gastrojejunostomy

Post pyloric feeding access can be obtained in patients with established gastrostomy access by the insertion of an extension device that threads through the existing gastrostomy lumen into the jejunum. A dedicated gastrojejunostomy combination must be used, as most basic gastrostomies cannot house jejunal extensions. Direct puncture techniques can also be used to place gastrojejunal tubes under X ray guidance. These tubes have a gastric internal retention device that can be either a balloon or disc like bumper.

Jejunostomy

Jejunostomies create a stoma tract between the jejunum and the abdominal surface, and can be placed surgically

or radiologically. Jejunostomy insertion is indicated when major gastrointestinal or hepatobiliary surgery necessitates post pyloric feeding, e.g. oesophagogastrectomy, or if the clinical condition increases the likelihood of gastric stasis secondary to ileus or pseudo ileus, e.g. acute pancreatitis. A feeding jejunostomy should be considered if gastric feeding has failed, and may provide a useful route that avoids parenteral nutrition. There is no internal retention device to avoid bowel obstruction so these tubes must be secured externally. The tubes usually directly puncture the jejunum though some are designed to be tunnelled under the skin and are held in place using a felt like cuff under the skin surface.

A whole protein feed should be well tolerated in jejunostomy feeding. However, if there is pancreatic or biliary insufficiency, or if the jejunostomy has been sited in the lower small bowel, a peptide based or elemental feed may be indicated. Feed usually commences at a low volume (20–30 mL/hour) and is increased slowly until the optimum feeding rate is achieved. Continuous feeding over 24 hours may prevent tube blockage. Jejunostomy tubes often have a thin diameter, e.g. 9 FR, and therefore regular flushing of the tube with water may be necessary to prevent blockage.

Enteral feed delivery

A feeding regimen should be written for nursing staff, or for patients/carers to refer to if enteral feeding takes place in their own homes. The regimen should include the feed to be used, feeding times, drip rate and additional fluid requirements. Timings should include feed breaks to encompass the psychosocial aspects of feeding, together with the influence on other clinical interventions, e.g. physiotherapy and drug–nutrient interactions. Patients wishing to pump feed at home when they are alone or unsupervised should have the risks explained to them, and this should be documented in their care plan, as some local policies may advise against this.

It is usual to start feeding at no more than 50% feed requirements to ensure metabolic and gastrointestinal tolerance to the feed (NICE, 2006). Drip rates can then be increased at regular intervals until the maximum desired drip rate is achieved. Guidance for feeding patients at risk of refeeding syndrome is covered later.

Infusion rate

Bolus feeding

A bolus feed is the delivery of 100–300 mL of feed over a 10–30-minute period. Administration is usually by syringe, using the syringe barrel as a funnel to allow the feed to infuse using gravity or using the plunger. Bolus feeding can also be provided via a feeding pump, although it is important to check the maximum drip rate the feed pump can achieve before considering this option. The tube should be flushed before and after delivery of the feed bolus. Bolus feeding regimens are advantageous in that they can allow greater flexibility for the patient as they fit

with normal eating patterns and may be preferable for patients who do not wish to be restricted by feeding equipment for several hours a day. This type of feeding is also more physiologically normal and may improve blood glucose control in diabetic patients. Bolus feeding may also be the regimen of choice for patients who interfere with tubing and feeding equipment during continuous feeding. Patient positioning should also be considered; it is advisable for patients to remain in a semi upright position during and 1 hour post feeding (Metheny *et al.*, 2006).

Continuous feeding

Continuous feeding usually requires a pump and feeding set for administration and, if ready to hang formulae are not used, a feed reservoir. Continuous feeding usually refers to feeding at rates of 50–150 mL/hour over 16–20 hours, although 24-hour feeding is becoming more common in critical care for patients on sliding scale insulin. A rest period of at least 90 minutes is needed as it allows gastric pH to fall sufficiently to promote antibacterial conditions in the stomach (Bonten *et al.*, 1994). A longer planned rest period allows more flexibility, e.g. to catch up if feeding has been interrupted during the day, or to allow sufficient time for therapy. A rest period can provide an overnight break for those without urinary catheterisation and who may otherwise experience nocturia and interrupted sleep, or a rest period can be given during the day so the patient is unencumbered by enteral feeding equipment.

Continuous feeding is usually the feeding method of choice for patients who are fed via a post pyloric route; however, bolus feeding is not contraindicated for these patients and can be used if tolerated. In deciding whether continuous and/or bolus feeding would be most appropriate, patient preference, risk of tube dislodgement and mobility of the patient should be considered (NICE, 2006).

In patients at risk of pulmonary aspiration (particularly critically ill patients), regular aspiration of the nasogastric tube is routinely undertaken to assess adequacy of gastric emptying. However, recent studies do not support the conventional use of measuring gastric residual volumes (GRVs); instead, it is suggested to monitor trends to identify any gradual increase in residual volumes, and levels up to 500 mL in the absence of other signs of intolerance (McClave *et al.*, 2005) are acceptable. Poulard *et al.* (2010) found little benefit in stopping enteral feeding in patients who reached a subjectively selected GRV (see Chapter 7.17.1).

Enteral feed formulae

Enteral feeding formulae can be categorised into whole protein (polymeric) feeds, including disease specific feeds, and elemental or peptide feeds (see Table 6.4.1). A summary of enteral feeding products currently available in the UK can be found in Appendix A10.

Whole protein (polymeric) feeds

These require an intact gut for their digestion and absorption. The constituents of whole protein feeds are:

- **Protein** – the source is usually derived from milk or hydrolysed casein, although a soya protein formula is available for those with milk protein intolerance.
- **Carbohydrate** – is usually in the form of maltodextrin, glucose, sucrose or corn syrup solids.
- **Dietary fibre** – various feeds are available containing added soluble and insoluble fibre. Insoluble fibre has most effect on gut barrier function, while soluble fibre can increase short chain fatty acid production (Silk, 1993). Therefore, a mixed fibre source (as is found in most commercially available feeds) is advised. Elia *et al.* (2008) suggest that fibre supplemented enteral formulae have important physiological effects and clinical benefits, and may help to reduce the incidence of diarrhoea in hospital patients.
- **Fat** – the source is usually a vegetable oil derivative, although many feed companies are now reblending fats to alter the ratio of n-3 to n-6 polyunsaturated fatty acids (PUFAs) and increase the monounsaturated fat content. n-3 PUFAs may be provided by the use of canola or rapeseed oil, or by fish oils to provide direct sources of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Provision of n-3 PUFAs can down regulate the inflammatory response by reducing arachidonic acid (n-6 PUFA) metabolites, but the mechanism to convert n-3 PUFAs to the active EPA and DHA is impaired in the severely ill.

- **Vitamins, minerals and electrolytes** – in the UK, all enteral feeds provide 100% of the recommended nutrient intake (RNIO for micronutrients (excluding electrolytes) in a specified volume of feed (usually within 1–1.8L of standard enteral feed). Current levels of micronutrients must comply with the European Community (1999) Directive on Dietary Foods for Special Medical Purposes (1999/21/EC).

Types of whole protein feeds can be categorised as:

- **Standard adult formulae** – provide 1 kcal/mL (4.18 kJ/mL) and are suitable for the majority of patients; available with and without fibre.
- **High energy adult formulae** – provide 1.2–2.4 kcal/mL (5.02–10.03 kJ/mL) and are useful for patients on fluid restriction or with increased nutritional requirements, e.g. burns patients. Electrolyte and protein content of these feeds are variable. Fibre containing energy dense feeds are also available, but only up to energy densities of 2 kcal/mL.
- **Low energy formulae** – provide 1–1.2 kcal/mL (4.18–5.02 kJ/mL) and 1000 mL of these usually meets the nutritional needs of patients with low energy and/or fluid requirements, e.g. elderly bed bound patients.
- **Disease specific enteral formulae** – a variety of enteral feeds are provided for a variety of conditions. However, dietitians should consider the use of specific products within the context of the patient's clinical status, and not take the manufacturer's recommended client group as the sole indication for use. A brief overview of some disease specific feeds is given in the Table 6.4.1.

Table 6.4.1 Condition specific feeds

Type of feed	Comment
Renal feeds	Suitable for patients on electrolyte and fluid restrictions Similar or lower protein to energy ratio compared with standard feeds Energy dense versions for fluid restriction are available, with subtle modification of other nutrients, e.g. higher water soluble vitamin content to allow for intradialytic losses
Low sodium feeds	Standard feeds with a sodium content reduced to 10–15 mmol/L. Clinical hypernatraemia is often secondary to dehydration, so the use of a standard feed (providing 35–40 mmol of Na/L) provides less sodium than plasma levels Low sodium feeds may be beneficial for patients with ascitic liver disease
Respiratory feeds	Contain a higher percentage energy content from fat, which reduces the amount of carbon dioxide produced from feed metabolism – may be useful in patients with respiratory failure. However, evidence of the benefit of these feeds is limited and avoidance of overfeeding is as clinically significant as the choice of feed in respiratory failure (Malone, 1997)
Immune feeds	Contain variable amounts of specific amino acids or fats, together with altered levels of specific micronutrients that have an attributed immune benefit, e.g. glutamine, arginine, dietary nucleotides, fish oils, beta-carotene and fructo-oligosaccharides More expensive than standard feeds Evidence that they may benefit some postsurgical or septic patients (Galban <i>et al.</i> , 2000)
Elemental/peptide feeds	Provide nitrogen in the form of free amino acids or peptides Indicated in the presence of severe maldigestion or malabsorption The majority of patients can tolerate whole protein feeds even in the presence of some degree of gut malfunction With severe gut impairment, a predigested formula may be indicated. Appropriate use of these feeds may reduce the requirement for parenteral nutrition (Hamaoui <i>et al.</i> , 1990) No clinical benefit in using peptide feed rather than whole protein feed in patients with Crohn's disease (Zachos <i>et al.</i> , 2006)

Drug–nutrient interactions

Enteral feeding may interfere with the dosage, presentation and action of many drugs. Crushing oral preparations to pass down a tube may compromise their activity, cause tube occlusion and has the potential to cause fatality, particularly if slow release preparations are used. Some medications are not available in liquid form; therefore, alternative formulations or preparations should be sought to deliver the medication safely. Drugs should not be added to the feed infusion, as this may alter the stability of the medication and introduce a potential route of contamination into the enteral feed. Liaison with a pharmacist will ensure optimal enteral feed and drug administration. A practical guide to administration of drugs during enteral feeding can be found on the BAPEN website (www.BAPEN.org.uk).

Common drugs such as phenytoin, ciprofloxacin, tetracyclines, penicillin, sucralfate and theophylline all bind to the feed and/or have altered absorption kinetics, so should be administered during a rest period. Other drugs that can be affected by/affect enteral feeds are digoxin, carbamazepine and antacids. For further reading, see Bradnam & White (2011) and Chapter 5.3.

Enteral feeding monitoring

The main objectives of monitoring nutritional support are to ensure that it is provided safely, complications are detected early and treated effectively, and nutritional objectives are met and/or reviewed, thus ensuring the effectiveness of the nutritional intervention. Close liaison with colleagues, patients and carers is vital when initiating and monitoring enteral nutrition (NICE, 2006) and all have a role to play in the monitoring process. For example, in the community, the patient and/or carer may be responsible for most of the monitoring. In hospital, the dietitian will not be directly responsible for performing all of the monitoring required but it is their responsibility, in conjunction with the wider multidisciplinary team and the patient, to agree an appropriate monitoring plan and to review the results. Table 6.4.2 details the range of parameters that should be considered for monitoring of nutritional support (NICE, 2006).

The frequency and choice of monitoring is dependent on many variables, including the nature and severity of the underlying disease state, whether previous results were abnormal, the type of nutritional support used, the tolerance of nutritional support, the nutritional care setting and the expected duration of the nutritional support (NICE, 2006). Monitoring frequency may need to be more intense at the start of treatment than at a later stage, but should continue throughout the episode of care. Monitoring should be interpreted with caution, as a full understanding of the meaning of a result is needed before any changes are made. There is no one test that will measure nutritional status and therefore a combination of clinical and laboratory results should be used. Additional guidance on monitoring patients on EN can

be found in Micklewright & Todorovic (2011) and NICE (2006).

Complications of enteral feeding

Refeeding syndrome

Refeeding syndrome is defined as *'the metabolic and physiological consequences of the depletion, repletion, compartmental shifts and interrelationships of the following: phosphate, potassium, magnesium, glucose metabolism, vitamin deficiency and fluid restriction'* (Solomon & Kirby, 1990). Refeeding syndrome can occur when a patient is fed after a period of starvation. Refeeding triggers include:

- A switch from fat to carbohydrate metabolism.
- Increased insulin release.
- Increased uptake of glucose, phosphate, potassium, magnesium and water into the cells.
- Synthesis of lean tissue.

This can lead to fluid retention and low serum levels of potassium, magnesium and phosphate (Solomon & Kirby, 1990; Brooks & Melnik, 1995). NICE (2006) defines at risk patients as those who have had very little or no food intake for >5 days, especially if already undernourished [body mass index (BMI) <20 kg/m²; unintentional weight loss of >5% within the last 3–6 months]. High risk patients are those with any one of the following:

- BMI <16 kg/m².
- Unintentional weight loss of >15% within the last 3–6 months.
- Very little or no nutrition for >10 days.
- Low levels of potassium, magnesium or phosphate prior to feeding.

or those with two or more of the following:

- BMI <18.5 kg/m².
- Unintentional weight loss of >10% within the last 3–6 months.
- Very little or no nutrition for >5 days.
- A history of alcohol abuse or some drugs, including insulin, chemotherapy, antacids or diuretics.

It is important to note that patients with normal levels of potassium, magnesium and phosphate prior to the commencement of feed can still be at risk of refeeding syndrome (Marinella, 2004; NICE, 2006).

Refeeding syndrome can occur in patients fed orally, enterally or parenterally. Although possible, it is less likely to occur in those fed orally (Fung & Rimmer, 2005) since starvation is usually accompanied by a reduction in appetite. However, care should be taken when prescribing oral nutritional supplements. If a patient is considered at risk of refeeding syndrome, they should be fed using the following guidelines (NICE 2006):

- *At risk patients:*
 - Introduce feeding at a maximum 50% of total energy requirements for the first 2 days before increasing to full requirements if no biochemical abnormalities.

Table 6.4.2 Monitoring of patients receiving enteral nutrition

Monitoring parameter	Examples of monitoring	Rationale
Nutritional intake	Food charts, fluid charts, patient reporting	To compare prescribed with actual volume of feed delivered To facilitate transition between different forms of nutritional support To prevent over or under hydration To take account of energy and electrolyte content of IV/enteral fluid infusions
Anthropometry	Weight, body mass index, mid upper arm circumference, triceps skin fold thickness, hand grip dynamometry	To monitor changes in nutritional status To ensure nutritional objectives are met
Clinical chemistry	Biochemistry, haematology	Aids interpretation of hydration status, metabolic stress, specific nutrient deficiencies and metabolic abnormalities.
Clinical condition	Consciousness, swallow status, temperature	To observe changes which may affect nutritional requirements and most appropriate route of access To ensure that the type of nutritional support being provided remains appropriate To monitor for presence of infection
Medications prescribed	Drug charts	To be aware of side effects that may affect tolerance of enteral tube feeding, e.g. nausea/altered bowel habit To be aware of possible drug–nutrient interactions To be aware of drugs that may affect timing of enteral tube feeding To ensure that drugs are in appropriate form for administration via feeding tube To reduce incidence of tube blockage To be aware of the importance of adequate flushing of tubes before and after administration of medication To be aware of medication that may contribute to energy intake, e.g. propofol
Gastrointestinal tolerance	Stool charts, gastric residual volumes	To monitor bowel function and tolerance of feed To assess gastric emptying and therefore determine appropriateness of gastric feeding
Feeding device	Observe position and condition of feeding tube and site of tube insertion	To ensure appropriate position of feeding tube To monitor for signs of infection and or irritation To observe for leaks and cracks in tube
Nutritional goals and outcomes	Dependent on specific goals set but likely to include a measure of nutritional intake and nutritional status	To ensure progress towards agreed objectives of nutritional support To ensure clinical effectiveness of dietetic intervention To ensure objectives remain realistic and achievable To ensure that nutritional interventions remain appropriate to overall care of patients

- Meet full requirements for fluid, electrolytes, vitamins and minerals from day 1 of feeding.
- **High risk patients:**
 - Consider starting nutrition at a maximum 10 kcal/kg (41.8 kJ/mL) and increase slowly to meet full requirements by 4–7 days. Any increase in feed should be dependent on trends in biochemistry.
 - Potassium, magnesium and phosphate supplementation should be given from the outset (unless blood levels are already high).
 - Give thiamine and a multivitamin.
 - Restore circulatory volume and monitor fluid balance closely.
 - Monitor appropriate biochemistry, including, potassium, phosphate and magnesium.
 - In extreme cases (e.g. BMI <14 kg/m², very little or no nutrition for >15 days or prefeeding hypokalaemia, hypophosphataemia or hypomagnesaemia), consider starting feed at 5 kcal/kg (21 kJ/mL).

Close communication with the medical team is crucial to prevent and recognise refeeding syndrome. A clear plan should be formulated to ensure all team members are aware of their roles and responsibilities in close monitoring and treatment.

Aspiration

Aspiration risk for gastrostomy feeding is the same as for nasogastric feeding. Gastroparesis may be a result of disease management, starvation, or nerve damage, e.g. diabetic neuropathy (see Chapter 7.4.4). Regurgitation of stomach contents and aspiration into the lungs can cause asphyxia; even small amounts increase the risk of pneumonia. The aspiration risk has traditionally been assumed to increase with residual volumes of 200 mL or above (McClave *et al.*, 1992), but more recent evidence suggests this may be an over simplification, particularly in critically ill patients. This subject is discussed in more depth in

Chapter 7.17.1. Failure to establish gastric emptying is not a reason for immediate intravenous nutritional support. Reviewing current medications, e.g. opiates, and the commencement of prokinetic agents should establish adequate emptying (NICE, 2006). Post pyloric feeding should be considered before intravenous nutritional support.

If aspiration is a risk, the following actions may be taken:

- Elevate the head and upper body to at least 30 degrees and maintain this position during and 1 hour after feeding.
- Use prokinetic agents to stimulate gastric emptying, e.g. metaclopramide or erythromycin.
- Consider a post pyloric feeding route – jejunostomy feeding with aspiration of gastric contents by a nasogastric tube is the only safe way to prevent feed aspiration (Elpern, 1997).

Diarrhoea

Diarrhoea is common in enterally fed patients, but is rarely attributable to the enteral feed itself (Bowling & Silk, 1998), although may be attributed to the feeding mechanism. Prolonged use of antibiotics permits *Clostridium difficile* overgrowth and subsequent diarrhoea (Bliss *et al.*, 1998). Enteral administration of magnesium or electrolytes can cause osmotic diarrhoea. Osmolality of the feed is rarely a concern, and feed dilution exacerbates the problem. It is important to consider the following points for enterally fed patients who experience diarrhoea:

- Obtain a stool sample to exclude pathogenic bacteria overgrowth.
- Review the need for, and choice of, antibiotic.
- Ensure adequate hydration – additional fluid may be required as a result of increased losses.
- Reduction in infusion rate of post pyloric feed.
- Use of a peptide feed if malabsorption is suspected.
- Bile acid sequestrants, e.g. cholestyramine, if bile salt diarrhoea is suspected.
- Review medications (drugs in a sorbitol syrup containing ≥ 15 g of sorbitol can have a laxative effect).
- Consider a fibre feed – a significant reduction in diarrhoea has been shown when using a fibre supplemented enteral feed formula with hospital patients (Elia *et al.*, 2008).

Current evidence to support probiotic use in the management of diarrhoea in critically ill enterally fed patients remains unclear (Jack *et al.*, 2010).

Tube blockage

The small internal diameter (1–2 mm) of fine bore tubes increases the risk of occlusion. The most common cause is coagulation of feed by drug syrups and suspensions, combined with inadequate tube flushing, or obstruction by particles of crushed oral medications. Tube occlusion risk can be minimised by:

- Flushing the tube regularly with water.
- Flushing the tube with water following drug administration (and between drugs).
- Giving medicines individually rather than together, to avoid precipitate formation from drug interactions.
- Using drugs in syrup or dispersible form, rather than crushed tablets.

Consideration should be given to the type of water used to flush enteral feeding tubes. For gastric tubes the choice is tap, cooled boiled or sterile water, but a risk assessment should be undertaken as the choice may be different in the hospital and the patient's home. For post pyloric feeding, sterile water should always be used. Flushing with warm water should be tried initially to unblock a tube, along with manipulation of the tube. Soda water and sodium bicarbonate can also be effective in clearing a blockage. Cola, pineapple juice and lemonade should not be used as the acidity may contribute to occlusion by denaturing the proteins in the enteral feed (Beckwith *et al.*, 2004). Pancreatic enzymes are effective and can unblock a feeding tube blocked with feed within 10–20 minutes (Marcaud & Stegall, 1990); other agents are commercially available. Although gastrostomy tubes are larger in size (usually 12–20 FR), blockages can still occur and therefore measures to minimise risk should still be taken.

Microbiological contamination of feed

Enteral feeds provide an ideal growth medium for microbial contamination, but low counts of non-pathogenic bacteria are clinically unimportant. Bacterial growth within the feed can be minimised by practices such as:

- Using commercially prepackaged, sterile, ready to hang feeds (Beattie & Anderton 1999; 2001). Modular feeds carry a greater risk of microbiological contamination.
- Limiting the hanging time of the feed to a maximum of 24 hours or 4 hours for non-sterile feeds (Payne-James *et al.*, 1992).
- Replacement of reservoir and giving set daily.
- Filling the feeding reservoir with feed for up to 24 hours use rather than for only 4 hours (Patchell *et al.*, 1998).
- Hygienic handling of systems and adequate hand hygiene (Lee & Hodgkiss, 1999).
- Ensuring that systems marked as single use are used only once.
- Ensuring that reuseable equipment for single patient use, e.g. syringes, nasogastric tubes and guide wires, are cleaned, labelled and stored appropriately in accordance with local policy.

Additional care should be taken with jejunal feeds in patients with achlorhydria and immunosuppressed patients as their lack of gastric acidity and impaired immune function, respectively, may increase infection risk.

Accidental tube removal

Feeding tubes can become dislodged or removed accidentally. In the case of nasogastric tubes, the tube should

be removed completely and repassed (with the same tube and original guide wire if single patient use) and position reconfirmed. If a gastrostomy tube is accidentally removed, to prevent another procedure, it is important to replace the tube quickly to preserve the stoma tract that can start to heal immediately. Balloon replacement tubes can be used and a spare tube should be routinely supplied to the patient in case of such circumstances. Where there is no spare tube available, a Foley catheter can be used to maintain the tract until an appropriate feeding tube is reinserted, but Foley catheters must not be used for feeding. It is essential that patients and carers are aware of what to do should the feeding tube become dislodged or removed. Adequate training and education for patients, carers and professionals can ensure this is the case.

Stoma site problems

Stoma site complications include leakage, exit site infections, pneumo peritoneum, intra-abdominal abscesses, necrotising fasciitis, problems with self care secondary to poor placement and infection, which can be potentially fatal (Hanlon, 1998). Overgranulation is also a common stoma site problem, but can generally be reduced by correct positioning of the external fixation device (Best, 2004). Minor complications can usually be managed without admission to hospital; a swab of the site may be useful to rule out infection. Thorough hand hygiene and avoiding unnecessary dressings around the stoma site can help minimise the risk of such problems, as can good training for patients and carers regarding tube care. Regular assessment of the stoma site should be integrated into monitoring protocols. A specialist enteral nutrition nurse can also advise regarding treatment for minor gastrostomy related complications and often this service is supplied as part of the enteral nutrition contract for hospitals and community settings.

Buried bumper syndrome

Buried bumper syndrome (BBS) occurs when the gastric mucosa grows over the internal bumper of the gastrostomy tube, resulting in migration through, or into, the abdominal wall. This can result in mechanical feed delivery failure, pain, peritonitis and even death. BBS can be prevented by ensuring the tube is measured and fitted correctly, and regularly introduced into the stomach and rotated. Should BBS occur, the tube must be removed either endoscopically or surgically.

Enteral feeding equipment

The equipment required for enteral tube feeding depends on the method used. Bolus feeding requires only syringes for fluid and feed delivery. Continuous feeding requires a feeding pump, giving sets, syringes and possibly feeding reservoirs if a modular feed or extra water is being administered via the pump. Ambulatory feeding pumps are available for mobile patients. Syringes for enteral feeding

are either female luer lock or catheter tipped and must be NPSA compliant (NPSA, 2007). Syringes are available in several sizes from 5 to 60 mL. The largest size is used for water flushes and administration of feed; the smaller sizes can be used for more accurate measurement and administration of medicines.

Weaning from enteral nutrition

Although many patients will rely on enteral feeding as their sole source of nutrition for life, some may be able to resume oral feeding. Once oral feeding has been deemed safe to recommence, enteral feeding can be continued in conjunction with an oral diet during the transitional period. The feeding rate or bolus size can be increased to allow a longer rest period, a higher energy feed can be used or the feed can be reduced to provide <100% of estimated requirements. Bolus feeding or overnight feeding can be useful in ensuring nutritional requirements are met whilst encouraging daytime oral intake during the transitional period. Care should be taken to ensure that patients do not become dehydrated during the weaning process; additional fluid boluses can help to minimise this risk.

Home enteral feeding

Home enteral feeding (HEF) is an expanding area of nutritional support (BAPEN, 2010). The majority of home enterally fed patients have had a stroke, head and neck cancer or a degenerative disorder, e.g. Parkinson's disease or motor neurone disease (BAPEN, 2010). The dietitian's role in the discharge into the community of patients on nutritional support is integral to the process. Local policies and procedures should be in place for training, discharge planning and monitoring of the patient (Elia, 1994). Pressure on hospital beds often leads to early discharge of enterally fed patients, so it is important that patients are reviewed regularly during the initial period to ensure optimal nutritional support is achieved and that plans for discharge are made in an appropriate and timely manner.

Enteral feeds prescribed in the community are available on prescription, but the feeding equipment is financed by the primary care budget. Determination of who pays for the equipment must be confirmed before the patient is discharged. Most UK feed companies provide training, delivery of feeds and equipment, and servicing of pumps to community patients.

The discharge planning process should take into account the knowledge, skills and support network of those who will be responsible for caring for the tube and setting up the feed once the patient is home. The patient and family are usually encouraged to manage these themselves, with adequate training and support provided pre and post discharge. However, if this is not possible, the responsibility often falls to the district nursing teams. Many patients are discharged to nursing homes; therefore, adequate training for care staff should be arranged. The feeding regimen may be altered for discharge home

Table 6.4.3 Discharge planning for patients receiving enteral nutrition at home

Stage of discharge planning	Dietitian's role and responsibility
Decision made to insert feeding tube	Part of the multidisciplinary team; can offer advice regarding what enteral feeding will entail to ensure patients/carers make an informed decision
Decision made to discharge home	Inform home enteral feeding (HEF) dietitian Ensure patient and carers are appropriately trained to use feeding pump and care for the tube Provide written information and contact details Involve other services if required, e.g. district nurse Ensure feeding regimen is suitable for home
On discharge	Ensure patient is discharged with sufficient supply of feed and equipment until repeat prescription and delivery have been confirmed Order supplies, request feed prescription from GP and arrange ongoing delivery of feed and equipment Handover to HEF dietitian
Post discharge	Ensure patient and carers are familiar with management of tube and administration of feed Ensure patient has all necessary equipment Monitor nutritional support intervention and provide a follow-up plan

to best fit with usual home routines and patient/carer preferences. Table 6.4.3 outlines the steps in discharge planning and the dietitian's roles and responsibilities.

The role of the HEF dietitian not only involves the physical, biochemical and anthropometrical monitoring of patients, but also addressing the impact of this potentially life changing intervention. Quality of life issues should be examined, to ensure the feeding regimen is acceptable and suitable for the individual. Patient support groups, such as Patients on Intravenous and Nasogastric Therapy (PINNT), may be useful. Some HEF dietitians also take on the extended role of replacing balloon replacement gastrostomies and nasogastric tubes, and this can help prevent unnecessary hospital admissions, reduce the burden on the acute setting and enable feeding to continue with minimum disruption.

6.5

Parenteral nutrition

Melanie Baker and Lynn Harbottle

Key points

- Parenteral nutrition (PN) should only be used when the enteral route is inaccessible or inadequate.
- Parenteral nutrition can be given peripherally or centrally depending on the predicted length of duration, availability of venous access and nutritional requirements.
- Electrolytes and micronutrients must be added to all in one and individually compounded bags to meet individual nutritional requirements.
- Detailed prefeed assessment and close monitoring for metabolic, infectious or mechanical complications is vital.
- Nutrition teams have an important role in ensuring quality control around the initiation, supply, monitoring and auditing of PN practice and outcomes.

Parenteral nutrition (PN) refers to the delivery of all nutrients, electrolytes and fluid directly into a central or peripheral vein. It is a well established technique for providing nutritional support when the gastrointestinal tract is deemed unsafe or inaccessible, or if absorption via enteral or oral feeding is inadequate to meet full nutritional requirements (NICE, 2006). Previously, PN was considered to have greater complication rates than enteral tube feeding (ETF); however, many of these problems were due to inappropriate use, inadequate line care, unbalanced formulations and significant overfeeding (Koretz *et al.*, 2001). It has subsequently been shown to have similar complication rates to ETF (Woodcock *et al.*, 2001).

Until recently, recommendations regarding the use of PN restricted use to situations where it was to be the sole source of nutrition [and it was therefore referred to as total parenteral nutrition (TPN)]. It was considered that there was no clinical benefit in TPN unless it was to be required for >5 days. However, evidence now supports its wider use where oral feeding or ETF cannot be used and as a supplement to EN when the patient cannot tolerate sufficient EN to meet nutritional requirements (NICE, 2006). Even 1–2 days of PN can improve gastrointestinal tract function and clinical condition and should be considered for short term use in appropriate patients (Austin & Stroud, 2007).

Although PN is an essential and potentially life saving therapy, it is expensive and may be associated with a high risk of serious and, occasionally, life threatening compli-

cations, including line infections, micronutrient deficits, electrolyte disturbances, liver dysfunction, hyperglycaemia, hyperlipidaemia and cardiac failure (Austin & Stroud, 2007). It is therefore vital that it is administered appropriately and monitored closely. Where possible, patients should be informed of the potential risks and benefits before treatment, so they can make an informed decision about their treatment.

National and international organisations [British Association for Parenteral and Enteral Nutrition (BAPEN), National Institute for Health and Care Excellence, European Society for Parenteral and Enteral Nutrition, American Society for Parenteral and Enteral Nutrition] have repeatedly recommended the development of multidisciplinary nutrition support teams (NSTs), which include dietitians, to optimise management of patients on PN. Such teams have been shown to improve patient outcomes (Naylor *et al.*, 2004) and save costs (Kennedy & Nightingale, 2005). Despite this, only 60% of hospitals currently have nutrition teams (NCEPOD, 2010) and only 19% of adult PN cases received a good standard of practice, with a significant percentage of cases not receiving any dietetic input. The key recommendations of the NCEPOD study are:

- Multidisciplinary nutrition team management of all PN.
- Only use PN if enteral nutrition has been considered and ruled out.
- Avoid unnecessary delays in recognising the need for and instituting PN.

- Ensure robust assessment is in place and document the purpose and goal of PN.
- Ensure close clinical, biochemical and line monitoring, and clear documentation.
- Active assessment and regular review of intravenous fluid requirements and type.
- Increased education on PN.
- Local proformas and guidelines on use of PN.
- Central record of use and regular audit (a self assessment checklist and audit tool is available from NCEPOD, which can be used as a gap analysis tool in local risk assessments).
- Dedicated central venous catheter (CVC)/peripherally inserted central venous catheter (PICC) service.

Indications

Clinical indications

Parenteral nutrition should only be used when it is not possible to meet nutritional needs via the enteral route. An assessment of gastrointestinal tract function is required, ideally undertaken by a NST; however, some techniques historically used to assess gastrointestinal tract function, e.g. bowel sounds and gastric secretions, have been questioned (Schulman & Sawyer, 2005; Parrish & McClave, 2008). Recent advances have facilitated enteral nutrition use in clinical conditions for which PN was previously favoured, e.g. acute pancreatitis (McClave *et al.*, 2006) and post gastrointestinal surgery (Bozzetti *et al.*, 2001). Advances in ETF delivery techniques, particularly the use of postpyloric feeding tubes, have also reduced the need to give PN, e.g. after upper gastrointestinal tract surgery (Ryan *et al.*, 2006).

Intestinal failure is often short term and self limiting. Indications for short to medium term PN (<14–28 days), whether providing complete or supplementary nutrition, include:

- Major gastrointestinal surgery – where there is no suitable enteral feeding access or it is contraindicated, e.g. intra-abdominal sepsis or perforation.
- Enterocutaneous fistulae – where position, volume or sepsis prevent enteral feeding.
- Gastrointestinal obstruction – where enteral feeding access is not possible.
- Prolonged postoperative ileus.
- Severe malabsorption.
- Severe mucositis following chemotherapy.
- Multiorgan failure.

More prolonged intestinal failure may result in patients remaining PN dependent for months or even permanently [Home Parenteral Nutrition and Intestinal Failure Clinical Network (HIFNET), 2008; Smith *et al.*, 2011]. This may occur in:

- Short bowel syndrome – resulting from Crohn's disease, intestinal ischaemia, surgical complications.
- Motility disorders, e.g. scleroderma.
- Chronic malabsorption.
- Radiation enteritis.

Nutritional indications

Parenteral nutrition should be considered in those who are malnourished [body mass index (BMI) <18.5 kg/m², or >10% unintentional recent weight loss, or BMI <20 kg/m² and >5% unintentional recent weight loss) or are at risk of becoming so and who fit the clinical indications (NICE, 2006). It is *not* generally indicated in previously well nourished patients (BMI >20 kg/m² and <5% recent weight loss) exposed to short periods (up to 5 days) of inadequate nutrition.

Ethical considerations

Parenteral nutrition may not be appropriate if it prolongs an impaired quality of life unnecessarily, e.g. palliative treatment of advanced malignant disease, and the ethical aspects of feeding should be considered before treatment is commenced. If PN is initiated, its appropriateness and the patient's quality of life should be reviewed on a regular basis (Shang *et al.*, 2006).

Treatment goals

A thorough assessment should consider goals of therapy from the outset. The overall aim should be that gastrointestinal tract function will recover to facilitate adequate oral or ETF feeding, although a prolonged period of PN may be required for gastrointestinal tract adaptation or if further surgery is required to restore gut integrity and function. If gut function cannot be restored long term, home PN (HPN) may need to be considered.

Nutrition assessment

A detailed nutrition assessment should be undertaken before initiating PN (see Chapter 2.2). Clinical assessment should consider baseline biochemistry and hydration status, as well as noting concurrent fluids and electrolytes therapy. Table 6.5.1 shows the parameters to be considered.

Access routes

Parenteral nutrition may be administered via a central or peripheral vein, the choice being dictated by availability of venous access (Figure 6.5.1), nutritional requirements and anticipated PN duration. Catheter insertion should be performed according to strict aseptic criteria (Department of Health, 2001); many hospitals now have dedicated vascular access insertion services.

Peripheral catheters

Peripheral catheters are suitable for short term (<14 days) peripheral feeding (PPN) and avoid the clinical risks and costs of CVCs (Kohlhardt *et al.*, 1994). Patients must have good peripheral venous access. Thrombophlebitis is a common problem (Grant, 2001), which may be minimised by avoiding high osmolarity PN regimens. Only regimens clearly designated to be suitable for peripheral

Table 6.5.1 Baseline assessment of a patient requiring parenteral nutrition (PN)

Parameter	Rationale
Indication for PN	Degree of intestinal failure or reasons why enteral nutrition is not appropriate
Goal and expected duration of treatment	Goal of therapy should be determined from considering the overall clinical picture and patient prognosis
Access route for administration	To ensure PN is given via an appropriate route to reduce the risk of complications Central/peripheral route needs to be considered.
Previous nutritional intake	To predict the risk of refeeding syndrome when PN begins
Weight, anthropometry	Assessment of nutritional status and fluid balance
Body mass index (BMI)	Assess nutritional status
Percentage weight loss	Predict degree of malnutrition and refeeding risk
Clinical status – appearance, blood pressure, temperature	General condition, fluid balance, presence of infection, which will help inform on requirements
Drug therapy	Fluid/electrolyte content of concurrent treatment, e.g. IV fluids/medications Whether the patient is on appropriate medication to help promote gut function
Hydration status (fluid balance charts)	Fluid balance, additional gastrointestinal losses that need to be replaced, e.g. vomit, fistula, drain output
Urea and creatinine	Fluid balance, renal function
Electrolytes – sodium, potassium, calcium, phosphate, magnesium	Fluid balance, electrolyte status, refeeding risk
Full blood count and C-reactive protein	Presence of infection and anaemia
Albumin	Used in combination with inflammatory markers to assess catabolic state
Coagulation parameters	Before insertion of line

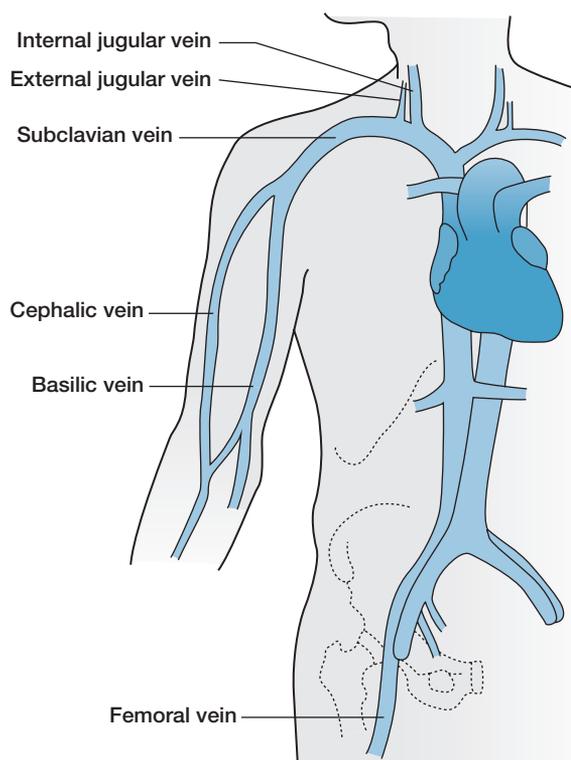

Figure 6.5.1 Access routes for parenteral nutrition [source: Dougherty L, Lamb J. (eds) 2008, figure 10.1, p. 263. Reproduced with permission of Blackwell Publishing]

use should be infused by this route. Therefore, PPN may not be suitable for patients with high requirements or who on a fluid restriction; there are limits to the additives possible (particularly potassium).

Central venous catheters

Indications for use of CVCs are (NICE, 2006):

- Patient expected to require PN for >14 days.
- Existing central access with a dedicated feeding lumen.
- No suitable veins for peripheral feeding.
- Specialised PN regimen requiring central access.

Central venous catheters should be inserted under ultrasound guidance (NICE, 2002) by experienced personnel and accessed via the subclavian (preferred), jugular or femoral veins. X ray confirmation of correct placement (catheter tip should lie at the junction of the superior vena cava and right atrium) and absence of insertion related complications should be ascertained before feeding is commenced. A variety of CVCs are available for feeding:

- Single or multi lumen.
- Tunnelled or non-tunnelled.
- Antibiotic impregnated.
- Implantable devices (ports).

Ideally, a dedicated single lumen line should be used. If a multi lumen line is used, all other lumens must be handled with the same meticulous attention to aseptic technique (Pittiruti *et al.*, 2009). Tunnelled lines can

reduce the risk of infection (Randolph *et al.*, 1998), allow easier dressing and reduce the risk of dislodgement (Garden & Sim, 1983). Tunnelled lines with a cuff when used long term tunnelling will allow fibrosis around the line, thus securing it.

Peripherally inserted central catheters

A PICC line is inserted into the antecubital fossa and the proximal end advanced into a central vein; therefore, it can be used to deliver hypertonic solutions. Where short to medium term PN is needed and a CVC is not otherwise required, a PICC can be used (Thompson, 1999). However, PICCs are associated with a higher incidence of placement complications, limit arm movements and can be prone to occlusion or kinking (Cowl *et al.*, 2000).

Administration

Parenteral nutrition bags should be removed from the refrigerator before administration and allowed to adjust to room temperature. Strict aseptic techniques should be applied when setting up and changing PN bags. Local policies for administration, line care and management of complications should be in place and strictly adhered to. All PN must be administered through volumetric pumps with occlusion and air in line alarms to prevent metabolic complications. Most PN is administered continuously over 24 hours, but cyclical infusion may have physiological and psychological advantages and can reduce thrombophlebitis in PPN patients (Kerin *et al.*, 1991). A continuous infusion reduces the number of times the line is accessed and is more appropriate for severely stressed patients, such as those in intensive care where fluid balance is more problematic.

Formulations

Various PN regimens are available and local decision making will depend on compounding facilities, contractual arrangements and the need for specialist feeds to suit specific patient populations, e.g. renal, neonatal. There are three main forms of PN regimen:

- *Ready made three chamber all in one (AIO) bags* where carbohydrate, amino acids and fat sources are in three separate chambers, with or without electrolytes, and are mixed just before use. These bags should never be used alone but should always be administered with a full complement of micronutrients (NICE, 2006).
- *Ready made non-chamber AIO bags* where macronutrients are ready mixed with electrolytes and micronutrients. These tend to have a shorter shelf life and need to be kept refrigerated.
- *Tailored bags* that are made specifically to an individual's requirements. This requires adequately resourced aseptic unit facilities and the number of hospitals equipped to supply such bags is limited.

The stability of PN bags is affected by volume, proportion of different constituents (particularly amino acids

and fat), amino acid formulation, glucose and electrolytes. Therefore, the final volume or amount of electrolytes provided may not exactly meet estimated requirements; all formulation requests should be discussed with the pharmacy. Bags should be made under full pharmacy aseptic conditions; it is not appropriate to make additions to bags at ward level.

Constituents

Macronutrients

Requirements for energy and protein should be estimated using standard methods (see Chapter 6.1). The relative contributions of fat, carbohydrate and protein (amino acids) energy provided in relation to requirements should be considered. In AIO regimens, the amount and percentage of macronutrients is fixed, but tailored regimens allow greater flexibility and may be indicated in specific circumstances, e.g. fat content may need to be reduced due to hepatobiliary complications in long term PN.

Protein

Protein is supplied as a balanced mixture of crystalline amino acids, or dipeptides for the less soluble heat labile amino acids, e.g. glutamine. The optimal PN amino acid profile remains unclear. Traditionally, amino acids were classified as indispensable (essential) or dispensable (non-essential); however, the latter are now considered essential under certain conditions (conditionally indispensable), e.g. glutamine (Laidlaw & Kopple, 1987; Grimble, 1993). Glutamine is not present in most commercially available amino acid solutions due to its instability. However, it can be added to a PN bag with other additions prior to administration.

Fat

Fat emulsions in PN commonly contain long chain triglycerides (LCTs) from soyabean or safflower oils and provide an energy dense yet isotonic alternative to dextrose. They also contain essential fatty acids to maintain cell membrane integrity and immune function. Fat emulsions are available in a range of concentrations (10–30%). Fat normally provides <50% of non-nitrogen energy needs in PN, and may help to minimise the risk of hyperglycaemia and abnormally high level of carbon dioxide in blood (hypercarbia). In some cases, e.g. PPN, fat may provide up to 60% of energy requirements. A minimum of 0.5 mg of LCT/kg/day is required to prevent essential fatty acid deficiency (Pullicino & Elia, 2001).

The high content of n-6 polyunsaturated fatty acids in lipid may have adverse effects on immunosuppression and pulmonary complications (Furukawa *et al.*, 1999; Askanazi *et al.*, 1981). Excessive amounts have been implicated in hypertriglyceridaemia and hepatobiliary disease. Increasingly, more diverse lipid preparations containing olive oil, medium chain triglyceride (MCT) and n-3 source appear to offer clinical benefits over soyabean oil based solutions. However, studies are based on small

numbers in diverse clinical situations and the optimal lipid profile for different conditions remains unclear.

Carbohydrate

Glucose is available in concentrations of 5–70%. In PPN formulations the concentration and percentage of glucose used is reduced as excess glucose can cause the following problems:

- Contribute to high blood glucose levels. This has been shown to adversely affect outcome in the critically ill (Van den Berghe *et al.*, 2001).
- Increase CO₂ production (Askanazi *et al.*, 1980), aggravating impaired respiratory function, which delays weaning of patients from artificial ventilation (Askanazi *et al.*, 1981).
- Cause hyperinsulinaemia, which prevents the mobilisation of endogenous lipid (Schloerb & Henning, 1998).
- Cause hepatic steatosis (Nightingale, 2003).

A maximum glucose oxidation rate of 4–7 mg/kg/min has been suggested (Burke *et al.*, 1979); by using both glucose and fat energy sources this should not be exceeded.

Electrolytes

The electrolyte content of PN should be based on individual patient requirements, including additional amounts to cover losses (fistula, vomit, refeeding risk) or reductions (renal impairment, fluid overload). Amounts provided should be modified according to serum levels and consideration of other sources, including intravenous fluids and medications. Trends in electrolytes should always be considered rather than one off levels (which may result from taking blood from the catheter during PN administration or haemolysed samples). Table 6.5.2 shows recommendations for making adjustments to standard PN regimens, where increases or reductions in electrolytes are required in response to monitoring (Austin & Stroud, 2007).

Micronutrients

The American Medical Association (1979) recommendations for the provision of micronutrients in PN are used.

However, requirements in the critically ill and metabolically stressed patients remain poorly elucidated. The acute phase response to stress will alter serum levels, thus making monitoring of micronutrient status difficult. Vitamin losses from PN solutions may occur due to oxidation, formation of insoluble precipitates and photodegradation; therefore PN bags should be covered to shield them from sunlight.

The needs of most patients can be met by water and fat soluble vitamins and trace element solutions devised for PN. However, these make little provision for the restoration of body stores. Severely depleted or metabolically stressed patients may therefore need additional amounts, e.g. iron resistant anaemia secondary to copper deficiency has been reported in a patient fed PN secondary to active Crohn's disease (Spiegel & Willenbacher, 1999). Other nutrient deficiencies may include selenium (resulting in cardiomyopathy) and chromium (impairs glucose tolerance factor, exacerbating hyperglycaemia).

Intravenous administration bypasses the normal process of selective absorption and liver processing, so markedly increasing the risk of over dosage of some micronutrients in PN feeding. The risk of toxicity from trace elements such as copper and manganese is high as both are excreted via the biliary tract and their excretion is compromised in the presence of cholestatic syndromes. Excess manganese has been shown to cause neurotoxicity in PN fed patients (Ejima *et al.*, 1992).

Monitoring

Monitoring of clinical state, nutritional requirements, anthropometry, biochemistry and line integrity is essential. The range and frequency of monitoring will depend on the nature and severity of illness, degree of malnutrition and length of time on PN (Austin & Stroud 2007; Micklewright & Todorovic 2005; NICE, 2006; Bowling, 2004).

Complications

Metabolic complications

These include deficiencies and excesses of fluid and nutrients, and occur if insufficient or excess nutrients are given

Table 6.5.2 Adjustments of parenteral nutrition formulations in response to monitoring

Electrolyte	Standard requirement* (not considering replacement of additional losses)	Usual level of adjustment**	Changes unlikely to be clinically significant**
Sodium	1.0–1.5 mmol/kg	Multiples of 40 mmol/day	±10–20 mmol
Potassium	1.0–1.5 mmol/kg	Multiples of 20 mmol/day	±5–10 mmol
Magnesium	0.1–0.2 mmol/kg	5–10 mmol/day	0–5 mmol
Calcium	0.1–0.15 mmol/kg	2.5–5 mmol/day	0–2.5 mmol
Phosphate	0.3–0.5 mmol/kg	10 mmol/day	0–5 mmol

*Elia (1990).

**Austin & Stroud (2007).

Table 6.5.3 Potential metabolic complications of parenteral nutrition

Complication	Possible causes	Prevention
Overhydration, oedema	Provision of excessive fluid, sodium	Detailed assessment of patient needs, including losses Consider other concurrent sources of fluid prior to deciding on PN volume
Hyperglycaemia	Excessive provision of glucose Severe metabolic stress Inappropriate insulin treatment	Max. GOR should not be exceeded Blood glucose should be regularly monitored Insulin should be provided if required
Electrolyte abnormalities, including refeeding syndrome	Inadequate or excessive provision in PN Overfeeding, especially initially	Detailed assessment and monitoring Proactive supplementation according to local guidelines, pharmacy, medical advice
Deranged liver function tests	Common in patients given PN but feed is rarely the main cause (Gabe & Culkin, 2010; Lee, 2006)	Rule out sepsis, medication, underlying liver disease Review total energy to avoid overfeeding from glucose and fat Consider type of fat given Consider cyclical feeding
Hypertriglyceridaemia	If metabolic capacity of the liver to clear fat is exceeded	Avoid excessive lipid provision Monitor and if found, reduce or occasionally remove lipid from PN for 2–3 days (Llop <i>et al.</i> , 2003)

GOR, glucose oxidation rate.

or an inappropriate combination of nutrients for that patient is infused, as shown in Table 6.5.3.

Mechanical complications

Insertion related complications include failure to insert, pneumothorax or haemothorax, thrombosis, cardiac arrhythmias and nerve injury (Bowling, 2004). Longer term complications include:

- Thrombus – the risk of thrombus local to the catheter tip increases the longer the catheter is *in situ*.
- Catheter occlusion due to kinking, luminal deposition of fibrin, lipid sludge or debris (after prolonged feeding). Treatment should be as per local protocols.
- Catheter fracture, which can be minimised by the use of connection devices or extension sets that reduce the need to clamp the catheter, and so prolong its life.
- Thrombophlebitis – if there is evidence of phlebitis in peripheral feeding, the feed should be stopped.
- Extravasation can occur when the line displaces from the vessel and nutrition solution infiltrates local subcutaneous tissue.

Infectious complications

Central venous catheter related infections can originate from endogenous skin flora (the most common source of infection), contamination of the catheter hub or contamination of the CVC from a distant site (Krzywda *et al.*, 1999); the exit site tunnel and/or catheter can be infected. Catheter related sepsis is a serious condition and should be treated immediately according to local policies. It can be prevented by:

- Strict adherence to aseptic techniques.
- Only experienced staff being permitted to handle PN lines.

- Using closed systems.
- Using dedicated lines where possible.

Weaning from parenteral nutrition

As intestinal failure resolves, oral or ETF nutrition should be reintroduced, accompanied by a reduction in PN infusion rate to avoid both fluid overload and overfeeding. If electrolyte balance is not an issue, this can be achieved by slowing the infusion rate (some hospitals allow each bag to be hung for >24 hours), which is simpler and cheaper than compounding a series of individually modified bags. Most patients can be transferred entirely onto ETF or oral feeding when intestinal tolerance of more than half of their total nutrient needs is established. Parenteral nutrition should not continue just to supplement a poor oral intake, without consideration of other enteral feeding routes. It should never be stopped abruptly as rebound hypoglycaemia can occur. Supplementary PN may not necessarily impair appetite (Reifen *et al.*, 1999), although many PN patients express early satiety. Weaning from PN is a key dietetic role, and many patients may be anxious about increasing oral intake, particularly after a prolonged period of gut rest.

Home parenteral nutrition

Home parenteral nutrition (HPN) is indicated for ongoing intestinal failure, either permanently or in situations where a prolonged period of PN is required before further surgery to restore gastrointestinal function. In the UK in 2009, Crohn's disease accounted for 22% of new HPN registrations, followed closely by surgical complications (20%) and vascular disease (19%). The use of HPN in cancer patients has been steadily increasing (Smith *et al.*, 2011). A specialist centre with the experience and the

required back up facilities should manage HPN patients; this is currently under review in England and Wales (HIFNET, 2008).

The role of a dietitian working with HPN patients encompasses the assessment and monitoring of nutritional status, the contribution of enteral intake to overall nutritional and fluid requirements (considering factors such as malabsorption), the design and monitoring of appropriate regimens, the development of evidence based nutrition education material for patients and carers and participation in audit and research, and should be a point of contact for patients, providing some psychological support (Baker & Farrer, 2006).

Protocols for the training of patients requiring HPN and their carers, and the recognition and management of problems are now readily available. The ability to counsel patients and relatives, and the availability of a 24-hour telephone contact number are important. There is a reported reduction in quality of life (social, psychological and physical parameters) in patients on HPN compared with those with an anatomical or functional short bowel not receiving HPN (Jeppesen *et al.*, 1999).

Regimens should be tailored to suit the patient's requirements and lifestyle, and can differ significantly from inpatient regimens in terms of their composition and frequency, as nutritional needs and activity levels may vary significantly. Infusions are commonly given over 10–12 hours nightly to allow for increased mobility during the day and to minimise hepatic abnormalities. In addition, to avoid hepatobiliary complications, total energy or lipid content may be reduced and some fat free bags may be indicated. Providing fluid balance is maintained, some patients may not require feeds every day.

6.6

Fluids and electrolytes

Alan Torrance

Key points

- Water has many functions in the body and is essential for survival.
- Regulation of body fluid is under tight homeostatic control; maintenance of fluid balance is an important aspect of dietetic management.
- Disorders of electrolyte and water balance are common in clinical practice, particularly as a result of surgery, trauma, disease and drug therapy.
- Appropriate treatment to correct any disorder needs to be based on a careful physical examination and interpretation of both serum and urine biochemistry.

Water is essential to life and, while humans can survive for several weeks without food, they cannot withstand water deprivation for more than a few days. Water has many vital functions in the body including:

- Solvent for ions and molecules.
- Transport medium, especially for the excretion of osmotically active solutes such as urea and salts.
- Lubricant.
- Temperature regulation.

In the UK there are no nationally agreed, evidence based recommendations for adequate intakes of water for the general public. However, in 2010 the European Food Safety Authority (EFSA, 2010) published dietary reference values for water (Table 6.6.1). The values given are for total water from fluid and water; EFSA estimated that in Europe 20% of water comes from food. It is important to note that this value is variable and can be as high as 40% in some countries, e.g. China where a lot of watery foods, e.g. soup, is consumed.

This chapter concentrates on clinical aspects of fluids and electrolytes. Resources on healthy hydration in the general public are given at the end of the chapter.

Body fluids

Water accounts for approximately 60% of the total body weight of a healthy adult, which is the equivalent of about 42L in a 70-kg man. Females generally have higher adipose tissue levels than men and the total body water

(TBW) content may be nearer 50% of total body weight. Lean body tissue has a high water content (75%) in contrast to 10–15% in adipose tissue. A newly born infant may have up to 80% of its body weight as water because of minimal fat stores. In contrast, the TBW in the elderly tends to be <50% of total body mass as muscle tissue (with its high water content) decreases with age.

Body fluid compartments

Total body water is generally considered to be divided into two main compartments; intracellular (inside the cells) and extracellular (outside the cells) fluid that are separated by the cell membrane. The extracellular compartment is further subdivided into the interstitial and intravascular (plasma) compartments. Of the 42L of fluid in a 70kg adult, 25L will be intracellular fluid (ICF) and 17L extracellular fluid (ECF), of which approximately 14L comprises interstitial fluid and 3L plasma fluid (Figure 6.6.1).

A number of factors influence and control the movement of fluid and other (substances) between the various compartments. The fluid volume contained in each compartment depends on the quantity of water present and its chemical composition. This is important for two reasons:

- Each fluid compartment contains one principal solute: potassium (intracellular), sodium (extracellular) and plasma proteins (intravascular). The volume of each compartment is controlled by osmotic pressure.

- Osmotic pressure depends on the total number of particles present in the fluid within a compartment.

Intravascular (plasma) compartment

The intravascular compartment contains proteins in plasma in a concentration of 70–80 g/L. Albumin is the largest single protein component with a concentration of 40–50 g/L, with the globulins (which are more diverse and larger) accounting for the remainder. Due to its higher concentration and low molecular weight, albumin produces almost 80% of plasma oncotic pressure. At the arterial end of the capillaries where hydrostatic pressure is greater than the plasma oncotic pressure, fluid moves from the plasma into the interstitial compartment. At the venous end of the capillaries where the plasma oncotic pressure exceeds the hydrostatic pressure, tissue fluid is drawn back into the intravascular space. The plasma protein concentration allows the heart to pump one-third of the extracellular fluid as the circulating plasma volume and also provides a continuous circulation of the total interstitial fluid, which bathes the cells of the body. Any small quantities of plasma protein and extra fluid that leak from the capillaries are taken up by the lymphatic system and returned to the systemic circulation.

Extracellular compartment

The size of the extracellular compartment (fluid) is determined by homeostatic control of both its tonicity and

volume. Changes in tonicity, detected by anterior hypothalamic osmoreceptors in the brain, affect both thirst and levels of arginine vasopressin [AVP; antidiuretic hormone (ADH)], which is produced in the hypothalamus and conveyed to the posterior pituitary where it is stored and subsequently released in response to a number of stimuli that alter both the intake and output of water.

Altered ECF volume can be detected by volume receptors in the circulation. These are present in the large veins and right atrium. The kidney also plays a significant role in controlling the ECF volume. Any reduction in systemic arterial pressure reduces renal blood flow and perfusion pressure. In this situation, renin secretion from the juxtaglomerular apparatus in the kidney is increased, resulting in angiotensin II production, which in turn stimulates aldosterone and AVP release. This causes sodium and water retention.

The sodium content (not concentration) in the ECF determines its volume. Homeostatic mechanisms are directed at controlling the retention or excretion of sodium. If a sodium load is added to the ECF, tonicity will increase, thirst will be stimulated and water retention via the kidneys will occur. This in turn will result in an increase in the ECF volume that will stimulate sodium and water loss, and the ECF volume will return to normal.

Intercellular compartment

The ICF has a volume of 25 L; it contains twice the number of osmotic particles as the ECF and therefore is twice the volume. The cell membrane is freely permeable to water and large macromolecules, but essentially impermeable to electrolytes, although there is movement to a limited degree of sodium and potassium against a concentration and electrical gradient to allow the export of water out of the cell in order to maintain cell stability. The ICF volume is sensitive to changes in the sodium concentration of the ECF. A high ECF (or serum) sodium concentration will result in water moving out of cells by osmosis. The reverse occurs with a low ECF sodium concentration.

Water homeostasis (balance) depends on the control of water intake and output. Water intake is usually dependent on the thirst mechanism that is stimulated by an increased serum osmolality (usually due to hypernatraemia or more rarely hyperglycaemia) or suppressed by a reduction in serum osmolality (normally due to hyponatraemia). Water output depends on water excretion by the kidneys and is influenced by three main factors: urinary dilution and concentration, sodium status and the concentration of circulating AVP.

Table 6.6.1 Reference values for adequate intake of water (EFSA, 2010)

	Age	Water adequate intake (mL/day)
Infants	0–6 months	680
	6–12 months	800–1000
Children	1–2 years	1100–1200
	2–3 years	1100–1200
	4–8 years	1600
	9–13 years	
	Boys	2100
	Girls	1900
	>14 years	As adults
Adults (including elderly)	Men	2500
	Women	2000
Pregnant women		+300
Lactating women		+600–700

28 kg Proteins, Lipids, Carbohydrate & Minerals	25L Intracellular Fluid	14L Interstitial Fluid	3L Plasma
---	----------------------------	---------------------------	--------------

Figure 6.6.1 Body composition and fluid compartments

Sodium homeostasis depends on renal excretion. The average dietary sodium content is in the region of 155 mmol/day. Of this around 2.5 mmol are excreted in sweat and faeces, and 150 mmol via the kidneys. Providing there are no significant extra renal losses, e.g. diarrhoea and vomiting, urinary sodium levels usually reflect dietary sodium intake.

Disorders of sodium and water balance

Disorders of sodium (and other electrolytes) and water balance are common in clinical practice, particularly as a result of surgery, trauma, disease and drug therapy. Appropriate treatment to correct any disorder needs to be based on a careful physical examination and interpretation of both serum and urine biochemistry. Any disorders of sodium and water balance will be reflected in the serum sodium concentration.

Sodium deficit

Sodium cannot be lost from the body without water. A sodium deficit may occur with diarrhoea, diuretic therapy, Addison's disease, diabetic ketoacidosis, ascites and chronic kidney disease. The result is a decrease in the ECF volume with associated hypertension and tachycardia. If the sodium deficit is severe, there is a risk of circulatory failure and renal failure, although ICF levels are unaffected. In the case of a sodium deficit, it is the total amount of ECF sodium that is important. There may be little change in the serum sodium concentration as water loss may increase as a compensatory effect. Sodium deficiency is normally treated with 0.9% sodium chloride.

Sodium excess

This can be caused as a result of a reduced sodium excretion, e.g. kidney usage, primary or secondary aldosteronism; or commonly in the clinical setting, by the administration of 8.4% sodium bicarbonate to correct a metabolic acidosis; or large volumes of 0.9% saline where there are hypotonic losses such as in diabetes mellitus. Where there is sodium retention there is expansion of the ECF volume; there may also be oedema and possibly hypertension. Increased serum sodium may stimulate thirst.

Water deficit

Water deficit usually results from an inadequate intake, often due to the inability to drink or inadequate intravenous fluid or excessive loss. Thirst and oliguria with highly concentrated urine will normally be present. There is less effect on the ECF volume than from the loss of a similar volume of isotonic fluid. Hyponatraemia is usually present.

Water excess

This is usually caused by either impaired water excretion, e.g. inappropriate (increased AVP secretion or renal

failure) or excessive water intake usually in association with impaired excretion. If severe, cerebral overhydration and oedema can occur. Hyponatraemia is usually present.

Hyponatraemia

Normal serum sodium is <135 mmol/L; as mentioned, hyponatraemia is usually a result of excess water. It can also occur due to a reduction in the ECF volume with a corresponding loss of total body sodium, although this is uncommon. The main causes of hyponatraemia are shown in Table 6.6.2.

Diagnosis

Diagnosis is based on the following signs:

- *Low serum osmolality* – if a measurement is not available, serum osmolality can be estimated as $2 \times [\text{Na} + \text{K}] + \text{urea} + \text{glucose}$ (mmol/L)
- *ECF volume depletion* – weight loss, no oedema and loss of skin elasticity will be present. This is likely to be associated with a loss of total body sodium that will require replacing.
- *Symptoms* – nausea, headache, confusion. Treatment needs to be rapid, usually by administration of small volumes of hypertonic saline, e.g. 100 mL of 1.8% saline with repeated estimations of serum sodium (Piper *et al.*, 2012).

Hyponatraemia can occur with an increased, normal or decreased ECF volume. In cases of an increased ECF, oedema will invariably be present. Cardiac failure, liver cirrhosis or nephritic syndrome renal failure are frequently causative factors.

Where the ECF volume is normal, hypothyroidism, glucocorticoid deficiency (secondary adrenal insufficiency impairs water excretion by increasing AVP release) and stress, pain or drugs (via stimulation of AVP release) are the usual causes. Very occasionally, syndrome of inappropriate ADH secretion (SIADH) may be the cause. The usual cause of both an increased and normal ECF volume is water excess. Treatment will depend on the primary cause, the degree of hyponatraemia present and the severity of symptoms. Specific causes should be treated where possible, e.g. replacement of thyroid or adrenocortical hormones, diuretics for oedema, removal of pain, stress and drugs affecting AVP, etc.

Management

Water restriction is the normal treatment in normal or increased ECF volume causes of hyponatraemia. Water restriction alone, however, will not on its own result in a satisfactory increase in serum sodium and the use of hypertonic saline (as outlined earlier) may be necessary. To be effective, water must be restricted to less than the sum of urine output plus an estimate of insensible losses.

Hyponatraemia and a decreased ECF volume is usually a result of gastrointestinal and third space (non-renal, non gastrointestinal) losses or renal losses of sodium. This is caused by sodium depletion and the standard treatment is to administer 0.9% saline at rates that will depend

Table 6.6.2 Main causes of hyponatraemia and hypernatraemia

	Hyponatraemia	Hypernatraemia
Diseases	Severe congestive cardiac failure Liver failure Nephrotic syndrome Acute or chronic kidney disease	
Extrarenal losses	Water losses – vomiting, diarrhoea, pancreatitis, burns	Water losses – respiratory, fever, exercise, insensible losses Sodium losses – diarrhoea, heavy sweating
Renal losses	Water losses – diuretics, salt losing nephritis (e.g. renal tubular acidosis), metabolic alkalosis, ketonuria (e.g. diabetes), alcohol, starvation or osmotic diuresis (e.g. glucose, urea)	Water losses – central or nephrogenic diabetes insipidus Sodium losses – salt losing nephritis, osmotic diuretics
Endocrine	Addison's disease, hypothyroidism, syndrome of inappropriate AVP (ADH) secretion (SIADH)	Primary hyperaldosteronism (Conn's syndrome), Cushing's disease
Others	Pseudohyponatraemia – hyperlipidaemia, myeloma Osmolal shift of sodium, e.g. due to hyperglycaemia	Administration of excess sodium – 8.4% NaHCO ₃ infusion, salt tablets

AVP, arginine vasopressin; ADH, antidiuretic hormone; SIADH, syndrome of inappropriate ADH secretion.

on whether a patient is asymptomatic or symptomatic. If it is considered necessary to infuse fluids rapidly to replenish a low ECF volume, isotonic fluids must be used to avoid sudden dangerous changes in serum sodium concentrations, which increase the risk of cerebral oedema (Neville *et al.*, 2010; White, 2006).

Hypernatraemia

In hypernatraemia the serum sodium is >135 mmol/L; the usual cause of hypernatraemia is water loss. The main causes are shown in Table 6.6.2.

Diagnosis

Diagnosis of hypernatraemia is based on the following criteria:

- **Increased heart rate and reduced blood pressure** – ICF volume is contracted and the patient is likely to be sodium and water depleted.
- **Urine osmolality** – urine will be concentrated, with a high osmolality of >1200 mOsmol/kg and a low volume. If the osmolality is low or very low, the patient may be receiving diuretics or suffering from diabetes insipidus, respectively.
- **Evidence of ECF expansion**, e.g. oedema and weight gain – an excess of sodium is likely, although this is rare. Hypernatraemia can occur with an increased, normal or low total body sodium. Due to the close relationship between sodium and water balance, the management of hypernatraemia depends on the status of the ECF volume (Piper *et al.*, 2012).

Management

In cases of ECF volume depletion, water should be replaced gradually, ideally by the oral route. If this is not possible (or if the plasma volume needs more rapid repletion, e.g. after blood loss), 0.9% saline is normally infused

intravenously initially and thereafter 5% glucose is the intravenous fluid of choice. Serum sodium levels should not be corrected by >12 mmol/24 hours. Any ongoing losses of water should be addressed, e.g. stopping diuretics, reducing gastrointestinal losses with antidiarrhoeal agents if appropriate or giving ADH if central diabetes insipidus is present.

Expansion of ECF volume is treated with diuretics to remove excess sodium and water. This is also the case when hypernatraemia is a result of excessive sodium administration (Sam *et al.*, 2012).

Potassium

Potassium (K⁺) is the principal intracellular cation, with intracellular concentrations of 150 mmol/L. It is important in enzyme and neuromuscular function. Most of the dietary intake (>90%) of potassium is excreted by the kidneys with any excess being excreted in the faeces.

Hypokalaemia

A range of clinical conditions can result in hypokalaemia, which may occur with or without a potassium loss (or deficit). The main causes of hypokalaemia are:

- Hypokalaemia without potassium loss:
 - Alkalosis (results in movement of K⁺ into cells in exchange for an equimolar number of H⁺).
 - Insulin excess (drives K⁺ into cells).
 - Dehydration (often mild hypokalaemia without evidence of K⁺ loss) (Armon *et al.*, 2008).
- Hypokalaemia with potassium loss:
 - Decreased dietary intake – alcoholism, anorexia nervosa.
 - Increased cellular uptake (common in hyperalimentation or treatment of megaloblastic anaemia).

Table 6.6.3 Protocol for the correction of hypokalaemia using an infusion of potassium chloride

Serum K (mmol/L)	Max infusion rate (mmol/h)	Max concentration (mmol/L)	Max dose/24 hours (mmol)
>2.5	10	40	200
<2.0	40	80	400

- Gastrointestinal loss – vomiting, diarrhoea, laxative abuse.
- Urinary loss – diuretics, leukaemia.

Management

In hypokalaemia where there is no potassium deficit, potassium replacement is usually unnecessary and treatment of the underlying cause will correct plasma levels. In cases of potassium deficit, replacement depends on the severity of the hypokalaemia and the magnitude of potassium loss:

- Serum K^+ >3 mmol/L – 100–200 mmol of K^+ are required for each 1 mmol/L rise in serum K^+ .
- Serum K^+ <3 mmol/L – 200–400 mmol of K^+ are required for each 1 mmol/L rise in serum K^+ . Potassium can be given orally but may result in gastrointestinal side effects, e.g. nausea, vomiting and diarrhoea; it is often administered intravenously as potassium chloride (KCl) in a controlled manner to reduce the risk of dangerous hyperkalaemia (Table 6.6.3).

Hyperkalaemia

Hyperkalaemia can occur in a variety of clinical settings, but is usually a result of renal failure. The main causes of hyperkalaemia are:

- Redistribution of K^+ from the ICF – acidosis, glucose loading in diabetes, beta-blockers.
- Potassium excess.
- Diminished excretion – acute or chronic kidney disease, K^+ sparing diuretics, Addison's disease, renal transplant, myeloma, ciclosporin.
- Excess K^+ input – diet, haemolysis, rhabdomyolysis, burns.

Management

In acute hyperkalaemia the aim is to protect the myocardium and move K^+ back into cells. The treatment of choice is normally 10% calcium gluconate (10–30 mL) and 50–150 mmol of sodium bicarbonate, followed by intravenous infusion of 100 mL of 50% glucose and 10 units of soluble insulin over 15–30 minutes. Chronic hyperkalaemia is usually managed using cation binding resins, diuretics (where appropriate) and dietary potassium restriction, e.g. chronic kidney disease, or renal replacement therapy, e.g. dialysis.

Calcium

Calcium is the body's most abundant divalent cation and has important roles in regulating neuromuscular function, myocardial contractility, hormone release and enzyme activity. Normally, about a third of dietary calcium is absorbed, mainly in the jejunum under the control of vitamin D. Disorders of calcium metabolism occur as either hyper- or hypo-calcaemia.

Hypercalcaemia

The main causes of hypercalcaemia are:

- Increased bone resorption:
 - Cancer.
 - Primary hyperparathyroidism – adenoma, hyperplasia.
 - Immobilisation.
 - Endocrine – thyrotoxicosis, glucocorticoid deficiency.
- Increased gastrointestinal absorption.
- Vitamin D excess.
- Granulomatous disorders – sarcoidosis, tuberculosis.

Management

Acute hypercalcaemia often occurs in conjunction with ECF depletion, and expansion of the ECF compartment with intravenous normal saline may be sufficient on its own to control the hypercalcaemia and stimulate calcium excretion. Calcitonin and diuretic therapy may also be commenced, providing renal function is adequate. Treatment of chronic hypercalcaemia depends on the primary cause. Sarcoidosis, adenoma and other malignancies, vitamin D excess and immobilisation may all respond to corticosteroids or oral phosphate.

Hypocalcaemia

The main causes of hypocalcaemia are:

- Hypoalbuminaemia.
- Low parathyroid hormone (PTH):
 - Hypoparathyroidism.
 - Hypomagnesaemia.
- Acute pancreatitis.
- Low vitamin D levels:
 - Vitamin D deficiency.
 - Malabsorption.
 - Alcoholism.
 - Hyperphosphataemia.

Management

Acute hypocalcaemia is normally treated with intravenous calcium gluconate. If hypomagnesaemia (which reduces parathyroid hormone secretion) is also present, intravenous magnesium sulphate will be necessary. In chronic hypocalcaemia, treatment is designed to increase intestinal calcium absorption through calcium and vitamin D supplementation.

Phosphate

Phosphate is the body's most abundant divalent anion with an ICF concentration of about 80 mmol/L. Organic

phosphates, phospholipids and phosphate containing nucleotides are vital to normal cell function. Inorganic phosphate is a major component of ATP and oxidative metabolism. About 60–65% of dietary phosphate is absorbed throughout the small bowel. Disorders of phosphate metabolism occur as either hyper- or hypophosphataemia.

Hyperphosphataemia

The main causes of hyperphosphataemia are:

- Renal:
 - Reduced glomerular filtration rate.
 - Acute and chronic kidney disease.
- Increased phosphate intake:
 - Enteral or parenteral nutrition.
 - Phosphate enemas and laxatives.
- Reduced renal excretion:
 - Hypoparathyroidism.
 - Increased growth or thyroid hormone levels.
 - Hypovolaemia.
- Redistribution – cell breakdown:
 - Trauma, haemolysis and burns, rhabdomyolysis.
 - Chemoradiotherapy.

Management

In acute hyperphosphataemia, if renal function is adequate, removal of the cause will resolve the raised serum phosphate level. Chronic hyperphosphataemia is usually due to chronic kidney disease and is treated with a combination of dietary phosphate restriction and oral phosphate binders.

Hypophosphataemia

The main causes of hypophosphataemia are:

- Redistribution:
 - Glucose and insulin administration.
 - Respiratory alkalosis.
 - Catecholamines.
 - Parenteral nutrition and anabolism.
- Gastrointestinal:
 - Reduced phosphate intake, vomiting.
 - Malabsorption, diarrhoea.
- Renal phosphate reabsorption or phosphate loss:
 - Vitamin D deficiency.
 - Hyperparathyroidism.
 - Diabetic ketoacidosis.
 - Renal replacement therapy.
 - Hypervolaemia.

Management

Mild to moderate hypophosphataemia can usually be resolved by treatment of the underlying disease. Severe hypophosphataemia requires phosphate supplementation. This can be given either orally or intravenously, but preferably orally to reduce the risks of hyperphosphataemia and metastatic calcification associated with intrave-

nous administration. Phosphate supplementation should not exceed 200 mmol/24 hours.

Magnesium

Magnesium is the second most abundant intracellular cation after potassium. It plays an important role in neuromuscular and enzyme function. About 50% of dietary magnesium is passively absorbed, mainly in the duodenum and jejunum. Disorders of magnesium metabolism present as either hyper- or hypomagnesaemia.

Hypermagnesaemia

The main causes of hypermagnesaemia are:

- Kidney disease – acute or chronic.
- Reduced excretion:
 - Sodium depletion (magnesium reabsorption is increased).
 - Mineralocorticoid deficiency and hypothyroidism (both promote magnesium reabsorption).
- Administration of magnesium:
- Tissue breakdown – rhabdomyolysis, burns, diabetic ketoacidosis.

Management

Treatment is initially by removing the underlying cause of the hypermagnesaemia and then by removing excess magnesium. If this is associated with renal disease, dialysis may be necessary. In severe hypermagnesaemia, intravenous calcium may be given to counteract the cardiac effects of magnesium.

Hypomagnesaemia

The main causes of hypomagnesaemia are:

- Reduced intake – decreased oral intake, malnutrition, prolonged intravenous therapy.
- Increased gastrointestinal excretion:
 - Vomiting and diarrhoea/malabsorption.
 - Extrarenal losses, e.g. intestinal or biliary fistulae.
 - Prolonged nasogastric suction.
 - Short bowel.
- Redistribution – glucose, insulin.
- Increased renal excretion:
 - Drugs – diuretics, ciclosporin, cytotoxics, e.g. cisplatin.
 - ECF expansion.
 - Renal tubular acidosis.
- Endocrine:
 - Diabetes, hyperthyroidism, potassium or phosphate deficiency.
 - Hypercalcaemia.
 - Hyperaldosteronism.

Management

Magnesium replacement can be given orally or intravenously (as magnesium sulphate). As a general rule, 1–2 mmol/kg can be used to correct any deficit. Intrave-

nous administration should not exceed 50mmol in 12 hours.

SECTION 7

Clinical dietetic practice

7.1

Respiratory disease

Peter Collins and C Elizabeth Weekes

Key points

- Malnutrition is common in patients with chronic obstructive pulmonary disease (COPD) and tuberculosis (TB).
- Routine nutritional screening using a validated screening tool should be carried out in all patients to identify those at risk and to initiate treatment.
- Nutritional requirements in COPD and TB have yet to be fully established.
- Nutritional support is an effective treatment in the management of malnutrition in COPD but its role in the management of TB has yet to be determined.

More than 40 different conditions affect the lungs (Table 7.1.1), which impact on breathing ability and cause mortality and morbidity (British Thoracic Society, 2006). In the UK, one person in seven is affected by chronic respiratory disease, most commonly chronic obstructive pulmonary disease (COPD) or asthma. Globally, respiratory disease is the second biggest killer after cardiovascular disease (World Health Organization, 2004).

A number of local symptoms that result from respiratory disease can affect nutritional intake and nutritional status, e.g. dyspnoea, cough and excess sputum production. At any stage in the illness, these symptoms may be compounded by acute exacerbations and increased infection, and influenced by age, the social and psychological effects of chronic illness and the presence of comorbidities. Any patient with respiratory disease may present with malnutrition; however, two respiratory conditions strongly associated with a high prevalence of malnutrition are COPD (Vermeeren *et al.*, 2006) and tuberculosis (TB) (Schwenk & Macallan, 2000). While adequate pharmacological treatment of TB often results in a cure and subsequent improvement in nutritional status (Schwenk *et al.*, 2004), the lack of a cure for COPD means that it is often progressively debilitating with an increasing impact on nutritional status. All respiratory diseases affect lung function to varying degrees but some, particularly COPD and TB, are also associated with chronic systemic inflammation that can have profound effects on skeletal muscle (sarcopenia and cachexia) and bone (osteoporosis).

Chronic obstructive pulmonary disease

The term COPD applies to emphysema, bronchitis or a combination of both. It was recently defined as '*... a preventable and treatable disease with some significant extra pulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterised by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases*' [Global Initiative for Chronic Obstructive Lung Disease (GOLD), 2010].

Patients usually present with a history of increasing dyspnoea over several years, chronic cough, muscle weakness and poor exercise tolerance secondary to muscle wasting; recurrent bronchial infections or weight loss may also be reported. Although COPD is incurable, early diagnosis and treatment can alleviate symptoms; unfortunately no treatment has modified the rate of decline in lung function (Celli *et al.*, 2004).

Diagnostic criteria and classification

Diagnosis relies on medical history and symptoms at presentation, as well as post bronchodilator spirometry to establish lung function [forced expiratory volume in one second (FEV₁) and forced vital capacity (FVC)]. Lung function results are compared with age and gender specific

Table 7.1.1 Characteristics of respiratory disease

	Examples
Chronic respiratory diseases	
Obstructive	Chronic obstructive pulmonary disease (COPD) Asthma
Restrictive	Pulmonary fibrosis Sarcoidosis
Vascular	Pulmonary embolism Pulmonary hypertension Cor pulmonale
Infective	Tuberculosis (TB)
Environmental	Pneumoconiosis Asbestosis
Genetic	Cystic fibrosis Alpha-1-antitrypsin deficiency
Acute respiratory disease	
Multiple causes	Adult respiratory distress syndrome (ARDS)
Infective	Pneumonia

Table 7.1.2 Grading of chronic obstructive disease (COPD) obstruction severity

COPD severity classification	Lung function
Stage I: mild	FEV ₁ /FVC <70%; FEV ₁ ≥80% predicted
Stage II: moderate	FEV ₁ /FVC <70%; FEV ₁ 50–79% predicted
Stage III: severe	FEV ₁ /FVC <70%; FEV ₁ 30–49% predicted
Stage IV: very severe	FEV ₁ /FVC <70%; FEV ₁ <30% predicted*

*Or FEV₁ <50% predicted in the presence of chronic respiratory failure (NICE, 2010); GOLD, 2010).
FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity.

standards to determine disease severity using the GOLD criteria (Table 7.1.2). A differential diagnosis of bronchitis is made when there is a history of chronic cough productive of sputum present on most days of the month for at least 3 months in 2 consecutive years.

Disease processes

While cigarette smoking and air pollution are the most important factors in the development of COPD, genetic predispositions also play a role (Pauwels, 2003). In addition to airflow limitation, pathological changes and inflammation induced damage in the lungs can lead to excess mucus secretion, ciliary dysfunction, pulmonary hyperinflation and gas exchange abnormalities, and may result in pulmonary hypertension and cor pulmonale.

Patients with COPD have an increased susceptibility to infection and often suffer acute recurrent infective exacerbations of the disease (IECOPD).

Burden of disease

In the UK there are currently 1 million individuals diagnosed with COPD; however, it is estimated 3 million have the disease (NICE, 2010). Around 30 000 people die as a result of COPD each year (British Thoracic Society, 2006). With an ageing population, increasing awareness of the disease and improved diagnostic methods, the number of individuals diagnosed with COPD is likely to rise.

Chronic obstructive pulmonary disease is the second largest cause of emergency admissions to UK hospitals, accounting for 130 000 admissions/year (British Lung Foundation, 2007), placing a huge operational burden on hospitals by taking up 1 million bed days annually (British Thoracic Society, 2006). Patients with COPD are primarily managed in the community and account for 1.4 million GP consultations/year (Healthcare Commission, 2006).

Social deprivation has been shown to be a significant independent risk factor for malnutrition in COPD (Collins *et al.*, 2010a) and is associated with increased frequency and duration of emergency hospital admissions (Collins *et al.*, 2010b).

Chronic obstructive pulmonary disease is associated with a poor quality of life that significantly declines as disease severity increases (Rutten-van Mólken *et al.*, 2006). In COPD the compounding effect of malnutrition has yet to be fully investigated, but is likely to be significant considering the negative effect of malnutrition on quality of life in other chronic conditions such as cancer (Andreyev *et al.*, 1998).

Nutritional impact

In epidemiological studies, a poor quality diet, especially low in fruit and vegetables and high in meat and potatoes, has been associated with an increased likelihood of developing COPD (McKeever *et al.*, 2010). There is a lack of studies investigating the potential benefits of dietary interventions to prevent the development of COPD in at risk populations and no studies demonstrating that increasing the intake of specific food groups, such as fruit and vegetables, has beneficial effects on outcome in patients with COPD.

Weight loss and being underweight are associated with poor prognosis and increased mortality, independent of disease severity (Landbo *et al.*, 1999). Until recently, weight loss in COPD was seen as inevitable and unresponsive to nutritional intervention. However, studies have shown that weight loss is reversible and a weight gain of kg is associated with a number of functional improvements (Stratton *et al.*, 2003; Collins *et al.*, 2012), as well as reduced mortality (Schols *et al.*, 1998). In malnourished COPD patients, an increase in weight of at least 2 kg should be a therapeutic target.

The exact prevalence of malnutrition in COPD is unknown since an accepted definition of malnutrition

does not exist. Reported prevalence rates vary considerably from 9–63% depending on the criteria used to define malnutrition, e.g. <90% ideal body weight (Metropolitan Life Insurance Company, 1959) or >5% recent weight loss, and the population studied, e.g. in- or out-patients (Weekes, 2005). Compared with chronic bronchitis, patients with emphysema are more likely to have a low body mass index (BMI) and to report unintentional weight loss (Guerra *et al.*, 2002). Little has been reported on the pattern of weight loss in patients with COPD; however, Weekes & Bateman (2002) reported significant unintentional weight loss (>5%) in 22% of COPD outpatients. In those who unintentionally lost weight, 41% reported a recent chest infection. Although many patients describe gradual weight loss over a number of years, in a subgroup of patients weight loss and muscle wasting follows a step-wise pattern related to acute illness (Schols & Brug, 2003).

In contrast to observations in the healthy population, survival in COPD appears to be improved in those who are overweight or obese (Landbo *et al.*, 1999; Vestbo *et al.*, 2006). This paradox extends beyond reduced mortality in COPD, with one study finding that overweight patients had lower early readmission rates (Steer *et al.*, 2010) and another that overweight and obese patients had fewer emergency hospital admissions and shorter lengths of stay (Collins *et al.*, 2011a).

Assessment of body weight alone is unlikely to be sensitive enough to detect all of those at nutritional risk, since a subgroup of COPD patients demonstrate loss of fat free mass (FFM) despite maintaining normal weight (Schols *et al.*, 1993; De Benedetto *et al.*, 2000). Depletion of FFM may have more profound effects on functional measures than depletion of body weight *per se* (Schols *et al.*, 1993). The proportion of patients with FFM depletion increases with disease severity (Schols *et al.*, 1993; Vermeeren *et al.*, 2006).

Altered body composition can be attributed to a number of factors, including the disease process itself (systemic inflammation), energy imbalance (positive or negative), medication treatment (oral corticosteroids) and lifestyle (inactivity). Loss of FFM, which often occurs with ageing, can be accelerated in the presence of chronic inflammatory disease.

Nutritional screening and nutritional assessment

As COPD patients readily pass between primary and secondary care, routine nutritional screening should be performed in all patients across both settings. Outpatients with COPD identified as at risk of malnutrition using a validated tool are at increased risk of hospitalisation, longer hospital stays and increased mortality (Weekes *et al.*, 2007; Steer *et al.*, 2010). Studies are needed to establish whether prompt identification and nutritional intervention in these patients reduces their poor clinical outcomes.

Anthropometry

Recent national guidelines for the management of COPD recommend the anthropometric assessment of patients

to determine BMI. Unfortunately, the guidelines make no recommendation for formal nutritional screening and the assessment of unintentional weight change (NICE, 2010). Anthropometric assessment in COPD is not straightforward due to changes in body composition and the presence of oedema, which is challenging since there are no agreed adjustment factors for oedema. In the presence of severe oedema, assessment of upper arm anthropometry is useful. A mid upper arm circumference (MUAC) of <23 cm often indicates a BMI of <20 kg/m² (Powell-Tuck & Hennessy, 2003). Mid arm muscle area (MAMA) of the non-dominant arm has been reported to be a better predictor of mortality in COPD than BMI (Soler-Cataluña *et al.*, 2005).

Bioelectrical impedance analysis (BIA) is increasingly being used in COPD to assess changes in FFM and as an illness indicator to help predict prognosis. Currently, there is no universal reference population for COPD using this technique and research is ongoing in this area.

Biochemistry

Hospitalised patients should be assessed for hydration status, clinical condition e.g. raised C-reactive protein, white cell count and low serum albumin levels, and nutritional markers. Patients could be at risk of refeeding syndrome if dietary intake has been poor for a prolonged period, and phosphate, potassium, calcium and magnesium levels should be reviewed prior to implementation of nutritional support in all patients with known risk factors (NICE, 2006a).

Clinical condition

Patients with COPD often present with a number of nutritionally relevant comorbidities, e.g. diabetes, gastro-oesophageal reflux, osteoporosis or depression, the management of which may require the patient to take a large number of different drugs (polypharmacy). Assessment of clinical condition should take account of any relevant changes in either comorbidities or pharmacological interventions. Altered swallowing physiology in COPD, particularly around the time of IECOPD, may increase aspiration risk (Teramoto *et al.*, 2002).

Dietary intake

Stable patients with COPD consume close to recommended daily amounts for both energy and protein (Vermeeren *et al.*, 1997; Weekes *et al.*, 2009), however, intake is compromised during IECOPD (Vermeeren *et al.*, 1997; Slinde *et al.*, 2003). Low intakes of calcium and vitamin D have been found in outpatients (Weekes, 2005; Anderson *et al.*, 2007), with a reported non-starch polysaccharide intake of <15 g/day (Weekes, 2005). This together with a sedentary lifestyle and limited fluid intake might predispose to constipation.

Economic and social status

Strong links exist between social deprivation and both the development of COPD and clinical outcome (Prescott *et al.*, 1999). Many patients with COPD are unable to

continue in employment as their disease progresses or have to decrease their working hours (Eisner *et al.*, 2002). Financial resources therefore may be limited and compromise ability to purchase food. A significant proportion of patients with COPD are housebound (Bestall *et al.*, 1999), which may be accompanied by social isolation and limited access to affordable food. Strategies for improving nutritional intake may need to include the use of meals on wheels type services and socialised eating opportunities such as lunch clubs.

Clinical management

In the absence of a cure, treatments available for the management of COPD rely almost exclusively on symptom management. Infective exacerbations of the disease are usually treated with inhaled and/or oral corticosteroid medication and antibiotics. The increased appetite and food intake that often accompanies courses of oral steroids is usually short term since patients are put on reducing doses as soon as possible to avoid complications of long term therapy. Many patients take medications to counteract osteoporosis. Gastrointestinal disturbances are known complications of antibiotic therapy and may impact on nutritional intake during and immediately after IECOPD.

Recent interest has focused on the levels of vitamin D in COPD patients as the vitamin is not only involved with bone physiology but also plays an important role in muscle function and adaptive immunity (Janssens *et al.*, 2009). Vitamin D deficiency is common in COPD and correlates with disease severity (Janssens *et al.*, 2010). In COPD patients waiting for lung transplantation, 50% were found to be vitamin D deficient (Forli *et al.*, 2004). Immobility, reduced sunlight exposure, reduced capacity of ageing skin to synthesise vitamin D and medications used to manage COPD all influence the osteoporosis risk in COPD. Vitamin D and calcium intakes should be considered in all COPD patients due to the high prevalence of both osteoporosis and vitamin D deficiency.

In patients receiving home oxygen therapy, consideration should be given to the possible effects on mobility, access to food and social life, all of which might impact adversely on nutritional intake. Prolonged periods on oxygen can cause dry mouth and this may affect the ability to taste, chew and swallow foods.

Smoking cessation is a major aim of COPD management. Current smoking status has been shown to be a significant predictor of malnutrition risk (Collins *et al.*, 2011b). An average weight gain of 3.8 kg in females and 2.8 kg in males has been observed in individuals who successfully stopped smoking for >1 year (Williamson *et al.*, 1991). Baseline weight in males did not affect the level of weight gained, but in underweight females the likelihood of gaining 13 kg or more was increased four fold in those who stopped smoking.

An increasing number of patients have lung volume reduction surgery and this has been shown to result in spontaneous weight gain (Christensen *et al.*, 1999), possibly due to a combination of reduced work of breathing,

improved gas exchange and reduced post prandial dyspnoea.

Nutritional requirements

The nutritional requirements of an individual with COPD will depend on their nutritional status, clinical condition, physical activity level, nutritional goals and likely duration of nutritional support (NICE, 2006a).

Energy

The energy requirements have yet to be fully characterised and studies of COPD have reported considerable variation in total energy expenditure (TEE) (Slinde *et al.*, 2006). While published prediction methods may provide adequate estimates of requirements for groups of patients, they have a poor predictive value for individuals (see Chapter 6.1). Weight stable outpatients with COPD may have requirements similar to others of their age and gender, but if their physical activity levels are compromised, energy requirements may be lower than for healthy individuals of the same age and gender (Slinde *et al.*, 2011). In stable outpatients, a modest increase in energy intake of 200–300 kcal/day has been shown to result in weight gain (Weekes *et al.*, 2009; Collins *et al.*, 2012) and therefore energy requirements are unlikely to be much above normal.

In IECOPD, resting energy expenditure (REE) may be up to 15–20% above predicted basal metabolic rate (BMR) (Schols *et al.*, 1991; Vermeeren *et al.*, 1997; Nguyen *et al.*, 1999), but since acute illness is usually accompanied by a decrease in physical activity, TEE may be similar to, or even slightly lower than, normal. During IECOPD, some patients may be identified as at high risk of refeeding syndrome; however, this is less likely with oral nutritional support than enteral or parenteral nutrition since acute illness is usually accompanied by a loss of appetite that limits spontaneous dietary intake. Practitioners should however take care not to over prescribe nutritional support (NICE, 2006a) and to follow national or evidence based local protocols for the management of refeeding in those patients identified as high risk.

There is little evidence that disease specific oral nutritional supplements (ONS) are more effective than standard ONS in this group of patients. There is a growing body of evidence demonstrating the effectiveness of immune modulatory enteral feeds in patients with acute respiratory distress syndrome (Gadek *et al.*, 1999) and acute lung injury (Singer *et al.*, 2006) who are ventilated. However, the efficacy of such feeds during the acute phase in COPD patients remains to be established.

Protein

While elevated protein turnover rates have been reported in COPD (Engelen *et al.*, 2000), there is currently no evidence to support prescribing protein intakes above general recommendations for chronic or acute illness (Table 7.1.3). It has been suggested that protein intakes at the upper end of those recommended by NICE (2006a), i.e. 1.5 g/kg/day, might be optimal during IECOPD (Vermeeren *et al.*, 1997).

Table 7.1.3 Nutritional management of chronic obstructive pulmonary disease (COPD)

	Treatment goals	Requirements	Interventions
Stable COPD (outpatients)	Maintain nutritional status <i>or</i> Improve nutritional status, e.g. post IECOPD	NICE guidelines (NICE, 2006a)* 25–35 kcal/kg/day 0.8–1.5g protein/kg/day 30–35 mL of fluid/kg/day <i>*For patients who are not severely ill or injured, nor at risk of refeeding syndrome</i> Alternatively use PENG guidelines (Todorovic & Micklewright, 2011)	Patients identified as at risk of malnutrition or as malnourished should either be managed by referral to a dietitian or by staff using protocols drawn up by dietitians, with referral as necessary (NICE, 2006a); provision of ONS should be considered in those with a BMI <20 kg/m ² (NICE, 2010; Collins <i>et al.</i> , 2012).
Acute exacerbation (inpatients)	Minimise effects on nutritional status	No specific recommendations can be made for energy due to the heterogeneity of the patient group and the changing clinical course during the acute phase. Intakes up to 1.5g of protein/kg/day may be justified in exacerbating COPD patients (Vermeeren <i>et al.</i> , 1997)	Maximise oral intake within limits of patient's clinical condition using low volume ONS between meals (Anker <i>et al.</i> , 2006) Consider supplementary tube feeding if unlikely to meet requirements for more than 5 days (NICE, 2006a)
Mechanical ventilation (ICU/HDU)	Minimise effects on nutritional status while avoiding complications of overfeeding	No specific recommendations can be made in this setting as conditions leading to the requirement for ventilation are often highly changeable Monitoring in this setting is vital in order to meet the nutritional needs of the patient In patients requiring prolonged ventilation, avoid overfeeding [see PENG guidelines (Todorovic & Micklewright, 2011) for maximal energy and macronutrient profiles for ventilated patients]	Commence enteral tube feeding as soon as possible; if high risk of delayed gastric emptying and aspiration use post-pyloric feeding (Heyland <i>et al.</i> , 2001). In acute respiratory distress disorder (ARDS) and acute lung injury (ALI), consider formulas containing n-3 fatty acids and antioxidants (Kreymann <i>et al.</i> , 2006)

IECOPD, infective exacerbations of chronic obstructive lung disease; ONS, oral nutritional supplements; ICU, intensive care unit; HDU, high dependency unit; PENG, Parenteral and Enteral Nutrition Group.

Micronutrients

Micronutrient intake is likely to be compromised in individuals who have diets deficient in energy and protein. Prescriptions for nutritional support should provide adequate electrolytes, minerals and other micronutrients, accounting for pre-existing deficits, excessive losses or increased demands (NICE, 2006a). It may therefore be necessary to advise the use of a multivitamin and mineral supplement if intake from diet and/or ONS is unlikely to be adequate.

Nutritional support

The reversibility of weight loss in COPD is dependent on the ability to address the underlying cause. An imbalance between energy intake and expenditure, which commonly occurs during IECOPD, should be amenable to targeted nutritional support. However, during the acute phase, in the face of significant inflammation, improvements with nutritional support are hard to achieve. Studies have shown that ONS are able to overcome energy and protein deficits at this time, whilst not affecting oral intake (Vermeeren *et al.*, 2004), and lead to significant improvements in respiratory function and a tendency for improved general wellbeing (Saundy-Unterberger *et al.*, 1997).

At different periods during the course of their disease, patients may experience one or any number of symptoms that could adversely affect intake. The most frequently reported symptoms likely to affect nutritional intake in COPD are anorexia, early satiety and dyspnoea (Cochrane & Afolabi, 2004). Patients with anorexia and post prandial dyspnoea may benefit more from low volume, high energy/protein ONS and/or advice on food fortification. In the presence of early satiety, small, frequent meals and snacks and/or energy dense ONS are recommended (Anker *et al.*, 2006).

While some symptoms experienced by patients with COPD may be amenable to nutritional intervention alone, others may require a combination of nutritional intervention and other therapeutic and/or pharmacological strategies. For example, in the management of eating related dyspnoea, liaison with the medical team or respiratory nurse could optimise oxygen therapy if appropriate, while nutritional interventions should be tailored to minimise the effects on dyspnoea of preparing and eating food.

Since most patients report experiencing several symptoms that affect dietary intake at any time, a range of dietetic strategies may be required to achieve an increase in intake. In a progressive, debilitating disease such as COPD, strategies may have to change over time to avoid

Table 7.1.4 Factors influencing progression from latent to active tuberculosis (TB) (Adapted from Bates *et al.*, 2004)

Individual	Household/community	Environmental
Age	Socioeconomic status	Availability of health services
Gender	Migrant status	Quality of healthcare
Nutritional status	Place of residence	Availability of appropriate treatment

Employment status		

taste fatigue and/or take into account changes in clinical, psychological or social status (Table 7.1.4).

Evidence base for nutritional support

The efficacy of nutritional support in COPD is controversial as a previous Cochrane Collaboration review concluded that nutritional support has no effect on anthropometry, lung function and exercise capacity (Ferreira *et al.*, 2005). However, other reviewers have suggested otherwise (Stratton *et al.*, 2003) and the most recent systematic review and meta-analysis found that nutritional support in stable COPD (non-exacerbating) is effective (Collins *et al.*, 2012). Further trials are required to examine the cost-effectiveness of nutritional support in improving clinical outcomes. There is a need for robust trials around food fortification and dietary counselling as these are often recommended as a first line treatment for malnutrition in COPD despite a paucity of evidence.

One randomised trial showed individualised dietary counselling by a dietitian together with a 6-month supply of whole milk powder (WMP) to be effective in improving intake and body weight in COPD (Weekes *et al.*, 2009). An important finding from this trial was that simply providing patients with dietary advice literature, without dietetic input tailoring advice, failed to result in any improvements. The efficacy of tailored dietary advice delivered by a dietitian and the provision of supportive literature in the absence of WMP remains unknown and urgently needs addressing. A *post hoc* cost analysis suggests it might be cost-effective for a dietitian to provide dietary counselling to individuals with COPD (Weekes *et al.*, 2006), but this needs to be supported by larger, adequately powered studies.

The current evidence for nutritional support is almost entirely based on ONS and is lacking for other forms of nutritional intervention. There is a need for trials comparing different nutritional intervention strategies, and their effects on mortality, clinical outcomes and cost-effectiveness (Collins *et al.*, 2012). Since ONS presumably produce clinical benefits through increased nutrient intake, a similar increase in nutrient intake achieved by dietary counselling should result in similar benefits

(NICE, 2006a). Confirmation of this should be a priority in dietetic research as it underpins many of the principles of the profession (Baldwin & Weekes, 2011).

The most effective setting for nutritional intervention in COPD is likely to be in outpatients, as these patients tend to be metabolically stable, less acutely unwell and more mobile. The nutritional enhancement of pulmonary rehabilitation (PR) is an area that is receiving increasing interest as multimodal therapy has been found to result in significant improvements not only in malnourished patients but also adequately nourished patients with COPD, suggesting a role for nutrition beyond simply treating malnutrition (Schols *et al.*, 1995; Steiner *et al.*, 2003).

Tuberculosis

Tuberculosis (TB) is an infectious bacterial disease caused by *Mycobacterium tuberculosis* and is transmitted via droplets from the throat and lungs of people with active TB. It most commonly affects the lungs but can affect almost any part of the body, infections of the central nervous system and abdomen being the most severe.

The global prevalence of TB was 14 million in 2004, with >60% of cases in sub-Saharan Africa and Asia (WHO, 2008). Although in Europe active TB cases have declined over the past 50 years, since the 1990s there has been an increase in some countries, including the UK (Health Protection Agency, 2010). Globally, 9.2 million new cases and 1.7 million deaths from TB occurred in 2006, and while the number of new cases per capita is falling in some regions of the world, this is not the case in Africa and Europe (WHO, 2008).

Diagnostic criteria

Tuberculosis is diagnosed by sputum smear microscopy followed by culture testing (NICE, 2006b). Patients with active TB usually present with symptoms of persistent cough, fever, night sweats, dyspnoea, haemoptysis (coughing up blood), weight loss and chest pain.

Disease processes

Following TB exposure, healthy individuals mount a cell mediated immune response involving T cells, macrophages and cytokines, which usually controls the infection. The majority of individuals remain in this asymptomatic (latent) phase and only about 10% go on to develop active TB, usually when their immunity is compromised. Worldwide more than 13 million individuals are coinfecting with HIV and TB and in many individuals infected with HIV, development of active TB is the first sign of AIDS.

A number of individual factors such as genetic predisposition (Malik & Godfrey-Faussett, 2005) interact with community and environmental factors, e.g. poverty and poor housing, to influence susceptibility to infection and progression to active TB (Table 7.1.4).

Disease consequences

Tuberculosis is amongst the top 10 causes of illness, disability and death, and is the leading cause of death from a curable infectious disease (WHO, 2008). It is currently estimated that about one-third of the world's population is infected. The main burden of disease in the UK is concentrated in certain urban areas, with 38% of cases in London (Health Protection Agency, 2010). The majority of cases occur in young adults and among non-UK born black African and South Asian ethnic groups. Since most cases occur during the economically productive years of life (19–49 years), the earning capacity of patients can be severely compromised (Frieden *et al.*, 2003). With the advent of effective anti-TB therapy in recent decades, mortality rates have decreased dramatically in industrialised countries.

Nutritional impact

The nutritional consequences of active TB are well recognised; yet little is understood of the complex interactions between TB treatment and nutritional status. Many patients experience severe weight loss and vitamin and mineral deficiencies. People with TB/HIV coinfection have a worse nutritional status as TB worsens malnutrition and malnutrition weakens immunity, thereby increasing the likelihood of progressing from latent to active disease.

Similar to other chronic diseases, a consistent relationship exists between TB incidence and BMI, with one review reporting that TB incidence increases exponentially as BMI decreases (Lönnroth *et al.*, 2010). Patients presenting with active TB are more likely to be wasted or have a low BMI than healthy controls (Paton & Ng, 2006). Nutritional status usually improves with anti-TB therapy, although recent evidence suggests that those who fail to put on weight during the early phase of treatment are more likely to suffer poorer outcomes, including death (Khan *et al.*, 2006; Bernabe-Ortiz *et al.*, 2011).

Nutritional management

The evidence surrounding best practice for nutritional management of TB is very limited, particularly in devel-

oped countries. Pragmatically, the underlying principles of nutritional screening and assessment would be the same as for any patient with the potential to benefit from nutritional support (NICE, 2006a). Patients with HIV/TB coinfection face particular challenges and poorer outcomes than those with either infection alone. For more information on the nutritional management of HIV/TB coinfection, see Houtzager *et al.*, (2010) and Chapter 7.11.3.

In patients with active TB, dietary intake is likely to have been poor for some time prior to diagnosis, and in those with disordered lifestyles, e.g. substance abusers, or limited access to food and drink, e.g. the shelter living homeless, nutritional intervention will need to include strategies for ensuring adequate intake throughout the treatment period. Similarly, exploration of the diet of recent immigrants and their potential access to traditional versus native foods may be necessary in order to provide appropriate advice to which patients are likely to adhere.

Clinical investigations and management

In confirmed smear positive cases, the standard treatment is short course chemotherapy for 6–8 months. A combination of drugs and high adherence is necessary to achieve a cure, and treatment usually takes place in two phases; the initial phase lasts 2–3 months and aims to kill active and dormant bacilli, and is followed by the continuation phase, which usually lasts 4–6 months. Patients with HIV coinfection will also be prescribed a variety of antiretroviral drugs that will significantly increase the pill burden, potentially impacting negatively on adherence.

Nutritional requirements

Energy

No studies designed to determine the energy requirements of patients with TB have been published. In the early acute phase of illness, any increase in BMR secondary to the inflammatory response is likely to be accompanied by a decrease in physical activity; thus, TEE may be similar to, or even slightly lower than, normal.

Protein

Protein loss occurs due to the catabolism induced by infection and this loss should be made good through the provision of additional protein. The capacity to retain protein is enhanced during the recovery phase of infection and it is essential that needs are met during this time (NICE, 2006a).

Micronutrients

At the time of diagnosis, patients with active TB may have low levels of several micronutrients, including vitamins C and E, retinol, zinc, iron and selenium (Papathakis, 2008). Daily micronutrient supplementation may be beneficial in those who have deficiencies, especially during the early months of therapy (Abba *et al.*, 2008), but, in the case of vitamin D, possibly only those with specific genotypes will benefit (Martineau *et al.*, 2011).

Nutritional support

Benefits in terms of weight gain and increased energy intake have been reported (Kennedy *et al.*, 1996; Paton *et al.*, 2004; Schwenk *et al.*, 2004; Sudarsanam *et al.*, 2011); however, it is difficult to distinguish whether improvement in nutritional status was due to control of the disease or to nutritional support, since nutritional status is related to both effective TB treatment and increased dietary intake. Currently, there is a lack of evidence regarding the effects of nutritional support in patients with active TB on outcomes such as hospitalisation, quality of life or functional measures (Sinclair *et al.*, 2011).

7.2

Dental disorders

Kathy Cowborough and Ursula Arens

Key points

- Dental disease has a significant impact on food intake, nutritional status and general health, particularly in older people.
- Damage to, or loss of, teeth may result from dental caries, acid erosion or periodontal disease.
- Prevalence is highest in children from socioeconomically disadvantaged groups. In older adults, root caries is a significant contributor to tooth loss.
- Dietary acid (mainly from soft drinks) causes dental erosion, resulting in irreversible tooth enamel loss and tooth destruction. The tooth enamel of young children is more susceptible and easily damaged.
- Fluoride, reducing frequency of consumption of sugar containing products and acidic drinks, and good oral hygiene are the most important preventative measures for dental health.

Dental disease is a major public health problem in the UK. Dental diseases can result in acute pain, disfigurement and tooth loss. It can affect food intake, nutritional status and general health, particularly in older people (Steele *et al.*, 1998) and therefore an important aspect of dietary assessment. Dental disease is mainly preventable and should not be viewed in isolation from other aspects of health (Moynihan, 2005). Damage to or loss of teeth may result from dental caries, acid erosion and periodontal disease.

Dental caries

Between 1993 and 2003 There was a decrease in dentine decay prevalence in 15-year-old children from 42% to 13%. Approximately half were found to be caries free, compared with just over one-third in 1993 and fewer than 10% in 1983 (Lader *et al.*, 2005). There were significant improvements in 5–8-year-old children with obvious decay in the primary milk teeth between 1993 and 2003. However, early childhood caries (ECC) affected one in 10 of 3–4-year olds in the UK. Improvements were also seen in the Adult Dental Health Survey 1998 compared with previous surveys (Kelly *et al.*, 2000), but mainly in younger adults (16–44 years). Decreases in the prevalence of caries have occurred largely as a result of the effects of fluoride and better oral hygiene. Over half of young people aged 4–18 years had evidence of dental caries in primary or secondary teeth (Walker, 2000), with

caries being more common in children from some minority ethnic groups (Holt *et al.*, 1996). There were regional variations in the prevalence of dental caries and an association with social and economic deprivation (Jones *et al.*, 1997; Walker, 2000). Dental health is particularly poor amongst immigrants and refugees (Davies, 1998; Gussy *et al.*, 2006; Sheiham, 2001).

Causation

Dental caries occur when carbohydrate from food and drinks reacts with dental plaque, a sticky film of bacteria that forms on all surfaces of the teeth, to produce acid. Within minutes of exposure of the bacteria to a carbohydrate, fermentation occurs, which results in acid production. At a pH of <5.5, tooth enamel begins to be demineralised and become porous. At this stage, surface damage to tooth enamel can be repaired as enamel is constantly dissolved (demineralisation) and reformed (remineralisation). Acid produced by bacterial action dissipates after about 30 minutes and, once the pH rises above 5.5, enamel is remineralised with calcium and phosphate released from saliva. However, remineralisation requires acidity to remain above pH 5.5 for a period of time. If carbohydrate is eaten frequently, there will be insufficient time for remineralisation to take place. This results in continually repeated, gradual loss of enamel and damage to the dentine. Eventually, the enamel collapses to form a cavity and the tooth is progressively

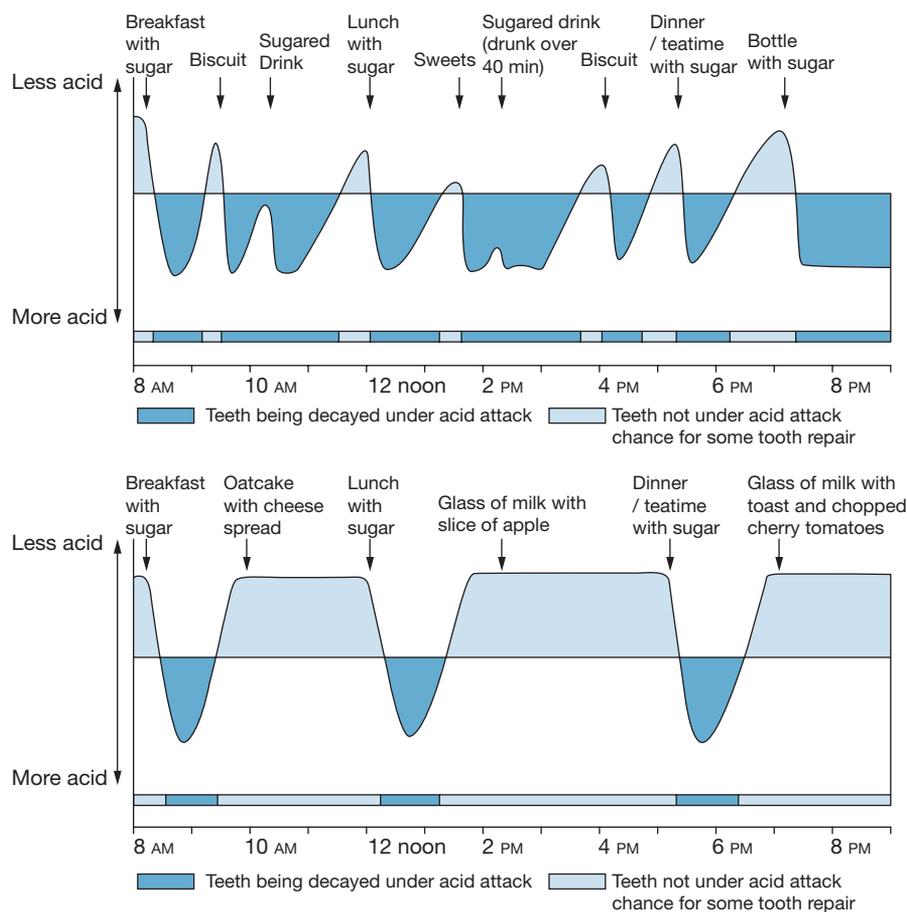

Figure 7.2.1 Stephan curve demonstrating the effect of eating frequency on mouth acidity (source: NHS Scottish Executive 2011 www.child-smile.org.uk/professionals/childsmile-manual.aspx Appendix 5 – Stephan Curve – Example 1. Reproduced with permission of NHS Scottish Executive. Information licensed under the Open Scottish Parliament Licence v. 1.0)

destroyed. This is illustrated in a Stephan curve as shown in Figure 7.2.1.

Children's teeth are particularly vulnerable to this process during the first 6 years of life when tooth enamel is being developed and is relatively soft. Caries can also attack the roots of teeth if they become exposed due to gum recession, which is a common problem in older adults. The National Diet and Nutrition Survey (NDNS) of older adults found a strong relationship between the presence of root decay and the frequency of intake of sugar rich foods (Steele *et al.*, 1998).

Factors affecting caries development

Several factors influence the formation of dental caries.

Type of carbohydrate

All carbohydrates are cariogenic, although there is considerable variation. Sucrose, glucose, maltose and fructose are most cariogenic as they are a readily available substrate for oral bacteria. Sugars such as lactose or galactose are less cariogenic; in addition, they are found in foods high in protein, calcium and phosphates, which help neutralise acids. The sugars that are potentially damaging to dental health are classified as non-milk extrinsic sugars (NMES); these include all added sugars, and sugars

in fresh fruit juice, honey and syrups. Starch can contribute to caries as saliva contains amylase, which breaks it down to glucose and maltose in the mouth. However, this varies with the type of starch and the way it has been processed (Grenby, 1997; WHO/FAO, 2003). Fructooligosaccharides may be as acidogenic as sucrose (Moynihan *et al.*, 2001). Sugar alcohols, e.g. xylitol, mannitol and sorbitol, are not fermentable and hence are non-cariogenic.

Frequency of exposure

Both total sugar intake and the consumption frequency are associated with caries development. However frequency of consumption may be the more significant factor (Holt, 1991; Touger-Decker & van Loveren, 2003). Small, frequent amounts of sugars cause more damage than the same quantity consumed on a single occasion. Acid conditions in the mouth are perpetuated, preventing remineralisation and permitting longer periods of demineralisation to occur. In young children, the combination of poor oral hygiene, limited exposure to fluoride and frequent exposure to sugary snacks and drinks results in ECC, particularly in infants who continually suck a bottle containing sugar containing drinks (Ismail, 1998; Levine & Stillman-Lowe, 2009). Frequency of sugar consumption

is an important aspect of dental health, but its contribution to caries development is less if there is good dental hygiene.

Food texture

Small particles of sticky foods may be left wedged between the teeth, so allowing continual acid production. Therefore, foods such as dried fruit, e.g. dates and raisins, have a much greater cariogenic potential than fresh fruit (Edgar, 1993).

Oral hygiene

Failure to clean teeth regularly results in the build up of tooth plaque and the accumulation of food debris in teeth crevices, providing substrate for continuous bacterial acid production. Poor oral hygiene in children has a greater impact on the levels of caries associated microorganisms than the frequency or amount of sugar consumed (Beighton *et al.*, 1996). In the 1998 NDNS, an association between caries and consumption of sugar confectionery was only seen in children whose teeth were brushed less than twice a day (Gibson & Williams, 1999). Lack of oral hygiene measures is likely to account for a significant proportion of the excessive caries prevalence in deprived groups.

Salivary flow

Saliva helps protect against dental caries by removing food particles from teeth, neutralising acids and delivering minerals to the tooth to enhance rates of remineralisation. Salivary flow can be stimulated by eating foods that require chewing or which stimulate saliva production, e.g. hard cheeses (Rugg-Gunn & Nunn, 1999) or chewing sugar free gum (Murray *et al.*, 2003). Reduced saliva production may be associated with the development of root caries in older adults. Saliva flow may be reduced in poorly controlled diabetes.

Tooth decay resistance

There is considerable individual variability in the resistance of tooth enamel to decay due to the influence of genetic factors on tooth production. Children and the elderly (with worn enamel) are at greater risk. Fluoride markedly increases enamel resistance as it results in the formation of fluorhydroxyapatite crystals in the tooth matrix, which are more resistant to acid erosion than unfluoridated hydroxyapatite.

Dental erosion

There is a gradual loss of tooth outer substance, particularly of the very hard outer enamel layer, with ageing. This can be due to a triad of factors:

- *Attrition* – wearing away of teeth by tooth to tooth contact during normal chewing.
- *Abrasion* – wearing away of teeth as a result of external objects applied to the tooth surface, e.g. brushing teeth too strongly or using a toothbrush with hard bristles.

- *Erosion* – wearing away of teeth due to acids in the mouth from foods consumed. This is in contrast to acids of bacterial origin.

The signs of dental erosion are changes to the appearance of the tooth and at a later stage, increased sensitivity of the tooth, leading to pain when eating foods that are very hot or very cold, sweet or acidic. In the last two decades there has been an increased awareness of dental erosion, particularly in children and teenagers. An increase in the observation of dental erosion in young people may be associated with recent changes to diet. The survey Children's Dental Health in the UK (O'Brien, 1994) showed that half of all 6 year olds were found to have erosion, and in one-quarter of children, erosion had resulted in some exposure of dentine. One-third of 14-year-old children had some erosion of their permanent teeth. Wear of permanent teeth is a lifelong process; therefore, the extent and severity of damage can be highest in older people. However, because the most damaged teeth may have been lost or removed, there may be lower occurrence figures in remaining teeth. In the 1998 report NDNS of people aged 65 years and over, severe wear of teeth was recorded in 15% of the dentate (having natural teeth) free living participants (Steele *et al.*, 1998). This figure for tooth wear included, but was not exclusively due to, damage from acid erosion.

Some sources of acid affecting teeth can be intrinsic. Gastric reflux (the regurgitation of stomach acids) increases the acidity of the mouth, and may occur occasionally during illness, or more regularly in people who are obese or alcoholic, or during pregnancy. The observation of tooth damage from acid may be a sign of bulimia. Regurgitated acids from the stomach are very erosive to teeth, and some treatments are available to inhibit reflux or neutralise the acidity of gastric juice, if this occurs regularly (O'Sullivan & Milosevic, 2008).

Extrinsic sources of acid are mainly from foods and drinks consumed in the diet. Acidic foods include many fruits, particularly citrus fruits and their juices; vinegars, salad dressings and pickles; alcoholic drinks, including wines, ciders and alcopops; fruit teas; carbonated drinks, especially those with flavourings such as citric and phosphoric acid; and sour flavoured sweets. Although there is some decrease in pH in carbonated water compared with still water, in practice fizzy waters seem not to affect oral acidity.

Other factors affecting erosion

In addition to the acidity of the food, other factors may influence the risk of dental erosion to teeth.

Titrateable acidity

There may be differences in pH values of foods and values obtained when adding buffering solutions to different foods (titrateable acidity); the latter is thought to be a better measure of the erosive risk of the food. Buffering capacities have been shown to be high for fruit juices and fruit based carbonated drinks, and lower for non-fruit flavoured and sparkling waters (although still water and

milk have the lowest capacities) (Edwards *et al.*, 1999; Dugmore & Rock, 2004).

Frequency and timing of consumption

The frequency of exposure has a greater effect than the quantities of the risk factor. Because the production of saliva is lowest during sleep, the consumption of acidic foods just before rest may result in greater erosive damage.

Consumption in relation to tooth brushing

If teeth are brushed after consuming acidic foods, components of the dissolved enamel will be removed, reducing subsequent remineralisation. Tooth brushing should not be before half an hour after consuming acidic foods; rinsing with water may be an alternative way to support mouth freshness after meals.

Method of consumption

Frequent sipping and swishing of acidic drinks may increase acid erosion of tooth enamel; consuming drinks through a straw may reduce tooth contact with acid liquids.

Other foods

The consumption of dairy foods may prevent the demineralisation that occurs after consuming acid foods. Eating very small amounts of cheese after consuming acid drinks supports remineralisation of the enamel; possibly due to the alkaline properties of dairy foods or their promotion of salivary flow.

Periodontal disease

Gingivitis is the initial stage of periodontal disease when the gums become inflamed by plaque that accumulates next to the gum margin. In its early stages, gingivitis can be slowed by regular dental treatment to remove plaque and tartar (calcified plaque) from the gum margins. If gingivitis persists, periodontal disease develops beneath the gum surface, leading to destruction of bone and loosening of the tooth, which may eventually fall out. There is little evidence for an association between diet and periodontal disease (WHO/FAO, 2003), Periodontal disease and resultant tooth loss impairs the ability to chew and can restrict food choice (Sheiham *et al.*, 1999), and for older adults this can have a significant impact on their nutritional status. People with natural teeth are more likely to consume foods that require chewing, such as fresh fruit and vegetables, and as a result have higher intakes of some vitamins (Steele *et al.*, 1998). The 2003 Children's Dental Health Survey (Lader *et al.*, 2005) showed that the prevalence of periodontal disease was increasing; 68% of teenage boys and 56% of teenage girls had signs of dental plaque and gingivitis.

Dental and oral health promotion

Dental disease is not inevitable and can be prevented by changes in behaviour. Effective and evidence based messages to prevent dental disease should incorporate good oral hygiene practices, dietary practices and fluoride protection, as shown in Table 7.2.1.

Table 7.2.1 Practical measures to provide dental protection

Protective factors	Practical measures
Reducing the frequency of consumption of sugars	Consume sugar containing foods and drinks with meals Limit between meal snacks containing sugars, particularly sticky foods like dried fruit Use sugar free medicines wherever possible
Reducing exposure to acid erosion	Limit consumption of acidic drinks between meals – water, tea/coffee without sugar, or plain milk are suitable Avoid acidic food or drink immediately before brushing teeth or after brushing teeth at night
Ending a meal with foods that buffer acids	Cheese and milk assist remineralisation
Good oral hygiene	Children's teeth should be brushed with a small pea sized amount of low dose fluoride toothpaste when teeth erupt Correct brushing and flossing teeth and gums to remove plaque and debris at base of teeth Avoid brushing teeth immediately after consumption of acidic food or drink as this may hinder remineralisation; it should not be overlooked in those unwell or require care Essential for patients undergoing radiotherapy for head or neck cancer or chemotherapy, who may be more susceptible to dental caries (Bothwell, 1987; Dreizen <i>et al.</i> , 1977)
Exposure to fluoride	Topical application, e.g. toothpastes, mouth rinses or tooth coating Flouridated drinking water Fluorides supplements should only be prescribed by a dental practitioner on an individual basis (SIGN, 2005)
Increasing salivary flow	Consuming foods that require mastication, e.g. wholegrain foods Eating foods that increase salivation, e.g. cheese, peanuts Chewing sugar free gum
Regular dental checks	To correct early problems To remove build up of plaque and tartar

Specific guidance for particular population subgroups

Dental health promotion is relevant to the whole population, but is particularly important for those in high risk groups, such as infants, especially at the time of weaning, children and adults living in deprived circumstances, and elderly people.

Infants

Dental health in infants can be improved by adhering to the following recommendations:

- Prolonged bottle feeding should be discouraged and discontinued after 1 year.
- From the age of 6 months, infants should be introduced to drinking from a non-valve, free flowing cup as well as use of a bottle.
- Infants and young children should never be given a bottle or beaker containing sugary drinks as a comforter.
- Dummies or comforters should not be dipped into honey or sugary drinks (Armstrong *et al.*, 2008).
- Soya based formulae can cause tooth decay as they contain sugars (SIGN, 2005).
- Weaning practices can have a major influence of both immediate and future dental health (Holt & Moynihan, 1996) and should be low in sugars and acids.
- Milk or water are the preferred drinks; other drinks, e.g. fruit juices and concentrates, should be limited and given only at main meals. They should not be given in bottles or at bedtime.

Children

Parents and carers can improve a child's dental health by:

- Limiting sugar containing and acidic drinks, especially between meals.
- Making the majority of drinks milk or water.
- Restricting sugary or acidic drinks at bedtime or during the night.
- Supervising teeth cleaning (ideally up to the age of 6 years) with a fluoride containing toothpaste (SIGN, 2005).
- Ensuring children have regular dental check ups.

Elderly people

Elderly people experience changes that may affect good dental health, including:

- Decreased salivary flow.
- Decreased manual dexterity.
- Impaired cognitive function.
- Polypharmacy.
- Swallowing difficulties.
- Reduced thirst and fluid intake.

Factors that should be considered in this age group include:

- Daily tooth or denture cleaning, especially in those unable to do this themselves.
- Avoiding frequent consumption of sugary foods, while still maintaining enjoyment of food.
- Encouraging the consumption of foods that promote salivary flow.
- Monitoring use of over the counter medicines such as cough sweets, laxatives, antacids and various tonics – these should be taken at meals only, if possible.
- Having regular dental checks to identify problems and ensure that dentures fit properly.

7.3

Dysphagia

June Copeman and Karen Hyland

Key points

- People with dysphagia cannot swallow food or fluid effectively.
- Potential consequences of dysphagia include choking, aspiration, dehydration, malnutrition and death.
- Food suitable for inclusion in an individual's diet depends on the assessed grade of consistency required. Single texture foods are easier to eat than foods with multiple textures. It is important that adequate nutrients and energy are consumed at all times.
- Frequent monitoring is required because the individual's condition may change.
- People with dysphagia may become dehydrated if they cannot swallow normal fluids; thickened drinks may be needed.

Swallowing is a highly complex process requiring appropriate posture of the head and neck, good lip and tongue movement, and the presence of the swallow reflex. Many factors can impair the ability to swallow and the physical and nutritional consequences of this can be profound, even life threatening.

Dysphagia is defined as difficulty in swallowing caused by neurological or structural damage, which interferes with the efficient movement of food and fluid from the mouth to the stomach. It is a common consequence of many different types of illness or injury resulting in mechanical or neurological impairment of the swallowing process (Table 7.3.1). Dysphagia is most likely to be encountered in patients with stroke, progressive neurological disorders, e.g. Parkinson's disease, motor neurone disease and multiple sclerosis, anoxic brain injury, other conditions such as learning disabilities, some cancers or injury affecting the head and neck. The specific feeding difficulties that arise depend on the precise motor function, behaviour or cognitive deficit that has occurred. This chapter refers to dysphagic people over the age of 5 years. The normal swallow does not mature fully until this age, and details of the management of dysphagia in infants and young children should therefore be sought in paediatric textbooks.

The normal swallow

The normal swallow can be divided into four main stages and impairment in any one of these can result in dysphagia:

1. *Preparatory stage* – this stage is mainly under voluntary control, comprising the transfer of food (or liquid) into the mouth. As food or liquid approaches the mouth, the head moves forward, the tongue protrudes and the lips and jaws open in preparation. Food and drink is placed in the mouth and the lips and jaw close to seal the mouth. The sight, smell and taste of the food will have stimulated saliva production.
2. *Oral stage* – this stage, where food is prepared for passage from the mouth into the pharynx, is also mainly under voluntary control. The tongue moves the food and positions it between the teeth. Chewing (mastication) is achieved by up and down, and rotary movements of the jaw in order to grind the food and mix it with saliva. The tongue forms a central groove to collect the food, with its tip sealed against the hard palate. The resulting bolus is propelled backwards by the posterior movement of the tongue.
3. *Pharyngeal stage* – this is an involuntary stage where the food bolus passes from the mouth through the pharynx and into the oesophagus. At the same time, the airway is temporarily sealed off to prevent the entry of food or fluid into the lungs. The process is initiated when sensation of the bolus at the anterior faucal arch (towards the back of the mouth) stimulates the swallowing centre in the brain stem. The swallow reflex is then triggered:
 - The soft palate elevates to seal off the nasopharynx.
 - The larynx elevates and so forces the epiglottis down to cover the larynx.
 - The vocal cords (within the larynx) close.

Table 7.3.1 Common causes of dysphagia

Mechanical	Oesophageal stricture Oesophageal spasm Cancers in the head, neck and oesophageal areas Cancer treatment including radiotherapy/surgery to head and neck area Pharyngeal pouch Injury or surgery to the tongue, lips, mouth or jaw Severe infections of the mouth or throat, e.g. oral thrush or ulcers Postural problems, e.g. severe kyphosis (curvature of the spine)
Neurological	Stroke Parkinson's disease Motor neurone disease Head injury Multiple sclerosis Cerebral palsy Dementia Huntington's disease Drug induced (psychotropic drugs)
Psychological	Globus hystericus Severe anxiety Severe depression

- Respiration stops momentarily.

Foods pass through the pharynx mainly by peristalsis, i.e. the muscles of the pharynx contract and move the bolus through, although gravity has some effect. The crico-pharyngeal sphincter relaxes and is opened by the upward pull of the larynx; the food bolus then passes into the oesophagus.

4. *Oesophageal stage* – this stage is also involuntary. The food bolus passes down the oesophagus into the stomach by peristalsis (wave like muscle contractions) and gravity, the cardiac sphincter relaxes and food enters the stomach.

Consequences of dysphagia

Dysphagia is potentially fatal. For example, the presence of dysphagia following a stroke increases the likelihood of subsequent malnutrition (Foley *et al.*, 2009), mortality and disability at 90 days (Paciaroni *et al.*, 2004), with increased institutionalisation (Smithard *et al.*, 2007).

Attempting to swallow foods or liquids without the ability to do so carries a high risk of aspiration (foods or liquids entering the lungs). This, if extensive, can cause acute asphyxiation and in lesser degrees is a major contributor to chest infections, lung abscesses and aspiration pneumonia (Gordon *et al.*, 1987; Ramsey *et al.*, 2003; Ney *et al.*, 2009). Aspiration may also be silent, causing no outward signs of distress but still capable of causing pulmonary complications (Teasell *et al.*, 1996; Marik & Kaplan, 2003).

An impaired ability to swallow has many nutritional implications. The physical effects of dysphagia make the

process of feeding slow, difficult and tiring, and as a result food intake is often inadequate in terms of both quantity (sometimes further compromised by food leakages from the mouth) and variety of food consumed. Fear of choking (especially if there has been an unpleasant experience of aspiration) may cause food aversions or panic attacks at meal times. Other psychological factors such as depression or anxiety (stemming from the patient's reaction to the illness and its effects) may further depress appetite. Embarrassment, vulnerability and loss of enjoyment of eating as a social function should not be underestimated (Ekborg *et al.*, 2001; Martino *et al.*, 2009).

Physiologically, inadequate intake of food and fluid will lead to undernutrition, weight loss, compromised immune function and a high risk of dehydration. These may in turn lead to deterioration of the patient's physical or mental condition and delay recovery or hasten death. The consequences of dysphagia can be compounded by concurrent:

- General illness and frailty.
- Other comorbidities, e.g. diabetes.
- Difficulties with positioning.
- Ill fitting or absent dentures.

The dysphagia care team

Effective treatment of dysphagia, whether in primary or secondary care (own home, community centre, care home, hospital), requires multidisciplinary care with good communication mechanisms in place. Coordinated multidisciplinary pathways for the assessment of dysphagia and feeding problems, with subsequent agreed intervention, will facilitate cost efficient, appropriate care. Different professionals will have specific roles within the joint treatment plans, as shown in Figure 7.3.1.

Active participation of the client and carers, whenever possible, in any decision making is essential. Short and long term prognosis, ethical issues and quality of life should be considered as an integral part of this discussion. Agreed joint treatment plans should enable the client to be transferred between hospital, intermediate and community locations without appropriate interventions being compromised. In the community, liaison with social workers and support personnel, such as home carers, meals on wheels providers or commercial ready meal home delivery services, may be essential.

Management

Dysphagia requires prompt and skilled remedial action in order to reduce the risk of aspiration and minimise nutritional deterioration, particularly if the onset has been acute (Odderson *et al.*, 1995; Finestone *et al.*, 1995). Nearly half of all stroke patients admitted to hospital will have swallowing difficulties (NICE, 2008; SIGN, 2010) and considerably more among people with other neurological conditions. The primary aims of management by the team are to:

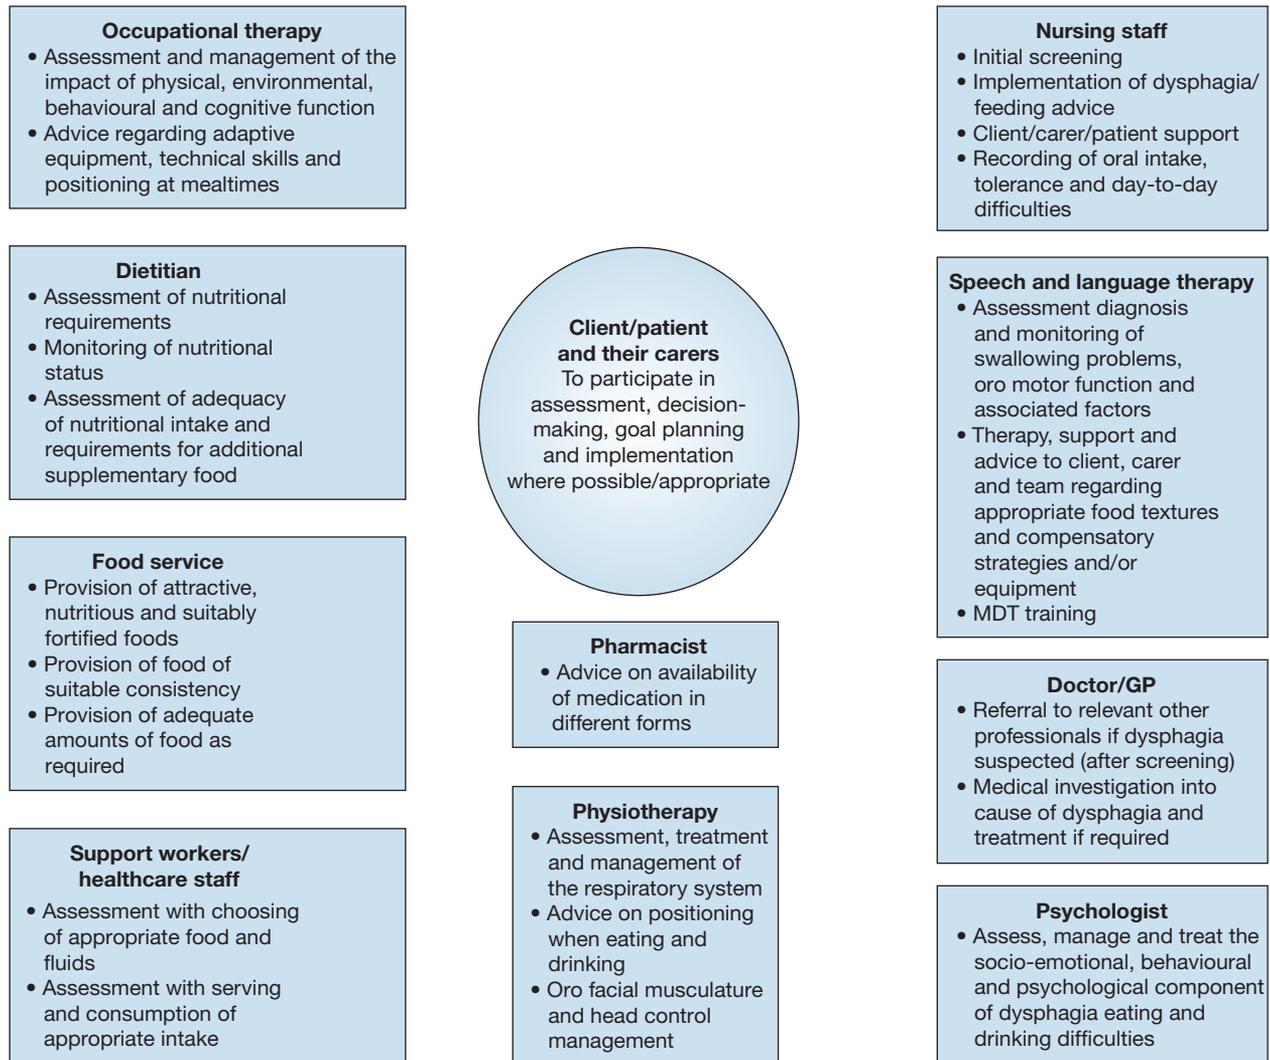

Figure 7.3.1 The role of the multidisciplinary team in the management of swallowing and feeding disorders [modified from King's College Hospital, Multi-disciplinary Working Party (2000)]
MDT, multidisciplinary team

- Assess the nature of the swallowing problem.
- Determine a safe and adequate feeding route.
- Determine the appropriate texture and consistency of orally consumed food and fluids.
- Ensure nutritional needs are met.
- Ensure fluid needs are met.
- Educate the patient, carers and other member of the care team.
- Monitor progress.
- Ensure continuity of care.

Warning signs of dysphagia

Early recognition of dysphagia is important to prevent unnecessary patient distress and for effective intervention. Typically, when several of the signs listed in Box 7.3.1 occur, the individual is likely to be experiencing swallowing difficulties and an assessment is required. This is particularly important in chronic long term condi-

tions such as Parkinson's disease where dysphagia gradually develops as the disease progresses.

Assessment of the swallowing problem

Suspected dysphagia should always be expertly assessed so that it can be managed most effectively (Finestone & Greene-Finestone, 2003). Following a stroke, it is recommended that all patients be given an assessment of swallowing ability using a validated tool and local guidelines administered by designated personnel (RCP, 2008). Patients with suspected difficulties should be referred to a speech and language therapist (SLT). If the initial assessment is inconclusive (difficulties at the pharyngeal stage can be particularly difficult to ascertain), videofluoroscopy (radiological examination of the swallowing process) may be carried out.

In primary care, a dysphagic patient identified by a GP, or district or community nurse should be referred to a

hospital for specialist assessment if this cannot be done within the community setting (care home, day centre, day hospital, own home). Dysphagia is a significant contributory factor to undernutrition in elderly people living in the community or care homes (Finch *et al.*, 1998), but its presence is unfortunately often regarded as being of little significance (BAPEN, 2011).

The first three stages of the normal swallow (preparatory, oral and pharyngeal) are most likely to be disrupted when there is neuromuscular dysfunction resulting in weakness, paralysis and/or sensory loss in the muscles

Box 7.3.1 Warning signs of dysphagia

- Coughing/spluttering/choking during or after drinking
- Coughing/spluttering/choking during or after eating
- Dehydration
- Difficulty chewing/manipulating food and drink in the mouth
- Difficulty controlling food and drink in the mouth
- Drooling
- Dry mouth
- Easily distracted – forgetting to swallow
- Frequent chest infections
- Gurgly voice or altered voice after eating and drinking
- Increased shortness of breath/change in breathing after swallowing
- Not being able to swallow mixed consistency meals
- Not been able to swallow/food sticking in mouth
- Pain on swallowing
- Poor oral hygiene
- Pouching of food in the mouth
- Sensory loss and weakness in muscles of mouth and face
- Spilling of food/drink from the mouth
- Unable to clear own saliva/secretions
- Very poor physical posture with neck touching chest
- Vomiting after meals
- Weight loss

associated with swallowing, e.g. as a result of stroke, motor neurone disease and anoxic brain injury. The oesophageal stage is more likely to be affected by mechanical problems such as stricture, e.g. oesophageal carcinoma. The type of problems that can result are summarised in Table 7.3.2.

Determining a safe and adequate feeding route

The first priority is to decide whether feeding via the oral route is safe. If it is not, alternative routes have to be considered, e.g. nasogastric, surgical gastrostomy, percutaneous endoscopic gastrostomy (PEG) and parenteral nutrition (see Chapter 6.4 and Chapter 6.5).

Determining the appropriate texture and consistency of orally consumed food and fluids

After establishing that the patient can safely manage an oral intake, the SLT will provide guidance on appropriate texture modification to ensure safe transport of food and drink and minimise the risk of aspiration (Rosenvinge & Starke, 2005). Liquid or puréed diets may be appropriate for patients with dysphagia of mechanical origin who are unable to chew, e.g. those with a fractured jaw. However, in patients with oropharyngeal disorders, diets comprised of thinned and fluid foods increase the risk of aspiration because:

- They cannot be controlled in the mouth.
- The disordered swallowing mechanism cannot respond in time and with sufficient control to protect the airway.
- They lack the taste, temperature and pressure requirements to elicit an adequate swallow and protective reflex.

Foods and liquids therefore need to be modified to a consistency that provides the patient with best control over the rate at which they pass through the pharynx (Curran & Groher, 1990).

A comprehensive review by Penman & Thomson (1998) highlighted wide variation among dietitians, SLTs and other health professionals in their description of different food textures. They suggested that collaboration between

Table 7.3.2 Disruption of the normal swallowing process

Stage of the normal swallow	Affected by	Consequences
Preparatory stage	Reduced range of movement of facial muscles, lips, tongue and jaw Loss of sight, smell and/or taste	Difficulty in getting food/liquid into the mouth Difficulty in sealing the mouth Reduced saliva production
Oral stage	Reduced range of movement of facial muscles, lips, tongue and jaw, and lack of saliva Postural problems	Difficulty in mastication Difficulty in forming a food bolus Difficulty in controlling a food bolus Difficulty in swallowing a food bolus
Pharyngeal stage	Absence of swallow reflex	Inability to swallow safely
Oesophageal phase	Impaired peristalsis or obstruction	Food fails to move into the stomach Aspiration after the swallow

the SLT and dietetic professions was needed to produce national guidelines on the use of textured diets in the management of dysphagia. In 2002, a Joint Working Party of the British Dietetic Association (BDA) and Royal College of Speech and Language Therapists (RCSLT) (2002, reviewed in 2009) published the National Descriptors for Texture Modification in Adults. This was in response to the desire to standardise understanding of particular food and fluid consistencies between health professionals to aid effective communication and enhance patient care.

Poor use nationally and concerns relating to patient safety involving recorded incidents and deaths from aspiration pneumonia resulted in a collaborative venture led by the National Patient Safety Agency (NPSA, 2011). The expert reference group with representatives from the BDA, RCSLT, National Nurses Nutrition Group (NNG) and Hospital Caterers Association (HCA) developed Dysphagia Diet Food Texture Descriptors, endorsed by all organisations to be used by health professionals and food providers (NPSA, 2011). The texture consistencies are described as:

B = thin purée dysphagia diet;

C = thick purée dysphagia diet;

D = premashed dysphagia diet;

E = fork mashable dysphagia diet.

The food texture descriptor tables are comprehensive and include the full range of textures required to manage different types of dysphagia in adults. The tables are intended as a resource and do not in any way distract from an individual professional's own clinical judgement with regard to a particular client, and patient informed choice. The audit checklists produced enable food items to be measured against the standards for each texture. The NPSA group recommendations for future action include:

- A review of descriptors should be undertaken including health professionals and industry.

- All professional organisations should encourage their members to comply with the terminology and language used.
- Pictorial training aids should be developed to support texture descriptors for patients, carers and professionals.
- Industry should be encouraged to review their packaging to reflect colour codes proposed for each texture descriptor.

Commercial thickening agents derived from food starch are Advisory Committee on Borderline Substances (ACBS) prescribable for dysphagia and can be added to foods or liquids to provide the desired consistency and thickness (Box 7.3.2) or prethickened ready to use versions can be utilised (Table 7.3.3).

Foods suitable or unsuitable for inclusion in an individual's diet depend on the grade of consistency required. As a general guideline, single texture foods such as well mashed potato, semolina, custard, Greek yogurt, instant desserts and sieved soup are more appropriate than combination foods such as stews or risotto. Certain foods are considered high risk (Table 7.3.4) either because of their physical structure, e.g. beans with a skin, or difficulty of manipulation within the mouth, e.g. toffees or pie crust. Foods that change consistency from solid to liquid in the mouth, e.g. ice cream and sorbet, may also be unsuitable for patients dysphagic to liquids.

In addition to appropriate texture modification, the SLT may suggest other measures that may assist those with oropharyngeal disorders; for example, the use of cold or stimulating foods in those with delayed triggering of the pharyngeal swallow, or alternate mouthfuls of hot and cold foods for those with reduced oral awareness (Penman & Thomson, 1998). Other members of the care team, e.g. physiotherapist or occupational therapist, may provide guidance on the best posture or sitting position for eating, or the most appropriate eating utensils and drinking vessels. Use of drinking vessels that encourage the head

Box 7.3.2 Commercial proprietary thickeners

The following products, available in the form of powders comprised of modified food starch (generally maize), are ACBS prescribable to thicken foods and liquids in the management of dysphagia:

- Multi-thick (Abbott Nutrition)
- Nutilis (Nutricia Advanced Medical Nutrition)
- Resource Thicken Up Clear (Nestles Healthcare Nutrition)
- SLO Drinks (SLO Drinks)
- Thick and Easy Instant Food Thickener (Fresenius Kabi Ltd)
- Thixo-D (Sutherland Health Ltd)
- Vitaquick (Vitaflor International Ltd)

NB: The above products are *not* normally suitable for infants and young children.

Thickeners based on carob seed flour such as Carobel instant powder (Cow & Gate) are used to thicken infant feeds for the treatment of recurrent vomiting. They are *not* suitable for the management of dysphagia.

Full composition details of these products and prescribing indications can be found in the *British National Formulary* or the *Monthly Index of Medical Specialties (MIMS)* or obtained directly from the manufacturers.

Table 7.3.3 Prethickened commercial proprietary prescribable products

	Product (manufacturer)
Thickened desserts	Ensure Plus Crème (Abbott Nutrition) Forticreme Complete (Nutricia Advanced Medical Nutrition) Fortisip Fruit Dessert (Nutricia Advanced Medical Nutrition) Fresubin Creme (Fresenius Kabi Ltd)
Thickened drinks	Fresubin Thickened Stage 1 (Fresenius Kabi Ltd) Fresubin Thickened Stage 2 (Fresenius Kabi Ltd) Nutilus Complete Stage 1 (Nutricia Advanced Medical Nutrition) Resource Thickened Drink (Nestles Healthcare Nutrition) Resource Dessert Energy (Nestles Healthcare Nutrition) Resource Dessert Fruit (Nestles Healthcare Nutrition) Thick and Easy Thickened Juice Drink (Fresenius Kabi Ltd) SLO Cold Juice Drinks, Hot Chocolate, White Coffee (SLO Drinks Ltd)

NB: The above products are *not* normally suitable for infants and young children.

Thickeners based on carob seed flour such as Carobel instant powder (Cow & Gate) are used to thicken infant feeds for the treatment of recurrent vomiting. They are *not* suitable for the management of dysphagia.

Full composition details of these products and prescribing indications can be found in the *British National Formulary* or the *Monthly Index of Medical Specialties (MIMS)* or obtained directly from the manufacturers.

Table 7.3.4 High risk foods in dysphagia [modified from Joint Working Party of the British Dietetic Association and Royal College of Speech and Language Therapists (2002, reviewed 2009) and Dietitians Association of Australia and The Speech Pathology Association of Australia Ltd (2007)]

Food types	Examples
Chewy foods	Chewy sweets and toffees Marshmallows Chew bars, breakfast bars Chewing gum Chewy or crispy meat, e.g. crispy duck, bacon Cooked hard cheese, e.g. cheddar
Crumbly items	Bread crusts, pie crusts Crumble Dry biscuits/cakes
Crunchy foods	Toast Flaky pastry Dry biscuits Crisps, popcorn
Floppy texture	Lettuce, cucumber, uncooked spinach leaves
Hard foods	Boiled and hard sweets and toffees Nuts and seeds Raw vegetables
Husk	Sweetcorn Granary bread, bread with grains and seeds
Mixed consistency foods	Cereals which do not blend with milk, such as muesli Mince with thin gravy Soup with lumps, e.g. minestrone
Stringy, fibrous texture	Pineapple, runner beans, celery, rhubarb Steak
Vegetable and fruit skins (including bean skins)	Broad, baked, soya and black eyed beans, peas, grapes, sweetcorn, apple with peel

to tip back, e.g. feeder beakers, should be avoided. It is also important that patients and their carers are provided with specific guidance on texture modification measures and compensatory swallowing techniques to help minimise problems such as aspiration (DePippo *et al.*, 1994; Elmstahl *et al.*, 1999).

Meeting nutritional needs

As well as being of the appropriate consistency, the diet also has to be capable of meeting the individual's nutritional needs, with consideration of any other medical conditions, e.g. diabetes, coeliac disease, renal failure and dyslipidaemia, as well as cultural requirements. (Brody *et al.*, 2000). Where dysphagia is managed without dietetic input, these aspects are sometimes overlooked.

Key factors to consider in improving nutritional and fluid intake for modified texture diets are:

- Presentation and temperature of food.
- Flavour, taste and palatability.
- Texture of food.
- Nutrient dilution.
- Food fortification and or enrichment.
- Between meal snacks.
- Adequate fluid.
- Appropriate use of thickener.
- Posture and physical access to eating and drinking.

People with dysphagia often consume a very limited variety of foods, either because of the constraints imposed by the need for texture modification or because patients themselves limit their intake to the few foods they know they can tolerate. Retextured food can also look unappetising. Foods such as bread, fresh fruit, meat, pulses and nuts are often absent from the diet (Table 7.3.4) and as a result, intake of dietary fibre and micronutrients, e.g. some vitamins and minerals such as B₁₂, zinc and iron, may be inadequate. In addition, because dysphagia inevitably makes the process of eating difficult and a physical effort, the total quantity of food consumed may be insufficient to meet total energy and nutrient needs.

If intake remains inadequate, additional energy and nutrient supplementation may need to be considered (see Chapter 6.3). Sip feed supplements may, if necessary, be thickened to an appropriate texture with commercial thickeners (Box 7.3.2), or one of the more semi solid fortified dessert supplements may be used (Table 7.3.3) The adequacy of these measures should be continuously reviewed along with the progress of the dysphagia itself (see Monitoring progress later).

Ensuring fluid needs are met

Dehydration is a high risk in the dysphagic patient, so steps need to be taken to ensure that fluid intake is adequate. Speech and language therapist guidance on the appropriate degree of thickening should be followed. It should be borne in mind that the consistency of unthickened drinks may change with time and temperature. Some liquids become thicker as they cool, e.g. gravy,

home made custard and sauces, while others become more watery, e.g. manufactured custard from cartons or cans.

Most liquids, both hot and cold, can if necessary be thickened with one of the commercial thickeners available (Box 7.3.2) or alternatively a ready prepared thickened drink can be offered (Table 7.3.3). It is important that appropriate guidance with supporting written treatment plans, in line with a fluid texture modification table, are given to patients, carers and health and social care professionals. Potential issues include:

- Thickening fluids to the correct consistency can be difficult to achieve.
- Different commercial thickeners work differently.
- Mixing techniques and timing need to be taught to achieve the best results.
- Prethickened drinks and prethickened nutritional support drinks can be a useful choice to increase fluid and nutritional intake.

Rather than focus on thickening fluids with low palatability, it may be better to ensure sufficient fluid intake from foods of modified consistency (Vivanti *et al.*, 2009).

Educating the patient, carers and other member of the care team

People with dysphagia often need to be encouraged to eat. Factors such as anxiety or depression (often as a consequence of the underlying illness), confusion (perhaps as a result of stroke or dementia), fear (of choking) plus the sheer physical effort of consuming food all tend to act as barriers to eating. There are a number of difficulties inherent in producing/providing both texture modified food and fluids to a good standard, as well as meeting the aesthetic, cultural and nutritional requirements of the patient. The finished puréed product is not always acceptable due to the following:

- Some foods cannot be successfully puréed to a consistent smooth texture.
- Food served is not aesthetically acceptable due to poor appearance, presentation, colour and flavour.
- Inconsistent preparation of puréed foods so that the finished product is the wrong texture; this can still increase the risk of aspiration.
- Food items being diluted with non-nutritional fluid, e.g. water and gravy, that also increases the volume needed to meet energy and nutrient requirements.

To improve nutritional intake, consider the following:

- Use high energy liquids when puréeing to avoid diluting flavour and nutrient value e.g. oil, glucose and honey.
- Provide puréed between meal snacks, e.g. strained yoghurt, suitable dessert, fruit purées or cake, biscuits and sandwiches prepared using a thickener soaking solution.
- Enhance flavour of puréed main meals with condiments, sauces, spices, etc.

- Employ food fortification/enhancement, e.g. fats, sugar and protein – oils, honey, glucose, skimmed milk powder.
- Present food attractively – purée all components, i.e. protein, carbohydrate and vegetables separately, preferably using food moulds.
- Keep food at an appetising temperature (use plate warmers and heated dishes).
- Provide food and fluids that are hot or very cold, with or without being highly flavoured, as they can stimulate a stronger swallow.

Monitoring progress

In some patients, dysphagia may be regarded as stable, i.e. the level of dysphagia remains unchanged for a considerable period of time, but in most instances this is not the case. Following stroke or acute brain injury, there is nearly always some improvement or even complete resolution of dysphagia. Conversely, in progressive neurological disorders or terminal illness, dysphagia may gradually (or suddenly) worsen. Management of dysphagia should therefore be regarded as a dynamic process, which is likely to change with time, rather than as a static solution to a clinical problem (Finestone & Greene-Finestone, 2003). For this reason, frequent monitoring is essential to assess whether current measures are appropriate for the level of dysphagia and to identify when they need to be modified. This monitoring process requires close collaboration between all members of the care team, from carers or nursing staff who may be the first to notice feeding problems or improvements, to SLTs, dietitians and medical staff who can assess the situation and modify the care plan.

If dysphagia is resolving, patients may gradually progress towards a more normal diet in a stepwise process utilising the audit checklist (NPSA, 2011) and local guidelines. If dysphagia is worsening, or there are signs of aspiration such as choking or recurrent chest infection, a different grade of texture modification may be required. In some cases, it may be necessary to change to an alternative feeding route such as enteral feeding, sometimes as a temporary measure until a certain amount of recovery or remission has occurred.

Ensuring continuity of care

Measures need to be in place to ensure that the dysphagic patient in hospital receives continuing assessment and support following discharge back into the community. Many areas now have a liaison nurse who acts as a link between the primary and secondary care sectors, liaising with ward staff to ascertain a patient's needs and ensuring that district nursing services are aware of and able to meet these needs.

Community dietetic provision is variable. In some areas, community dietetic services are an integral part of primary care support teams; in others, liaison with hospital based dietetic departments will be required. When responsibility for dietetic care is transferred from second-

ary to primary care, it is vital that this is accompanied by the provision of relevant information. The community dietitian will require details of the following:

- Patient, including relevant medical and contact details.
- Discharge date.
- Discharge location.
- Details of the patient's GP.
- Details of the patient's carer and home circumstances.
- Details of the initial and most recent nutritional assessment, weight, and texture requirement and prescription.
- Details of dietary measures implemented (together with their acceptability and effectiveness).
- Type of follow-up required.

The patient's GP will require:

- A summary of the dietetic management of the patient to date.
- Details of any proprietary thickeners or supplements prescribed and predicted usage.
- An indication of likely future dietetic needs.

The patient (or carer) will require:

- Name and contact details of the dietitian responsible for their care.
- Written details of any dietary guidance they have been given.

7.4

Gastrointestinal disorders

7.4.1 Disorders of the upper aerodigestive tract

Poonam Gulia

Key points

- Patients with disorders of the upper aerodigestive tract are nutritionally vulnerable and pose exceptional nutritional management problems.
- Patients with oesophageal disorders may have an increased risk of developing malnutrition, and dietary advice may be required for altered food texture and to ensure nutritional adequacy.

Damage to or disease of the oral cavity, pharynx, hypopharynx and oesophagus can impair the normal swallowing mechanism. This has the potential to compromise nutritional intake because it can affect the amount and types of food consumed, and impact on the time and effort experienced by the patient at each stage of the normal swallow. Even minor disorders can have a major impact on nutritional status, particularly if they are persistent and occur in people whose nutritional status is already poor. As a result, food choice and consumption can be profoundly affected in both the short and long term. The upper aerodigestive tract can be affected by cancer (see Chapter 7.15.3) and several benign disorders that are described here.

Benign disorders of the aerodigestive tract

Micronutrient deficiencies

The rate of epithelial cell turnover of the oral mucous membrane is much more rapid than that of skin (3–7 days compared with up to 28 days). As a result, the oral cavity often demonstrates early signs and symptoms of systemic diseases and nutritional deficiencies (Thomas & Giant, 2010). The presence of minor oral disorders may suggest underlying micronutrient deficiency and poor nutritional status. Both iron deficiency anaemia and pernicious anaemia (B₁₂ deficiency) can result in the tongue becoming very red, sore and smooth. Deficiencies of most of the B group vitamins affect the soft tissues of the mouth, e.g. angular stomatitis (riboflavin deficiency) and cheilosis (angular stomatitis). Although cheilosis is a classic

symptom of pellagra (niacin deficiency), in the UK it is more likely to be a sign of generalised vitamin B deficiency and undernutrition. Vitamin A deficiency can cause xerostomia (dry mouth) and in children, can result in hypoplasia in tooth enamel and dentine, increasing the susceptibility to caries.

Fractured jaw

Most fractured jaws are treated by open reduction and internal fixation using titanium miniplates and microplates without the need to keep the jaws wired together (Perry *et al.*, 1999). Patients are encouraged to mobilise the jaw gently to avoid stiffness or trismus (contraction of the jaw muscles), but are advised to have a soft diet with adequate fluid replacement. The use of nutritionally complete liquid feeds is advisable to ensure that energy and nutrient needs are met, and that scrupulous oral hygiene can be maintained for the weeks following fixation. On the rare occasions of intermaxillary fixation, when the jaws remain wired for approximately 4–6 weeks, a liquid diet will be necessary. As the wires are relaxed and ultimately removed, the diet should be regraded from a liquid to a soft or semi solid diet, with protein and energy supplements if indicated, until a normal diet can be taken.

Oesophagitis

Oesophagitis is inflammation of the mucosal lining of the oesophagus and is usually a consequence of gastro-oesophageal reflux (GORD) (see Chapter 7.4.3). Symp-

toms develop if reflux becomes frequent and the mucosa of the oesophagus becomes sensitive to the acidic reflux material. Dietary management is as for GORD, with the patient being advised to consume soft, bland and non-irritant foods and liquids whilst the symptoms are acute.

Achalasia

Achalasia is characterised by weak peristalsis of the oesophagus and the inability of the lower oesophageal sphincter to relax after a swallow; it is relatively uncommon. Food collects in the oesophagus, causing discomfort, and eventually may pass through the sphincter by the action of gravity and the weight of food consumed. Regurgitation of food is common but lacks the bitter taste of acid or bile that is characteristic of reflux. Aspiration of food from the oesophagus may lead to pneumonia. Repeated collection of food in the oesophagus can irritate the mucosa, resulting in secondary oesophagitis and pain. Loss of weight is uncommon unless the patient becomes fearful of eating. Relief may be obtained by advising the patient to:

- Consume small, frequent meals.
- Avoid fried foods or any other foods that aggravate dyspepsia.
- Avoid very hot or cold foods (these tend to increase the intake of air into the stomach).
- Avoid strong tea, coffee, large amounts of alcohol.

The patient may also find that standing up during a meal, drinking a glass of water and exhaling hard may help to force food into the stomach. If dietary measures are ineffective, surgical myotomy or mechanical dilatation may be necessary.

Oesophageal perforation

If the oesophagus perforates spontaneously or is perforated as a result of dilatation, oesophagoscopy or caustic

burns, any food or liquid consumed would enter the thoracic cavity with potentially fatal consequences. The perforation may be allowed to heal naturally or may need surgical repair. Patients should not be fed orally; enteral tube feeding or parenteral feeding may be necessary.

Benign oesophageal stricture

Benign stricture usually results from mucosal injury, either as a consequence of chronic GORD or damage following intubation with wide bore gastric tubes. Stricture may initially be due to muscular spasm, or it may result from physical scarring and thickening of the oesophageal wall. The first symptom is usually difficulty in swallowing solid foods or foods sticking, particularly items such as doughy bread or tough meats, which tend to remain as a bolus as they pass down the oesophagus. Dysphagia with solid foods may soon progress to dysphagia with semi solids or liquids. Appetite is usually reduced and severe weight loss may be reported. Patients may suffer these difficulties for some time before seeking help, and may be dehydrated and malnourished on presentation. Some patients who are depleted may need intravenous rehydration and nutritional support prior to treatment, which is usually by oesophageal dilatation. If GORD has been a contributory factor, it is important that this is corrected to prevent recurrence of the stricture.

7.4.2 Orofacial granulomatosis

Helen Campbell, Jeremy Sanderson and Miranda Lomer

Key points

- Orofacial granulomatosis (OFG) is a rare condition defined by chronic granulomatous inflammation of the lips, oral cavity and sometimes the face.
- It is predominantly an idiopathic disease, although approximately one-quarter of patients present with concurrent Crohn's disease.
- The management of OFG requires a multidisciplinary approach.
- A cinnamon and benzoate free diet is the primary treatment of choice and assumes an increased sensitivity to these compounds.
- It is important that patients are closely monitored and regularly reviewed.

Orofacial granulomatosis (OFG) is a rare condition defined by chronic granulomatous inflammation of the lips, oral cavity and sometimes the face (Wiesenfeld *et al.*, 1985). The typical presentation involves lip swelling and erythema (Campbell *et al.*, 2011; Wiesenfeld *et al.*, 1985). Inside the mouth, the buccal mucosa (inside of the cheeks), gingivae (gums), buccal sulcus (adjoining areas between the gingivae and buccal mucosa) and floor of the mouth can all be affected with swelling, erythema, nodular swelling, tags and ulcers. Lip fissures (cracking) are common and can be prone to bacterial or candida infections that often exacerbate symptoms. Intraoral fissuring can also be present. The tongue, palate and throat are less commonly involved and overall the disease is generally painless except when ulcers are present. Patients are most upset by the physically disfiguring and chronic nature of the disease, which is often difficult to treat and can last for months or even years.

Orofacial granulomatosis predominantly exists as an idiopathic disease, although approximately one-quarter of patients can also present with concurrent Crohn's disease (Campbell *et al.*, 2011). Consequently, OFG is often called oral Crohn's disease. Other more historical nomenclature can include chelitis granulomatosa and Mischer's chelitis. A small proportion also present as Melkersson Rosenthal syndrome, diagnosed when the additional features of a fissured tongue and facial palsy are present (Rogers, 1996).

Diagnosis

Expertise in this condition is rare and often patients undergo a variety of ineffectual treatments, allergy testing and other investigations for prolonged periods prior to an accurate diagnosis. The diagnosis is made through expert examination and exclusion of other granulomatous conditions (such as sarcoidosis and tuberculosis) (Grave *et al.*, 2009). Confirmation of the diagnosis is normally made from histopathological findings that identify non-caseating granulomas from biopsies taken from the affected sites. Patients with OFG are normally diagnosed as young adults, although it can present at any age (Campbell *et al.*, 2011).

Aetiology and epidemiology

The cause of OFG is unknown, but is thought to involve an allergic component. The heterogeneous nature of the condition indicates a number of different causes and early studies identified an array of foods believed to be dietary triggers, exclusion of which often improved symptoms (Ferguson & MacFadyen, 1986; Wray *et al.*, 2000). Due to the rarity of OFG, there are no epidemiological studies. Most reports are UK based with higher patient numbers being reported in Scotland (Gibson *et al.*, 2000) and Ireland (Fitzpatrick *et al.*, 2011), suggesting a Celtic predominance.

Management

Ideally, the management of OFG requires a multidisciplinary approach. Patients are referred mainly from specialists in oral medicine, gastroenterology, dermatology, allergy clinics and dentists (Campbell *et al.*, 2011). Close collaboration with medical colleagues in oral medicine can be helpful, particularly for expertise in objective examination and documentation of progression or regression of clinical features. In the event of gastrointestinal symptoms, patients should receive an opinion from a gastroenterologist.

The treatment of OFG is challenging and patients often suffer from episodes of relapse and recurrence that can be upsetting and frustrating. The cinnamon and benzoate free diet is the primary treatment of choice and assumes an increased sensitivity to these compounds (Campbell *et al.*, 2011). The mechanism remains unclear, but the diet originates from a retrospective study investigating patch test data from a series of patients with oral mucosal disorders (Wray *et al.*, 2000). Patients with OFG had increased sensitivity to cinnamon, benzoates and chocolate. A subsequent study demonstrated significant benefit from dietary elimination of cinnamon and benzoate in up to 72% of patients (White *et al.*, 2006). Other dietary measures include use of liquid enteral feeds (taken orally) and, in particular, elemental diet has proven beneficial, particularly in children (Kiparissi *et al.*, 2006).

In the event of dietary failure, topical immunosuppression (e.g. beclamethosone mouthwash), topical hydrocortisone or topical tacrolimus can be used (Casson *et al.*, 2000; Leao *et al.*, 2004). Intralesional steroids can also be used, but recurrence is common, although reportedly less so with successive injections (Al *et al.*, 2009). Occasionally, systemic corticosteroids may be given, although again often only resulting in short term improvement. For refractory OFG, patients may require long term systemic immunosuppression, most commonly with a thiopurine (azathioprine or mecarptopurine). Antitumour necrosis alpha antibody infusions (infliximab and abdulimab) have been used if other treatment is unsuccessful (Elliott *et al.*, 2011; Leao *et al.*, 2004). In severe fibrotic disease, it may be necessary for patients to undergo a cheiloplasty to surgically debulk the lips (Kruse-Losler *et al.*, 2005).

Dietary management

The cinnamon and benzoate free diet can be used to treat OFG and offers a non-invasive therapy which provides benefit in up to 72% of patients and can avoid the need for systemic immunosuppression in approximately 25% of patients (Campbell *et al.*, 2010; White *et al.*, 2006). For this reason, dietary treatment is commonly used first, with other therapies being employed either in refractory OFG or when diet fails to provide sufficient benefit. Compliance can be difficult, although motivation is often sufficiently high to overcome this, particularly in those troubled by the disfiguring nature of the disease. However, data on

sources and levels of cinnamon and benzoates are scarce and so patients are likely to be inadvertently exposed to sources for which the existence of these compounds may be elusive. This could explain why patients often complain of recurrence despite strict adherence to the diet.

It is important to provide a structure for patients undertaking a cinnamon and benzoate restricted diet. Improvement in symptoms can take some time and can be frustrating, although some patients may see improvement within a few weeks. For this reason, it is important that patients are closely monitored and regularly reviewed. A diet history will identify the patient's current exposure to cinnamon and benzoates. Those regularly drinking soft drinks are most likely to be receiving the highest levels of benzoates as added preservatives. It is not uncommon for patients to be already avoiding foods they feel contribute to their symptoms. Consequently, nutritional adequacy could be challenged with further restrictions and this needs to be considered.

The cinnamon and benzoate free diet

Sources of cinnamon

Cinnamon (*Cinnamomum zeylanium* N.) is a spice originating primarily from Sri Lanka, and is commonly added to both sweet and savoury foods (Singletary, 2008). The main compound that provides the flavour and aroma is cinnamaldehyde and this is often cited as being the component to which patients demonstrate sensitivity on patch testing (Gruenwald *et al.*, 2010; Wray *et al.*, 2000). It is often used in Asian cuisine and curries, but can also be added to chewing gums, sweets, chocolates, alcoholic

beverages, fizzy drinks, cereals and bakery products such as cakes and breads. Other products that may include cinnamon include toothpastes, mouthwashes, perfumes, perfumed creams or make up, soaps and medicines. A food product that contains <2% of a spice is not required to be specifically labelled and can instead use the term spices or mixed spices (Food Standards Agency, 2008a; 2008b; HMSO, 1996) (see Chapter 4.5). Consequently, it is necessary to avoid products labelled with these terms. In addition, products labelled as allspice, mixed spices, curry powder and garam masala (a mix of spices used in Indian curries, which could include cinnamon or cassia) need to be avoided.

Cassia (*Cinnamomum cassia* Presl) is a close relative of cinnamon and is often used as a cheaper alternative. Sourced mainly from China, Indonesia and Vietnam, it has recently received some interest as it contains substantial quantities of coumarin, which is thought to be hepatotoxic and carcinogenic (Abraham *et al.*, 2010). It also contains cinnamaldehyde but in lesser quantities than cinnamon. Cassia therefore needs to be avoided on the cinnamon and benzoate free diet.

Sources of benzoates

Rich sources of naturally occurring benzoates requiring avoidance include a number of fruits, predominantly berries, vegetables and spices (Table 7.4.1) (Cressey & Jones, 2009; Heimhuber & Herrmann, 1990; Sieber *et al.*; 1989; Toyoda *et al.*, 1983a; 1983b). Cinnamon is also a naturally occurring source of benzoates. In addition to avoidance of these foods, it is necessary to exclude products that might contain them, e.g. soups, juices, sauces,

Table 7.4.1 Natural benzoates to exclude and some suitable alternatives

Benzoate rich foods to exclude	Alternatives
Fruit	
Dried fruit, fruit sauce Berries, e.g. blackberries, cranberries, blueberries, strawberries, raspberries Prunes, peaches, papaya, nectarines	All other fresh and frozen fruit, e.g. apple, orange, pear, banana, satsuma, tangerine, melon, pineapple, grapefruit, lemon, lime, grape, mango, rhubarb
Vegetables	
Avocado, pumpkin, kidney beans, soya beans, spinach Any juices, sauces, jams, pickles or other food products containing the above fruit and vegetables	Other vegetables, e.g. broccoli, cauliflower, cabbage, carrots, green beans, runner beans, broad beans, spring greens, lettuce, cucumber, onion, peppers, bean sprouts
Spices	
Cinnamon sticks, cinnamon powder, cassia sticks, cassia powder, cloves, nutmeg, 'spices', 'mixed spices'	Salt, pepper, all other fresh herbs, e.g. basil, parsley, mint, coriander, etc., clearly labelled single spices
Teas	
Any tea leaves, tea bags, chai tea, green tea, rooibos tea, fruit or herbal teas with tea leaves	Herbal infusions, coffee
Dairy	
Blue cheeses, gorgonzola, cheese with added fruit or spices listed above	All other cheeses, e.g. cheddar, feta, mozzarella, parmesan, brie, camembert, cottage cheese, etc.

Table 7.4.2 Preservatives to be avoided

E number	Benzoate
E210	Benzoic acid
E211	Sodium benzoate
E212	Potassium benzoate
E213	Calcium benzoate
E214	Ethyl 4-hydroxybenzoate or ethyl para-hydroxybenzoate
E215	Ethyl 4-hydroxybenzoate, sodium salt or sodium ethyl para-hydroxybenzoate
E216*	Propyl 4-hydroxybenzoate or propyl para-hydroxybenzoate
E217*	Propyl 4-hydroxybenzoate, sodium salt or sodium para-hydroxybenzoate
E218	Methyl 4-hydroxybenzoate or methyl para-hydroxybenzoate
E219	Methyl 4-hydroxybenzoate, sodium salt or sodium methyl-hydroxybenzoate

*Banned in foods produced within the European Union, but may be found in products in other countries.

pickles, breads and other baked goods. Vigilance with reading labels is therefore very important.

The highest contributors are benzoates used as preservatives added to foods, drinks, medicines and cosmetics. Table 7.4.2 lists the E numbers of the preservatives that should be avoided. The main foods to which these may have been added include soft drinks, pickles, jams, biscuits, cakes, preprepared ready meals, pickled fish, sauces, dips, yoghurts and confectionary (European Parliament and Council Directive, 1995). Therefore, all food labels need to be checked for the addition of benzoates.

A further source of benzoates and derivatives of cinnamon can include cosmetic and hygiene products. There is no evidence that currently suggests that these contribute to symptoms in OFG, but absorption of benzoates through the skin has been proven (Nair, 2001). Anecdotally, patients often complain of sensitivity to cosmetic products. Consequently, the recommendation is currently to limit exposure to cosmetics that contain cinnamates and benzoates, particularly products that come into direct contact with the lips or face, such as lip balms, make up, face cleansers, soaps, creams and sunscreens. Most high street products contain cinnamates and/or benzoates. However, it is possible to find cinnamon and benzoate free products in specialist health food shops or on the Internet.

Other considerations

Soya

Soya is a natural source of benzoates and should be avoided in the cinnamon and benzoate free diet. In recent years, soya has been increasingly used in many products;

soya flour is added to bread or other baked goods and soya lecithin is added as an emulsifier to many foods. The benzoate content in these foods has not been measured but, previously, the recommendation was to avoid all products with added soya flour and lecithin (E322) that could have been sourced from soya. More recently, this recommendation has been increasingly challenged and a recent enquiry of manufacturers suggests that the contribution of benzoates from these sources is comparatively low and perhaps negligible (Nagarajah *et al.*, 2008). Consequently, this recommendation has been changed and baked goods with added soya flour and products with soya lecithin no longer requires avoidance.

Tomato

Patients with OFG often complain of sensitivity to tomato, in particular cooked tomato sauces. The reason for this is unclear, but tomato does contain small amounts of benzoic acid (Sieber *et al.*, 1989). It is likely that concentrated sources of tomato, such as tomato purée, could have a higher concentration of benzoic acid. Consequently, the recommendation is to avoid concentrated sources of tomato and to use fresh tomato only in salads and cooking. Tomato ketchup also often has benzoates added to it as a preservative.

Chocolate

Patients often complain of sensitivity to chocolate and patch test studies have identified chocolate hypersensitivity in OFG (Wray *et al.*, 2000). Chocolate or cocoa has not been identified as a rich source of benzoic acid or other benzoates, although certain additions such as dried fruit and cinnamon could be contributing factors. Patients should be advised to avoid chocolate for the duration of the elimination diet.

Flavourings

Flavourings do not need to be specifically named on foods labels (Food Standards Agency, 2008b), but they may be derivatives of both cinnamon and benzoates (European Council and Commission Directives, 1992). Consequently, the recommendation is to exclude foods labelled as containing flavourings or natural flavourings.

Monitoring

Objective measures are helpful as change can be subtle. Photographs (both external and intraorally) can prove helpful and can be encouraging for many patients so that progression can be demonstrated. A structured oral examination and documentation of disease activity and severity can also be useful and should be a routine part of the multidisciplinary approach to this condition. The cinnamon and benzoate free diet should be tried for 12 weeks. In the event that significant benefit is demonstrated, this can be extended to maximise improvement. Prolonged or open ended time frames on this restrictive

diet are not recommended and will contribute to apathy and non-compliance. If no (or limited) improvement is demonstrated, then it may be necessary to consider other approaches, such as those described previously.

Dietary reintroduction

Following a 12-week dietary restriction, foods are reintroduced. Only one food should be reintroduced at a time. As symptom recurrence is often reported as delayed, it is useful to undertake the challenge over 2–3 consecutive days before commencing with another food. A structured symptom diary can be useful to help identify likely triggers. The highest sources of benzoates are from soft drinks and these are therefore often left until last (if they are reintroduced at all). Similarly, chocolate is often left until later. It is not uncommon to find that patients need to remain on a partially restricted diet long term, limiting exposure to overt sources of cinnamon, fizzy drinks and chocolate.

7.4.3 Disorders of the stomach and duodenum

Poonam Guila

Key points

- Disorders of the stomach and duodenum can have a significant effect on dietary intake and nutritional status.
- Management of disorders is often a combination of medical or surgical intervention alongside dietary changes.
- Dietary advice is based on control of symptoms and ensuring nutritional adequacy.

Cancers of the stomach and duodenum (see Chapter 7.15.3) and gastroparesis (see Chapter 7.4.4) are described in separately. Nausea and vomiting are symptoms, rather than conditions, and are included here for completeness.

Nausea and vomiting

Nausea and vomiting can be the pathological consequences of disease or its treatment (e.g. chemotherapy), physiological (e.g. morning sickness in pregnancy), drug induced (e.g. antibiotics) or psychological (e.g. bulimia nervosa) in origin. In healthy individuals, nausea and vomiting caused by infection or food poisoning usually resolve spontaneously. Eating should be ceased until acute symptoms have eased and replaced with frequent consumption of small volumes of water, sugar containing soft drinks or oral rehydration solutions.

Profuse or persistent nausea and vomiting may compromise intake of both food and fluids, and exacerbate an already poor nutritional status resulting from underlying disease. Dietetic management depends on the nature of the underlying problem. Measures that may help alleviate symptoms and other strategies to improve oral nutritional intake are described in Chapter 6.3.

Gastro-oesophageal reflux disease

Gastro-oesophageal reflux disease (GORD) is a term used to describe a range of symptoms, including acid reflux (with or without pain), heartburn and oesophagitis. Heartburn is a common accompaniment to indigestion and is characterised by a sharp, burning pain either just below the sternum or between the shoulder blades. This chest pain may be so severe that it may be mistaken for angina. It is caused by the reflux of the stomach contents (containing acid and enzymes) into the oesophagus, some of which may reach the mouth or be sensed in the back of the throat (Figure 7.4.1). This irritates the oesophageal mucosa, causing pain, and repeated attacks may cause mucosal damage and inflammation (oesophagitis). This in turn increases the risk of developing Barrett's oesophagus and possibly adenocarcinoma of the oesophagus (NICE, 2004). Reflux may occur as a result of the following conditions (Figure 7.4.2):

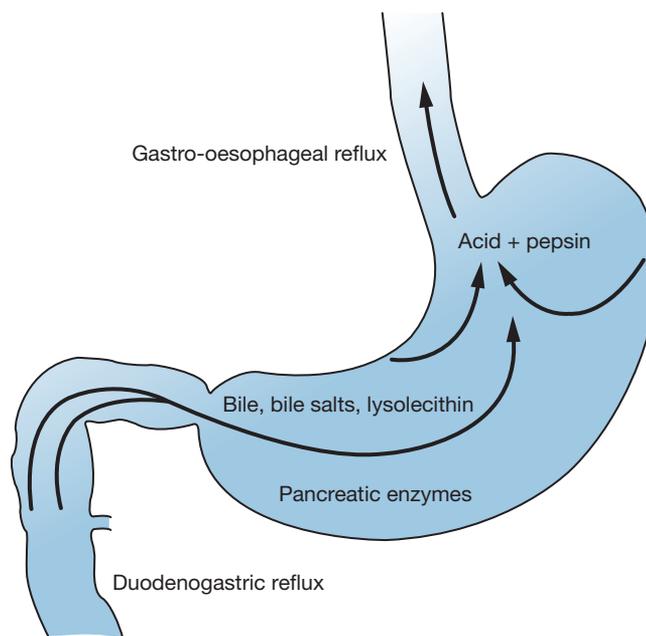

Figure 7.4.1 Constituents of gastro-oesophageal reflux

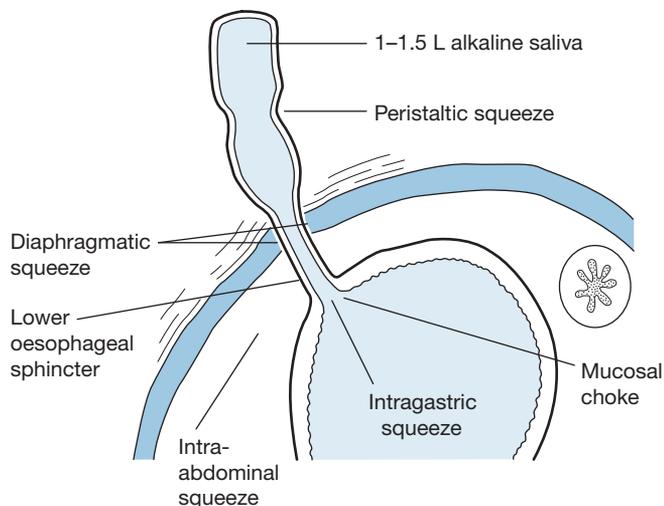

Figure 7.4.2 Factors preventing the reflux of food and regurgitation of food from the stomach

- Weakness of the sphincter at the junction of the oesophagus and stomach.
- High pressure within the stomach, e.g. consumption of a large quantity of food or liquid.
- High pressure from the abdominal area, e.g. obesity, pregnancy.
- Hiatus hernia resulting in impairment of the pinchcock mechanism of the diaphragm (see later).

Although not well supported by clinical data, diet and lifestyle factors remain important instruments for the overall management of GORD (Tytgat *et al.*, 2008). The effectiveness of commonly advised measures, such as reduction of intake of heavily spiced or fatty foods, alcohol intake and smoking cessation, in relieving gastro-oesophageal reflux *per se* have not been conclusively established in well controlled trials. There is sufficient evidence that supports the fact that obesity, in particular abdominal obesity, plays a key role in determining GORD. Controlled weight loss (by diet or surgery) is effective in improving GORD symptoms and risk of oesophageal adenocarcinoma (Festi *et al.*, 2009). Measures that are generally accepted as being helpful are:

- Eating smaller volumes at regular intervals.
- Avoiding rich or fatty foods.
- Avoiding highly spiced or irritant foods known to exacerbate symptoms.
- Avoiding excessive consumption of tea, coffee or alcohol.
- Chewing foods well.
- Avoiding eating late at night.
- Avoiding bending, lifting or lying down after meals.
- Reducing weight if obese.
- Avoiding excessive consumption of tea, coffee or alcohol.
- Avoiding smoking.
- Sleeping in a semi upright position or with the head of the bed raised a few inches to help prevent nocturnal symptoms of reflux.

Additional symptom relief is obtained by use of H₂ receptor antagonists (e.g. cimetidine, ranitidine), proton pump inhibitors (e.g. lansoprazole, omeprazole), prokinetics (e.g. metoclopramide, domperidone) and alginates. Patients with more severe symptoms refractory to lifestyle and drug therapy may be offered surgery, e.g. Nissen fundoplication where the fundus of the stomach is wrapped around the distal end of the oesophagus to create a one way valve.

Dyspepsia

Dyspepsia (indigestion) is a condition characterised by abdominal discomfort, bloating or early satiety on eating. It is important to establish the cause as it may be due to GORD, poor eating habits or a symptom of underlying, possibly serious, disease. Simple indigestion can nearly always be alleviated by the diet and lifestyle measures described earlier for GORD.

Hiatus hernia

The diaphragm has several openings through which the abdominal viscera can enter the thorax. The opening for the oesophagus, the hiatus, is loosely attached to the oesophagus. In middle age this attachment weakens and abdominal pressure may cause the hiatus to herniate (tear). This is likely to happen as a result of becoming overweight, but may also occur as a consequence of pregnancy, chronic coughing or chronic constipation due to straining. The major symptoms are pain and discomfort as a result of reflux and oesophagitis. Patients may also complain of the sensation of foods such as doughy bread or fibrous foods, e.g. salad, nuts or seeds, sticking in the gullet.

In some patients, the priority is weight loss, which will reduce abdominal pressure and may also be advisable if surgical repair is necessary. Symptom relief from GORD may be obtained by following the preventive measures listed earlier. If particular foods cause dysphagic symptoms, they should be avoided. Patients with chronic constipation should be encouraged to increase their fibre and fluid intake.

Gastritis

Gastritis, inflammation of the gastric mucosa, may be acute erosive or chronic atrophic gastritis. Alcohol, non-steroidal anti-inflammatory drugs (NSAIDs), chemical irritants and exposure to certain pathogens may trigger acute gastritis that results in pain, nausea and vomiting; usually of short duration. No particular dietary changes are usually required, although adequate hydration is important during any period of vomiting, and small meals should be taken at regular intervals.

Chronic gastritis may follow repeated attacks of acute gastritis and is closely associated with *Helicobacter pylori* infection, which is treated by eradication therapy, usually along with a proton pump inhibitor. Dietary advice should be based on the following:

- Identifying and attempting to correct dietary and lifestyle factors that are contributing to the condition, e.g. alcohol, smoking, drugs and poor eating habits.
- Encouraging a balanced diet based on healthy eating principles together with a sensible meal pattern.
- Correcting deficiencies, e.g. iron, vitamin B₁₂, that have resulted from repeated bleeding and reduced production of intrinsic factor.

Peptic ulcer

A peptic ulcer is erosion in the mucosal lining of the stomach or duodenum. Duodenal ulcers are more common and often occur in the duodenal cap; duodenitis (inflammation) is invariably present. Ulceration may also occur in the pyloric antrum and the resultant scar tissue may cause pyloric stenosis, resulting in delayed gastric emptying and the accumulation of fermenting food debris in the stomach, causing discomfort, nausea, vomiting and halitosis (bad breath). If untreated, ulcers can eventually

result in perforation of the gastric or duodenal wall, a potentially fatal complication.

The principle cause of peptic ulcer is the bacterium *H. Pylori* and NSAID use (Yeomans, 2011). Factors such as a stressful lifestyle, irregular meals, eating too quickly, inadequate mastication and smoking exacerbate ulcer formation and may adversely affect the healing process. Treatment of peptic ulcer has been transformed by the use of antibiotic treatment to eradicate *H. pylori*. To promote healing, this is usually accompanied by a 4–8-week course with an H₂ receptor antagonist or proton pump inhibitor to reduce gastric acid production. Most patients will benefit from healthy diet and lifestyle advice to minimise the risk of recurrence.

Gastric resection and reconstruction

Gastric surgery can have a considerable impact on subsequent food intake, weight recovery and quality of life. Pouch and Roux-en-Y reconstruction following gastrectomy is associated with improved quality of life and reduced complications of gastrointestinal function post-operatively, i.e. reduced reflux symptoms and dumping effects (Zong *et al.*, 2011). Increasingly, laparoscopic techniques are being used for the removal of early gastric cancers.

As a result of the combination of cachexia and chronic symptoms, such as nausea, vomiting or discomfort on eating, gastric carcinoma patients often present in a significantly malnourished state and nutritional support measures should be instituted early, preferably perioperatively, via the enteral rather than parenteral route (see Chapter 7.15.3). Early postoperative enteral nutritional support can be established via a jejunostomy or nasojejunal tube placed intraoperatively. Jejunal feeding may also be required for certain patients receiving palliative treatment for gastric outlet obstruction (see Chapter 6.4).

Disturbances in gastrointestinal function often occur following gastric resection and reconstruction that may affect nutritional intake and nutritional status (see Chapter 7.17.5). Some of these problems occur soon after eating; others result from the long term consequences of disturbed gastric function and include:

- Rapid emptying of the stomach remnant or increased intestinal motility.
- Reduced secretion of intrinsic factor (check vitamin B₁₂ status).
- Reduced secretion of pancreatic enzymes.
- Inadequate mixing of food with enzymes and bile.
- Reduced absorption of certain foods, especially protein and fat.
- Rapid absorption of glucose (dumping syndrome).
- Abolition of the normal pH gradient in the small intestine.

Early symptoms

Small stomach syndrome

The majority of patients experience early satiety and may feel distended and uncomfortable during or after eating.

This is particularly likely after total and partial gastrectomy, but may also occur after vagotomy and pyloroplasty. Small, frequent meals should be eaten and fluids consumed separately from solid foods (see Chapter 6.3).

Dumping syndrome

Early dumping occurs soon after eating and involves sweating, dizziness, faintness, a rapid, weak pulse and hypotension as a response to the rapid and early delivery of a hyperosmolar load into the jejunum. The symptoms, which usually recede 2–3 months after surgery, may be relieved by consuming small meals, limiting the consumption of rapidly absorbed carbohydrate (low glycaemic index) and avoiding liquids with meals.

Late dumping may make patients feel weak, faint, cold and sweaty about 2 hours after a meal as a result of over production of insulin in response to the rapid absorption of glucose. The symptoms can be managed by following the advice for early dumping along with regular consumption of starchy carbohydrates.

Diarrhoea

Diarrhoea frequently occurs following vagotomy or total gastrectomy, but may reduce with increasing time after surgery. Antidiarrhoeal agents such as codeine phosphate or loperamide may alleviate the problem.

Bile vomiting

Pancreatic and biliary secretions may accumulate in the afferent loop and, after a meal has left the stomach, can enter the gastric remnant, causing nausea and vomiting. It may be treated by prokinetics and, if refractory, may need surgical correction.

Long term consequences of gastrectomy

Several long term consequences of gastrectomy impact on nutrition.

Weight loss and undernutrition

Weight loss and nutritional inadequacy are common and nearly always reflect poor dietary intake. This may be precipitated by early satiety, dumping syndrome and side effects of treatments such as radiotherapy or chemotherapy. Dietary guidance should aim to improve meal frequency and nutrient density via appropriate food choice and enrichment measures; supplementation may also be indicated.

Malabsorption

Malabsorption of fat may cause steatorrhoea. Energy intake should be increased to compensate for faecal energy losses and to ensure that intake of iron, calcium and fat soluble vitamins are not compromised. Steatorrhoea should not be treated by dietary fat restriction alone. If symptoms are particularly troublesome, a proportion of dietary fat can be isocalorically substituted by either glucose polymers or medium chain triglycerides (MCTs). Medical management involves the use of antidiarrhoea medication, bile acid binders and possibly pancreatic enzyme replacements.

Anaemias

Iron deficiency anaemia can occur as a result of poor iron intake and reduced absorption; therefore, haematological status should be regularly assessed. Pernicious anaemia can be a secondary consequence of gastrectomy as a result of the loss of intrinsic factor (produced by gastric parietal cells) or reduced absorption of vitamin B₁₂, which can be supplemented by intramuscular injection. Megaloblastic anaemia may result from folate deficiency, particularly if dietary intake is poor and malabsorption is present; oral supplementation may be necessary.

Dietary guidance following gastric reconstruction should focus on the need for:

- Small, frequent, regular meals.
- Avoiding large quantities of fluids at meal times.
- Eating a variety of nutrient dense non-bulky, i.e. not high fibre, cereal foods and small amounts of fruit and vegetables.
- Boosting nutrient intake via food enrichment strategies if food intake is compromised.
- Nutritional supplements or micronutrient preparations as indicated.

- Suggesting remedial dietary measures for dumping syndrome or malabsorption if present.

7.4.4 Gastroparesis

Sarah Wilson

Key points

- Gastroparesis is associated with numerous medical conditions and may be induced by medication.
- Chronic symptoms may lead to serious nutritional consequences, including fluid and electrolyte imbalance and nutritional deficiencies.
- Treatment is supportive and aims to improve symptoms, restore nutritional status and optimise glycaemic control in patients with diabetes.
- Dietary advice may include a reduction in the size, fat and fibre content of meals, as well as texture modification. Enteral or parenteral nutritional support may be indicated if oral intake is inadequate or poorly tolerated.

Gastroparesis is a condition describing disordered motility of the stomach. It is characterised by a delay in gastric emptying in the absence of any obstruction (Bouras & Scolapio, 2004).

Normal gastric motility

Relaxation of the fundus (proximal stomach) allows the stomach to accommodate large volumes of food. Contractions of the antrum (distal stomach) grind food and gastric juices into liquid chyme. Coordinated contractions between the stomach and duodenum pump chyme through the pylorus in tightly controlled spurts. Gastric

motility is controlled by smooth muscle lining the gut and interstitial cells of Cajal within smooth muscle, which act as electrical pacemakers to generate contractions.

The rate of gastric emptying is influenced by complex neural and hormonal signals produced in response to meal composition (Karamanolis & Tack, 2006). Receptors in the small intestine detect distension, pH and the products of digestion, such as fatty acids, peptides and amino acids. Gut mucosal cells release various hormones in response to these products of digestion, which either stimulate or inhibit gastric emptying (Camilleri, 2006). This feedback process is regulated by the autonomic and enteric nervous system, as shown in Figure 7.4.3.

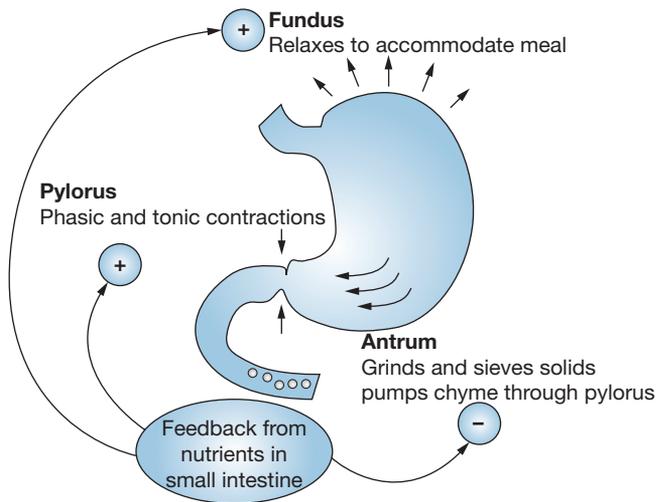

Figure 7.4.3 Motor events during normal gastric emptying (source: Rayner & Horowitz 2005. Reproduced with permission of Macmillan Publishers Ltd)

Causes

It is thought that gastroparesis is primarily caused by neuropathy or myopathy resulting in impaired fundus relaxation, decreased antral contractions, spasm of the pylorus, gastric arrhythmia or a combination of these factors (Tack, 2007). The result is undigested food that remains in the stomach for longer than normal, leading to mild to severe gastrointestinal symptoms. In patients with diabetes, gastroparesis may lead to poor glycaemic control.

Gastroparesis is more common in women and may be acute or chronic depending on the underlying aetiology. The main causes of chronic gastroparesis are idiopathic (unknown), diabetes mellitus and post surgery (Soykan *et al.*, 1998). Conditions associated with gastroparesis include (Parkman *et al.*, 2004; Rayner & Horowitz, 2005):

- Idiopathic.
- Diabetes.
- Surgery affecting the stomach or vagus nerve.
- Critical illness.
- Gastro-oesophageal reflux disease.
- Chronic liver, renal or pancreas disease.
- Cancer, e.g. pancreatic, gastric, oesophageal.
- Connective tissue disorders, e.g. scleroderma.
- Neurological disorders, e.g. Parkinson's disease.
- Conditions affecting the nervous system, e.g. enteric neuropathy.
- Motility disorders, e.g. chronic intestinal pseudo obstruction, constipation.
- Infection, e.g. virus.
- Anorexia nervosa.
- Medication induced.

Chronic gastroparesis may contribute to patient morbidity and severely affect quality of life (Parkman *et al.*, 2004). Severe gastroparesis is associated with multiple hospital admissions and longer length of stay (Kashyap & Farrugia, 2010).

Idiopathic gastroparesis

Idiopathic causes may affect up to a third of patients with gastroparesis and are more common in women (Soykan *et al.*, 1998). Acute onset occurs in 50% of patients with idiopathic gastroparesis (Parkman *et al.*, 2011). It is suspected that viral infection may be responsible for gastroparesis in this subgroup (Bityutskiy *et al.*, 1997).

Diabetic gastroparesis

Gastroparesis affects up to 50% of patients with diabetes mellitus (Horowitz *et al.*, 1996); it is more common in patients with type 1 diabetes. Chronic hyperglycaemia causes damage to the vagus nerve, which regulates gastric emptying. Loss of the interstitial cells of Cajal and neuronal nitric oxide synthase (nNOS) may also play a role in the pathogenesis (Kashyap & Farrugia, 2010). Gastroparesis may worsen glycaemic control as the stomach does not empty regularly, leading to episodes of hyperglycaemia as well as hypoglycaemia. Acute hyperglycaemia may itself slow the rate of gastric emptying (Schvarcz *et al.*, 1997). Poor glycaemic control as a result of gastroparesis may inaccurately imply poor concordance with dietetic advice. Gastroparesis should be suspected if glycaemic control is poor despite reported compliance to diet (Patrick & Epstein, 2008).

Post surgical gastroparesis

Gastroparesis has been reported after gastric resection, Roux-en-Y gastric bypass, Whipple's procedure, fundoplication, oesophagectomy, vagotomy and after heart and lung transplant (Parkman *et al.*, 2004). It is thought to result from damage to the vagus nerve during surgery and may also be induced by certain medications (Parkman *et al.*, 2004):

- Fibre.
- Alcohol.
- Tobacco.
- Marijuana.
- Antacids.
- Opioids.
- Calcium channel blockers.
- Proton pump inhibitors.
- L-dopa.
- Lithium.
- High dose tricyclic antidepressants.
- Anticholinergics.
- Progesterone.
- Ocreotide.

Symptoms

Symptoms of gastroparesis range from asymptomatic to severe and may include:

- Nausea.
- Vomiting.
- Abdominal bloating.
- Early satiety and/or post prandial fullness.
- Abdominal pain.

- Reflux and/or retching.
- Poor glycaemic control.
- Constipation or diarrhoea.

Symptoms of gastroparesis usually occur >1 hour after a meal (Karamanolis & Tack, 2006). More immediate symptoms suggest a psychosomatic or other cause (Bouras & Scolapio, 2004). The Gastroparesis Cardinal Symptom Index (GSCI) is a validated patient questionnaire that can be used to quantify the severity of symptoms (Revicki *et al.*, 2003). However, studies have shown the relationship between severity of symptoms (GSCI scores) and gastric emptying rate is poor, suggesting other factors, such as visceral hypersensitivity, may contribute to symptoms (Cassilly *et al.*, 2008).

Nutritional consequences

Many patients with gastroparesis initially present as overweight or obese; therefore signs of malnutrition may be missed (Bizer *et al.*, 2005). Gastrointestinal discomfort as a result of gastroparesis may lead to anorexia, food aversions and an unbalanced or reduced oral intake. Vomiting may result in oesophagitis, fluid and electrolyte disturbances, pulmonary aspiration and harm dentition (Bouras & Scolapio, 2004). Inadequate oral intake may result in protein energy malnutrition, weight loss and micronutrient deficiencies. Poor oral intake, weight loss and electrolyte losses from vomiting may result in a high risk of refeeding syndrome.

Poor glycaemic control may increase risk of micro- and macro-vascular complications of diabetes. Delayed gastric emptying may result in impaired absorption of medications, affecting the treatment of other medical conditions. Undigested food in the stomach may form into solid masses called bezoars, which can exacerbate symptoms of gastroparesis and cause obstruction (Tack, 2007). Many patients with gastroparesis endure symptoms for many years before receiving an accurate diagnosis and suffer from depression and anxiety (Soykan *et al.*, 1998).

Few studies have investigated the nutritional status of patients with gastroparesis; however, anaemia, dehydration, deficiency of vitamin D, thiamine and zinc, and inadequate oral intake of calories, protein and other micronutrients have been observed (Brown *et al.*, 1999; Ogorek *et al.*, 1991). There is a need for further research in this area and for vigilant nutritional screening due to the potential risk of refeeding syndrome and micronutrient deficiencies.

Nutritional assessment

A detailed nutritional assessment is required to ensure an effective treatment plan.

Anthropometry

Measures include:

- Weight, height, waist circumference (consider ascites, oedema, dehydration).
- Weight history and percentage weight loss if relevant.
- Body mass index (BMI) or mid upper arm circumference (MUAC).
- Calculate nutritional requirements based on need for weight gain or loss or if the underlying aetiology indicates additional stress, e.g. cancer, post surgery.

Biochemistry

The following should be assessed:

- Urea, creatinine, sodium, potassium, magnesium, phosphate and corrected calcium to assess hydration, renal function, electrolyte depletion and risk of refeeding syndrome.
- Blood glucose levels pre and post meals and HbA_{1c} for patients with diabetes.
- Haemoglobin, ferritin, folate and B₁₂ levels to detect anaemia.
- Albumin, transferrin and prealbumin are poor markers of nutritional status in the presence of raised inflammatory markers such as C-reactive protein and erythrocyte sedimentation rate.
- Liver function – may be affected by parenteral nutrition.
- If micronutrient or trace element deficiency is suspected, check 25-hydroxycholecalciferol (vitamin D), zinc, selenium and copper.

Clinical status

The following should be assessed:

- Establish underlying aetiology, e.g. diabetes, post surgery or idiopathic.
- Observations, e.g. temperature, fluid balance.
- Bowel form, frequency and incidence of constipation or diarrhoea. The Bristol Stool chart is helpful to clarify stool form (Lewis & Heaton, 1997).
- Symptom history, type and pattern, duration and frequency. Severity of symptoms can be rated using the GSCI questionnaire (Revicki *et al.*, 2003). A food and symptom diary may help to identify any patterns.
- Any problems with dentition that may affect the patient's ability to chew food.
- If the patient has diabetes, frequency of blood sugar monitoring, insulin injection site (if relevant), incidence and treatment of hypoglycaemia.
- Intake of herbal or sports supplements, laxatives, vitamin and mineral preparations, prescription and non-prescription medications. Note medications that may delay gastric emptying (see Chapter 7.4.3).

Dietary assessment

The following should be assessed:

- Diet history – current intake versus usual intake.
- Previous dietary measures tried.
- Evidence of disordered eating, e.g. bingeing or self induced vomiting.

- Percentage of oral intake vomited if relevant.
- Meal pattern.
- Portion sizes.
- Food intolerances and/or allergies.
- Tolerance to different textures – solid, soft, puréed, liquid.
- Dietary balance – proportion of carbohydrate, protein, fat, fruit and vegetables.
- Fibre intake – soluble and insoluble sources.
- Fluid intake – alcohol, carbonated drinks, caffeine, etc..
- Dietary sources of iron, folate, thiamine, calcium, vitamin D and other at risk micronutrients.

Socioeconomic status

The following should be assessed:

- Smoking.
- Illicit drugs use; note those that delay gastric emptying as listed under Post surgical gastroparesis.
- Physical activity.
- History of depression and/or stress.
- Patient's understanding of normal digestion and nutrition.
- Motivation and support.
- Stage of behavioural change and barriers to change.
- Cooking skills and facilities, e.g. equipment to blend food.

Clinical investigation and management

Gastroparesis is diagnosed by demonstrating delayed gastric emptying after other causes are ruled out, such as obstruction by endoscopy or barium studies, and any psychological cause, such as bulimia nervosa or rumination syndrome.

Investigations

Nuclear scintigraphy is the gold standard measure of gastric emptying. Retention of >10% of gastric contents after 4 hours of an isotope labelled test meal indicates abnormal emptying (Tougas *et al.*, 2000). Results must be interpreted carefully as test meals vary between centres and even in normal subjects daily gastric emptying varies by 20% (Patrick & Epstein, 2008). The severity and frequency of abnormal gastric emptying should be considered to determine a clinically significant diagnosis of gastroparesis (Tack, 2007).

Other measures of gastric emptying include the Smart Pill, ¹³C-octanoic acid breath testing, magnetic resonance imaging and ultrasonography. Manometry studies measure motility patterns in the stomach and duodenum. Different patterns indicate neuropathy or myopathy and may help to determine the underlying aetiology of gastroparesis. Electrogastrography may provide information on gastric dysrhythmia (Patrick & Epstein, 2008). Many of these investigations are expensive and available only in a research setting.

Treatment

Treatment aims to optimise management of the underlying cause of gastroparesis, improve glycaemic control in patients with diabetes, reduce symptoms and restore nutrition and hydration.

Medications

Prokinetics are used to accelerate gastric emptying; however, studies have not shown an associated improvement in symptoms (Sturm *et al.*, 1999; Talley, 2003). Antiemetics may help to reduce nausea; some antiemetics need to be taken 30 minutes prior to meals for best effect. Low dose tricyclic antidepressants may relieve symptoms of nausea, vomiting and pain. Some medications delay gastric emptying and should be avoided (see Chapter 7.4.3).

Botox

Botulinum toxin injected into the pylorus to reduce pylorospasms has not shown any benefit in double blind placebo controlled trials (Arts *et al.*, 2007; Friedenber *et al.*, 2008).

Gastric electrical stimulation

This involves surgical insertion of a gastric pacemaker to stimulate gastric contractions. Studies have shown that gastric electrical stimulation (GES) improves symptoms of nausea and vomiting in some patient groups; however, there is little evidence that the procedure improves gastric emptying rate (Abell *et al.*, 2003; McCallum *et al.*, 2011). The National Institute for Health and Care Excellence (NICE, 2004) has approved the use of GES in specialist units for patients with nausea and vomiting uncontrolled by medications.

Continuous insulin pump

This may improve glycaemic control in patients with diabetes through the more precise use of short acting insulin. Research is being undertaken into the potential benefit in patients with gastroparesis.

Surgery

A venting gastrostomy may relieve symptoms in some patients but be counterproductive in others (Kim & Nelson, 1998; Bouras & Scolapio, 2004). As a last resort, a subtotal gastrectomy may provide symptom relief in refractory patients with postsurgical gastroparesis (Eckhauser *et al.*, 1998).

Psychological measures

Limited evidence has suggested biofeedback and acupuncture may improve symptoms of gastroparesis in some patient groups (Rashed *et al.*, 2002; Wang, 2004).

Nutrition

Dietary modification may improve tolerance to oral intake, although there is little evidence to support this

(Karamanolis & Tack, 2006). Nutritional status should be restored through the provision of fluid, electrolytes, and macro- and micro-nutrients using the safest and best tolerated form of oral, enteral or parenteral support.

There are no controlled trials of nutritional intervention on clinical outcome in patients with gastroparesis (Abell *et al.*, 2006a). The diet currently recommended for patients with gastroparesis is one based on small frequent meals that are low in fat and fibre, and texture modified (Parkman *et al.* 2004). Large, nutrient dense meals may slow gastric emptying due to the time required for the stomach to grind contents down and negative feedback from the small intestine (Hunt & Stubbs, 1975; Camilleri, 2006). Fat in general delays gastric emptying (Cunningham & Read, 1989; Lin *et al.*, 2001). However, in clinical practice, fat is often well tolerated in liquid form and enables the provision of adequate calories (Parish & Yoshida, 2005). Removal of fibre naturally present in food accelerated gastric emptying in one study (Benini *et al.*, 1995). However, in another study, the addition of fibre did not affect gastric emptying rate (Bianchi & Capurso, 2002). Soluble fibre may increase symptoms of bloating (Bianchi & Capurso, 2002). Insoluble fibre may increase risk of bezoar formation (Abell *et al.*, 2006b; Rayner & Horowitz, 2005). Liquids empty faster than solid meals and many patients with gastroparesis have normal liquid emptying times (Read & Houghton, 1989). Homogenised food may also empty faster than solids (Karamanolis & Tack, 2006).

Advice should consider overall dietary balance, fluid and micronutrient intake, as well as glycaemic control in patients with diabetes. Adequate fluid intake should be encouraged to replace losses and prevent constipation. Carbonated drinks may exacerbate symptoms of bloating (Parkman *et al.*, 2004). Excess alcohol and smoking may delay gastric emptying and should be discouraged (Bujanda, 2000; Miller *et al.*, 1989).

Dietetic strategies

As there is a lack of evidence, the following strategies should be tried but adapted to individual patient symptoms:

- Encourage small frequent meals.
- Reduce fat and fibre:
 - Limit fried foods and nutrient dense meals such as takeaways.
 - Fat in liquid form may be well tolerated and a useful source of energy.
 - Reduce intake of very fibrous foods such as stringy fruit and vegetable skins, pips, seeds and high fibre muesli, etc.
- Modify texture:
 - Liquid, puréed, or soft foods may be better tolerated than solid meals.
 - Adapt texture to symptoms, e.g. if symptoms are worse at night, encourage greater intake of liquid calories during the evening.

- Food fortification may be required to ensure adequate energy intake.
- Optimise glycaemic control:
 - Establish regular meal pattern.
 - Encourage more frequent blood sugar monitoring before and after meals.
 - Consider giving short acting insulin after meals rather than before.
 - Ensure appropriate treatment of hypoglycaemia.
- Other:
 - Consider a multivitamin supplement if diet is inadequate.
 - Patients may benefit from sitting upright during meals.
 - Encourage patients to chew food well.
 - Reduce stress at meal times.

Nutritional support

Patients unable to maintain an adequate oral intake may require enteral or parenteral nutritional support. Oral liquid supplements are often well tolerated, including those containing fat. Patients with diabetes should be offered milk style supplements in preference to juice style supplements as a first line measure. Nasojejunal (NJ) feeding is recommended for patients with vomiting and nausea who are unable to tolerate gastric feeding. Following a successful trial of NJ feeding, jejunostomy placement may maintain hydration and nutrition; however, it is associated with significant complications, including tube displacement and infection (Jones *et al.*, 2003; Fontana & Barnett, 1996). A surgically placed needle-catheter jejunostomy may be preferable to a gastrostomy with a jejunal extension, as the extension tubes often migrate back into the stomach (Karamanolis & Tack, 2006).

Continuous feeding is generally better tolerated than bolus feeding (Abell *et al.*, 2006b). Fibre free feeds may be better tolerated in gastric feeding and in jejunal feeding if small bowel overgrowth or intestinal dysmotility is suspected (Parish & Yoshida, 2005). In studies of gastrostomy fed paediatric patients, whey based formulae decreased gastric emptying time; however, there are as yet no studies confirming this effect in adults (Fried *et al.*, 1992).

Parenteral nutrition may be indicated during acute exacerbations of symptoms or for patients with severe intestinal dysmotility who do not tolerate jejunal feeding (Bouras & Scolapio, 2004).

Effective management of patients with gastroparesis requires a multidisciplinary team approach with close liaison between medical and surgical teams, nursing staff, dietitian, psychologist and pharmacist (Abell *et al.*, 2006a).

7.4.5 Disorders of the pancreas

Mary Phillips

Key points

- Pancreatic disease presents complex multifactorial nutritional challenges.
- Enteral feeding with a peptide feed is the feeding regimen of choice in acute pancreatitis, with emphasis on achieving this early in the disease process.
- Pancreatic cancer and chronic pancreatitis are both associated with progressive malnutrition and patients benefit from early dietetic intervention.
- Pancreatic surgery is highly complex and pre- and post-operative optimisation of nutritional status is required.
- Long term micronutrient deficiencies are becoming more apparent, and screening for these is recommended.
- Probiotics are not recommended in severe acute pancreatitis.

Pancreatic disorders may be benign or malignant, and include acute and chronic pancreatitis and pancreatic cancers. The nutritional consequences of these conditions are diverse and often complicated to manage and therefore present many challenges for dietitians. The pancreas has three main functions that are essential in the digestion and absorption of food and nutrients (Neoptolemos & Bhutani, 2008a,b):

- **Endocrine:**
 - Release of insulin and glucagon from islet cells mainly located in the tail of the pancreas.
- **Exocrine:**
 - Release of digestive enzymes from acinar cells found mainly in the head of the pancreas.
 - Release of bicarbonate to neutralise gastric acid.

Pancreatic enzyme release is stimulated in three phases. The taste and smell of food stimulates an initial release of pancreatic enzymes (cephalic phase). This is followed by the second surge, which is believed to be triggered by gastric distension (gastric phase). The third, and most significant, stimulant of pancreatic enzyme release occurs when the products of digestion are delivered into the duodenum (intestinal phase). This final stage is responsible for the ongoing release of enzymes for 2–3 hours post prandially (Keller & Layer, 2005).

Acute pancreatitis

Acute pancreatitis is an inflammatory condition with an overall mortality of 10–15% (Mann *et al.*, 1994, Corfield

et al., 1985); most commonly associated with gallstone disease or high alcohol intakes. Other causes include trauma, surgery, hypertriglyceridaemia, endoscopic retrograde cholangiopancreatography (ERCP) and drug reaction. In some patients the cause is unknown (Neoptolemos & Bhutani, 2008a,b). Acute pancreatitis usually presents with severe abdominal pain, caused by the auto activation of enzymes within the gland. In the initial stages the treatment is conservative, consisting of pain relief and organ support where necessary. Keeping the patient nil by mouth reduces pancreatic stimulation.

On admission patients are scored to predict disease severity using one of a number of scoring systems. These include Apache II or RANSON criteria, and more frequently the modified Glasgow (or Imrie) score (Table 7.4.3). Increasingly, C-reactive protein (CRP) is considered an independent marker of severity (UK Working Party on Acute Pancreatitis, 2005). In cases of mild pancreatitis most patients are kept nil by mouth until the pain has resolved; however, in some units oral feeding is started early. Recent studies suggest initiation of early oral diet may reduce length of stay when compared with fasting or clear fluids only (Sathiaraj *et al.*, 2008, Eckertwall *et al.*, 2007). The hospital stay is usually short, but if gallstones are the cause of the pancreatitis, a laparoscopic cholecystectomy should be performed.

Patients with severe acute pancreatitis (SAP) may present with, or develop, multiorgan failure or systemic inflammatory response syndrome (SIRS). These patients require intensive care support and may need multiple interventions with hospital admissions stretching over

Table 7.4.3 Modified Glasgow (or Imrie) severity scoring for acute pancreatitis

Parameter	Indicative level
P (PaO ₂ – arterial blood gas)	PaO ₂ < 7.9 kPa
A (Albumin)	<32 g/L
N (Neutrophils)	WCC > 15 mmol/L
C (Calcium)	<2 mmol/L
R (Renal)	Urea > 16 mmol/L
E (Enzymes)	LDH > 600 IU/L or AST > 100 IU/L
A (Age)	>55 years
S (Sugar)	Glucose > 10 mmol/L

A score of ≥ 3 within 48 hours of admission is predictive of severe disease (Blamey *et al.*, 1984) and an indicator for enteral feeding.

WCC, white cell count; LDH, lactate dehydrogenase; AST, aspartate transaminase.

many weeks or months. Comprehensive nutritional support is indicated and enteral feeding is considered to be the gold standard. However, parenteral nutrition may be needed when enteral nutrition is poorly tolerated, either as a sole source of nutrition or ideally, in addition to slow rate enteral feeding (Neoptolemos & Bhutani, 2008a,b; Sakorafas *et al.*, 2010).

Many complications of pancreatitis are septic in origin and the use of enteral feeding to reduce bacterial translocation has been widely studied (Sakorafas *et al.*, 2010). There are many complications of acute pancreatitis that can influence the delivery and tolerance of enteral feeding, including:

- Hyperglycaemia.
- Malabsorption.
- Weight loss and loss of muscle mass – often dramatic.
- Delayed gastric emptying and high nasogastric (NG) aspirates.
- Continuing high NG aspirates with jejunal feeding.
- Nausea and vomiting.
- Prolonged periods of nil by mouth for multiple procedures.
- Paralytic ileus secondary to electrolyte imbalance.
- Antibiotic related diarrhoea.
- Peripheral oedema.
- Gastrointestinal oedema – diarrhoea, obstruction.
- Ascites.
- Gastric varices.
- Colonic necrosis and faecal peritonitis.

Severe acute pancreatitis is usually treated aggressively with multiorgan support and antibiotics. In some instances, necrosis develops and the necrotic tissue is removed surgically with either an open necrosectomy or preferably, a minimally invasive necrosectomy to reduce the risk of further sepsis. The degree of necrosis and

damage arising from inflammation, and the location of such damage, will help predict any long term insufficiency. Extensive disease in the head of the pancreas is more likely to result in long term exocrine insufficiency [requiring pancreatic enzyme replacement therapy (PERT)], whereas disease centred in the tail of the pancreas is more likely to lead to endocrine insufficiency (type 1 diabetes mellitus).

Chronic pancreatitis

Chronic pancreatitis is a progressive inflammatory disease resulting in the destruction of the pancreas. The incidence is between 20 and 200 per 100 000. Chronic pancreatitis is caused by excessive alcohol consumption in 70–90% of cases (Neoptolemos & Bhutani, 2008a,b; Layer & Melle, 2005). In severe cases chronic pancreatitis causes intractable pain and severe malnutrition, leading to multiple admissions for procedures to reduce pain. These include coeliac or endoscopic plexus blocks; thoracic splanchnicectomy; gastric and biliary bypass surgery; ductal drainage procedures or even pancreatic resection. A multidisciplinary team approach is crucial in managing patients with chronic pancreatitis to prevent malnutrition, while managing exocrine insufficiency and optimising pain control.

Patients may be prescribed pancreatic enzymes for pain control, which some studies have suggested provide potential benefit due to a negative feedback mechanism inhibiting cholecystokinin (CCK) release (Hammer, 2010). There is no strong evidence of pain relief benefit provided by PERT, although there may be a benefit from enzymes in tablet rather than the enteric coated form (Khalid & Whitcomb, 2002).

Pancreatic cancer

Pancreatic cancer is the fifth most common cause of cancer death in the UK, with a median survival following diagnosis of 6 months. The high mortality is due to vague early symptoms (including nausea and vomiting, back pain and weight loss), resulting in tumours being diagnosed late, often after they have already metastasised. Early symptoms may include jaundice and new onset diabetes. Unfortunately 85% of patients with pancreatic cancer are identified as having non-resectable tumours at diagnosis, with the most common type of tumour being ductal adenocarcinoma (Neoptolemos & Bhutani, 2008a,b).

Patients who have operable disease and who are fit for surgery are likely to have one of the following procedures:

- Whipple's procedure – removal of the duodenum, head of the pancreas, gallbladder and distal stomach.
- Pylorus preserving pancreaticoduodenectomy (PPPD) – removal of the duodenum, head of the pancreas and gallbladder, but the stomach is left intact.
- Distal pancreatectomy – removal of the tail of the pancreas and usually the spleen.

- Total pancreatectomy – removal of the duodenum, the entire pancreas, gallbladder, usually the spleen, and sometimes the distal stomach.

Postoperatively, patients may experience delayed gastric emptying and/or dumping syndrome (depending on the extent of gastric resection), early satiety, endocrine and exocrine insufficiency, brittle diabetes (following total pancreatectomy) and in the long term vitamin and mineral deficiency.

Treatment options for non-resectable disease include chemotherapy, radiotherapy, palliative surgery (including gastric and biliary bypass), palliative biliary and duodenal stenting, and eventually palliative care (see Chapter 7.15.3).

Nutritional consequences of pancreatic disease

Regardless of whether pancreatic damage has arisen as a result of cancer, acute or chronic pancreatitis, or surgical resection, the nutritional consequences are similar, and can be classified according to their aetiology.

Pain

Pain is a key symptom in both benign and malignant disease, and can play a significant role in the development of malnutrition. Pain may be continuous, but is often associated with eating due to stimulation of the pancreatic secretions following ingestion. Consequently, patients may avoid eating in an attempt to minimise pain. Some patients benefit from soft or liquid based diets, which are thought to result in decreased pancreatic stimulation. (Jacobson *et al.*, 2007).

Endocrine insufficiency

Islet cells, which produce insulin, are predominantly located in the tail of the pancreas. Therefore, pancreatic disease affecting this area or resection of the distal pancreas may result in endocrine insufficiency. In patients with non-resectable malignant disease or chronic pancreatitis, this insufficiency may only become apparent over time. Diabetes caused by pancreatic resection may be brittle, with patients prone to sudden episodes of hypoglycaemia. Insulin is often required and care must be taken to ensure that malnourished patients do not receive inappropriate energy restrictive advice.

Exocrine insufficiency

Malabsorption as a result of exocrine insufficiency causes a variety of symptoms, including steatorrhoea (frequent, pale, loose, floating stools), abdominal bloating and flatulence, unexplained weight loss and micronutrient deficiencies, such as anaemia and fat soluble vitamin deficiency. Malabsorption is managed with PERT. Most patients with pancreatic disease will require PERT with each meal or snack, and with oral nutritional supplements (if prescribed). These enzymes should be given at

the beginning of the meal and the dose titrated up until symptoms of malabsorption are under control.

Management

Low fat diets

Exocrine insufficiency has historically been managed through restriction of dietary fat intake. It is now widely accepted that the use of low fat diets will exacerbate malnutrition and therefore fat restriction is only recommended for symptom control in those who do not respond to PERT (Lankisch, 1999). If nutritional support is indicated, patients should receive high energy, high protein advice in conjunction with PERT to manage exocrine insufficiency.

Pancreatic enzyme replacement therapy

The recommendations for the use of PERT are:

- Enzymes should be prescribed for use with all meals, snacks and nutritional supplements.
- Enzymes are most frequently prescribed in capsule form, although tablet, granules or powered forms are also available.
- Capsules should be swallowed whole at the beginning of the meal, with a cold drink to prevent denaturation of the enzyme.
- Where more than one capsule or tablet is prescribed at a time, their ingestion should be spread out through the meal.
- Enzyme activity peaks at 45 minutes and wears off after 2–3 hours, so enzymes should be given regularly with sip feeds consumed over >45 minutes.
- When granules or powdered enzymes are indicated, these products should be mixed with an acidic fruit purée, swallowed immediately without chewing and the mouth rinsed with a cold drink to prevent premature activation of the enzyme and enzymic damage to the oral mucosa (mouth ulcers).
- Where possible, peptide or elemental feeds should be used for enteral feeding; these feed formulae should not require the use of pancreatic enzymes for digestion.

Micronutrient deficiencies

Multiple micronutrient deficiencies have been associated with pancreatic insufficiency in both benign and malignant disease (Armstrong *et al.*, 2007; Dujsikova *et al.*, 2008). The most clinically significant is vitamin D deficiency, which is associated with osteopenia and osteoporosis (Dujsikova *et al.*, 2008). Routine supplementation with a calcium and vitamin D supplement (Armstrong *et al.*, 2007) and regular monitoring of vitamin D and parathyroid hormone (PTH), and DEXA scans are recommended routinely for patients with chronic pancreatitis (Duggan *et al.*, 2010). Case reports have highlighted incidences of vitamin A deficiency night blindness (Livingstone *et al.*, 2003), deficiencies of selenium, zinc and vitamin E. In addition, anaemia has also been reported (Armstrong *et al.*, 2007).

Enteral feeding

Acute pancreatitis

Historically, patients with SAP were kept nil by mouth for considerable periods of time and if patients were fed, it was usually parenterally (Mitchell *et al.*, 2003). Over the last 20 years, however, evidence has shown that enteral feeding is safer and is associated with reduced morbidity and mortality, and best practice is now to establish feeding via the enteral route early in the evolution of disease (Petrov *et al.*, 2009).

This is supported by a recent Cochrane review of randomised control studies comparing enteral and parenteral nutrition in pancreatitis, which concluded that enteral feeding was associated with a trend towards reduced length of stay and significant reduction in the development of multiorgan failure, systemic complications, need for surgical interventions and overall mortality when compared with patients receiving parenteral nutrition (Al-Omran *et al.*, 2010). Although this review included studies involving patients with pancreatitis of any severity, a subgroup analysis of patients with SAP found similar conclusions. These data were supported by three other meta analyses (Petrov & Whelan, 2010; Petrov *et al.*, 2008a; Marik & Zaloga, 2004) and a recent randomised study (Wu *et al.*, 2010).

The European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines concluded that there is strong evidence that enteral feeding in the first 5–7 days of mild pancreatitis is of no benefit but it is indicated in severe disease, even in the presence of complications such as fistula, pseudocyst and ascites, and that a peptide based feed should be used (Meier *et al.*, 2006). Although enteral feeding is acknowledged to be the optimal feeding route for patients with acute pancreatitis, debate remains as to whether gastric or jejunal feeding is most suitable, and how early enteral feeding should be initiated.

A recent systematic review on the safety and tolerance of NG feeding in SAP found that approximately 80% of patients tolerated full feeding (Petrov *et al.*, 2008b). It showed that there was no difference in mortality or feed tolerance between patients receiving NG or nasojejunal (NJ) feeding. However, an adequately powered randomised controlled study is needed to support the routine use of NG feeding in SAP. In practice, many patients present with nausea and vomiting, in which case NJ feeding is the enteral feeding route of choice. Further studies have reviewed the timing of initiation of enteral feeding, and concluded that there was significant reduction in the risk of multiorgan failure, infectious complications and mortality when enteral feeding was started within 48 hours of admission (Petrov *et al.*, 2009).

Patients with SAP do not normally commence oral intake until the abdominal pain has resolved, and enteral feeding should continue until oral intake sufficient to satisfy their requirements can be maintained. Patients will often require supplementary enteral feeding in addition to a good oral intake due to the high nutritional requirements associated with this disease. The earlier ESPEN guidelines set energy requirements for patients with SAP

at 25–35 kcal (100150 kJ)/kg in the active stage of the disease (Meier *et al.*, 2002).

Chronic pancreatitis

Up to 10% of patients with chronic pancreatitis have intractable pain and malnutrition that does not respond to oral nutritional support. Enteral feeding is often used in these cases, and jejunal feeding may be helpful in cases of duodenal stenosis, delayed gastric emptying or food avoidance due to pain (Meier *et al.*, 2006). Distal jejunal feeding can help to reduce the pain associated with chronic pancreatitis; this is known as *pancreatic rest* (Lordan *et al.*, 2009).

Postoperative enteral feeding

Many pancreatic centres use jejunal feeding post pancreatic surgery, although route, feed formulation and timing of initiation of enteral feeding varies widely across the UK. A solid evidence base is needed to determine best practice (Phillips *et al.*, 2009).

Novel substrates

Probiotics and immune enhancing products

Initial studies appeared to favour the use of probiotics in acute pancreatitis (Qin *et al.*, 2008; Olah *et al.*, 2002). However, probiotics are currently not recommended in acute pancreatitis following a large multicentred randomised double blind, placebo controlled trial in patients with SAP. Probiotic administration was associated with a significant increase in the incidence of bowel ischaemia and increased mortality in the supplemented group (Bessekink *et al.*, 2008). A recent systematic review on the composition of enteral feeds administered to patients with acute pancreatitis concluded that probiotic and immune enhancing products did not further improve patient outcome, and are therefore not recommended (Olah & Romics, 2010).

Antioxidants

Several studies have examined the use of antioxidants for pain control in chronic pancreatitis. A randomised placebo controlled double blind trial of antioxidant supplements found an increase in the number of pain free days in the supplemented group (Bhardwaj *et al.*, 2009). However, a meta analysis reviewing 22 randomised controlled studies concluded that there was insufficient evidence to support antioxidant therapy (Mohseni Salehi Monfared *et al.*, 2009). Subsequent studies in patients with acute pancreatitis confirm the need for further research (Sateesh *et al.*, 2009).

Eicosapentaenoic acid

Many studies have examined the use of fish oils in managing the dramatic weight loss seen in patients with advanced cancer, particularly pancreatic cancer. Some

studies have shown weight gain and improved quality of life when eicosapentaenoic acid (EPA) supplements are used (Fearon *et al.*, 2003) However, a Cochrane review that identified five trials (including a total of 587 patients) concluded there was insufficient data to establish whether oral EPA was more effective than a placebo in improving symptoms in patients with cachexia syndrome (Dewey *et al.*, 2007).

Drug interactions

Octreotide (Sandostatin®) is used to inhibit pancreatic secretions and may be used postoperatively to prevent or treat pancreatic leaks, or to treat neuroendocrine tumours. The product literature states a reduction in pancreatic trypsin release of 76% and in amylase of 84% (Berberat *et al.*, 1999), and similar reduction is also assumed for lipase secretion; the use of octreotide is therefore associated with worsening malabsorption (Witt & Pedersen, 1989).

Lanreotide® or Sandostatin LAR® are long acting versions of octreotide.

7.4.6 Malabsorption

Helen Truby, Kathryn Hart and Janeane Dart

Key points

- Malabsorption may be nutrient specific (affecting fat or carbohydrate) or more generalised (impairing the absorption of all or many nutrients). It may be the manifestation of a primary absorptive defect or a symptom of another underlying condition.
- Tests for malabsorption commonly measure malabsorbed compounds in urine or faeces, absorbed compounds in blood or breath, or the activity of digestive enzymes. Breath tests can also be used to make an indirect assessment of carbohydrate malabsorption.
- The aims of dietary treatment are replacement of lost fluid and electrolytes, symptom relief and achievement of nutritional adequacy (monitoring and replacing nutrient deficiencies).

Malabsorption has many different causes (Table 7.4.4). Dietary measures can be used to alleviate symptoms and nutritional supplementation may be necessary to correct nutritional depletion or prevent further nutritional deterioration. It is however vital that the underlying cause of the malabsorption is identified and, if possible, treated.

Diagnostic features

Clinical features of malabsorption may include some or all of the following:

- Diarrhoea or change in stool consistency.
- Abdominal distension.
- Flatulence or wind.
- Loss of weight in adults or growth failure in children.
- Hypoproteinaemia (or low albumin).
- Iron deficiency anaemia or low serum ferritin.

Generalised nutrient deficiencies are likely and the risk of specific deficiencies is heightened by disease or resection in particular sites of the gastrointestinal tract, chronic diarrhoea and/or self imposed dietary restriction (Figure 7.4.4). The elderly, infants and young children are particularly at risk of dehydration with loss of fluid and electrolytes during acute episodes of diarrhoea.

Very loose stools, with or without urgency, is the most common presenting feature and the nature of the stool often indicates the type or site of the malabsorption:

- *Fat malabsorption* results in steatorrhoea, where the stool is pale, malodorous, greasy and unformed. Stools are often difficult to flush and may leave a greasy residue in the toilet.
- *Carbohydrate malabsorption* more typically results in diarrhoea that is watery and frothy due to the presence of fermented sugars.
- If more than one nutrient is malabsorbed, e.g. due to loss of absorptive surface or pancreatic insufficiency, this distinction is less clear-cut and for milder forms of malabsorption, no stool abnormalities may be reported, e.g. iron deficiency anaemia is a common presenting feature of adults with untreated coeliac disease.

The term malabsorption is often used to incorporate states that should be more correctly defined as maldigestion. Maldigestion refers to any disruption to the digestive (rather than absorption) phases of food and nutrient processing, specifically those relating to enzyme activity.

Clinical tests

Investigations for malabsorption utilise either measurement of absorbed test substances in the blood or urine,

Table 7.4.4 Common causes of malabsorption

Reason for malabsorption	Common causes
Reduced absorptive capacity	Intestinal resection Short bowel syndrome Villous atrophy, e.g. coeliac disease; tropical sprue Active inflammatory bowel disease Gastro- and jejuno-colic fistulae Infiltration, e.g. amyloid, scleroderma, lymphoma Vascular insufficiency Mucosal damage, e.g. drugs or irradiation, or following surgery or serious gastroenteritic infection Some bariatric surgery procedures: biliopancreatic diversion with duodenal switch procedure, Roux-en-Y gastric bypass
Enzyme deficiencies	Disaccharidase deficiency, e.g. primary alactasia or secondary lactase deficiency Lipase and or proteolytic enzyme deficiency, e.g. pancreatic insufficiency
Intra luminal factors	High pH in duodenum, e.g. achlorhydria Low pH in duodenum, e.g. Zollinger–Ellison syndrome Bile salt deficiency, e.g. obstructive jaundice
Infection	Deconjugation of bile salts by bacterial colonisation of the small intestine, e.g. blind loop syndrome Competition for nutrients, e.g. parasitic infections Rapid intestinal transit time, e.g. gastroenteritis
Impaired transport mechanisms	Impaired fat transport, e.g. congenital lymphangiectasia, retroperitoneal fibrosis Impaired monosaccharide transport, e.g. congenital primary malabsorption of glucose and galactose, secondary glucose malabsorption following surgery, protein energy malnutrition or gastroenteritis

or quantification of unabsorbed substances in faeces and/or urine.

Fat

Although the 3-day quantification of stool fat has been the standard test for determining fat malabsorption, this test is poorly reproducible, non-diagnostic and unpleasant for the client. More specific tests using a single small stool sample, such as immunoreactive trypsinogen, faecal elastase-1, faecal chymotrypsin and faecal microscopy, are all used as indicators of pancreatic dysfunction. Breath tests for fat malabsorption, including the use of labelled (^{14}C) triolein or a labelled mixed triglyceride fat load may provide an assessment of both lipolysis and absorption in adults, but are not suitable for infants and very young children.

Carbohydrate

The most useful test for the diagnosis of carbohydrate malabsorption is the hydrogen breath test. Normally cells do not produce hydrogen but in the colonic gut flora will do so if a suitable substrate, such as an unabsorbed disaccharide, is present. The hydrogen then produced will be absorbed into blood and can be detected and measured as it is exhaled via the breath. Measurement of breath hydrogen following a test load of lactose (25–50g) is recommended for the diagnosis of lactose malabsorption, offering similar specificity and sensitivity to alternative methods (mucosal lactase assay and lactose tolerance test), but in a simpler and less invasive way. This test is associated with a false negative rate of up to 25% and a

trial of a lactose free diet may be considered if malabsorption is still suspected despite a negative test result. New criteria have been proposed to reduce the frequency of false negative results (Di Stefano *et al.*, 2004). In infants, unabsorbed lactose in the stool can be clearly identified by paper chromatography or other tests for faecal reducing substances.

The generic methods of breath testing, mucosal enzyme assays (via endoscopic biopsy) and oral tolerance tests can be applied to other disaccharides if specific malabsorption is suspected.

Tests for non-nutrient specific malabsorption

Non-nutrient specific malabsorptive diarrhoea may be caused by generalised loss of absorptive capacity, pancreatic insufficiency or small bowel bacterial overgrowth. Certain bariatric procedures deliberately induce modest (Roux-en-Y gastric bypass) or substantial malabsorption (biliopancreatic diversion with duodenal switch procedure), which then require specific dietetic advice to ensure micronutrient sufficiency (see Chapter 7.13.3). Similarly, malabsorption is often also a key feature of short bowel syndrome, and in these cases the dietitian needs to be actively involved in the management of nutrient, fluid and electrolyte abnormalities and symptom management (see Chapter 7.4.9).

Serological testing (IgA antiendomysial antibodies, antihuman tissue transglutaminase and IgG deamidated gliadin peptide) may be used to assess the likelihood of coeliac disease in symptomatic individuals, with confirmation using the gold standard method of endoscopic jejunal biopsy (see Chapter 7.4.7). No optimal test for

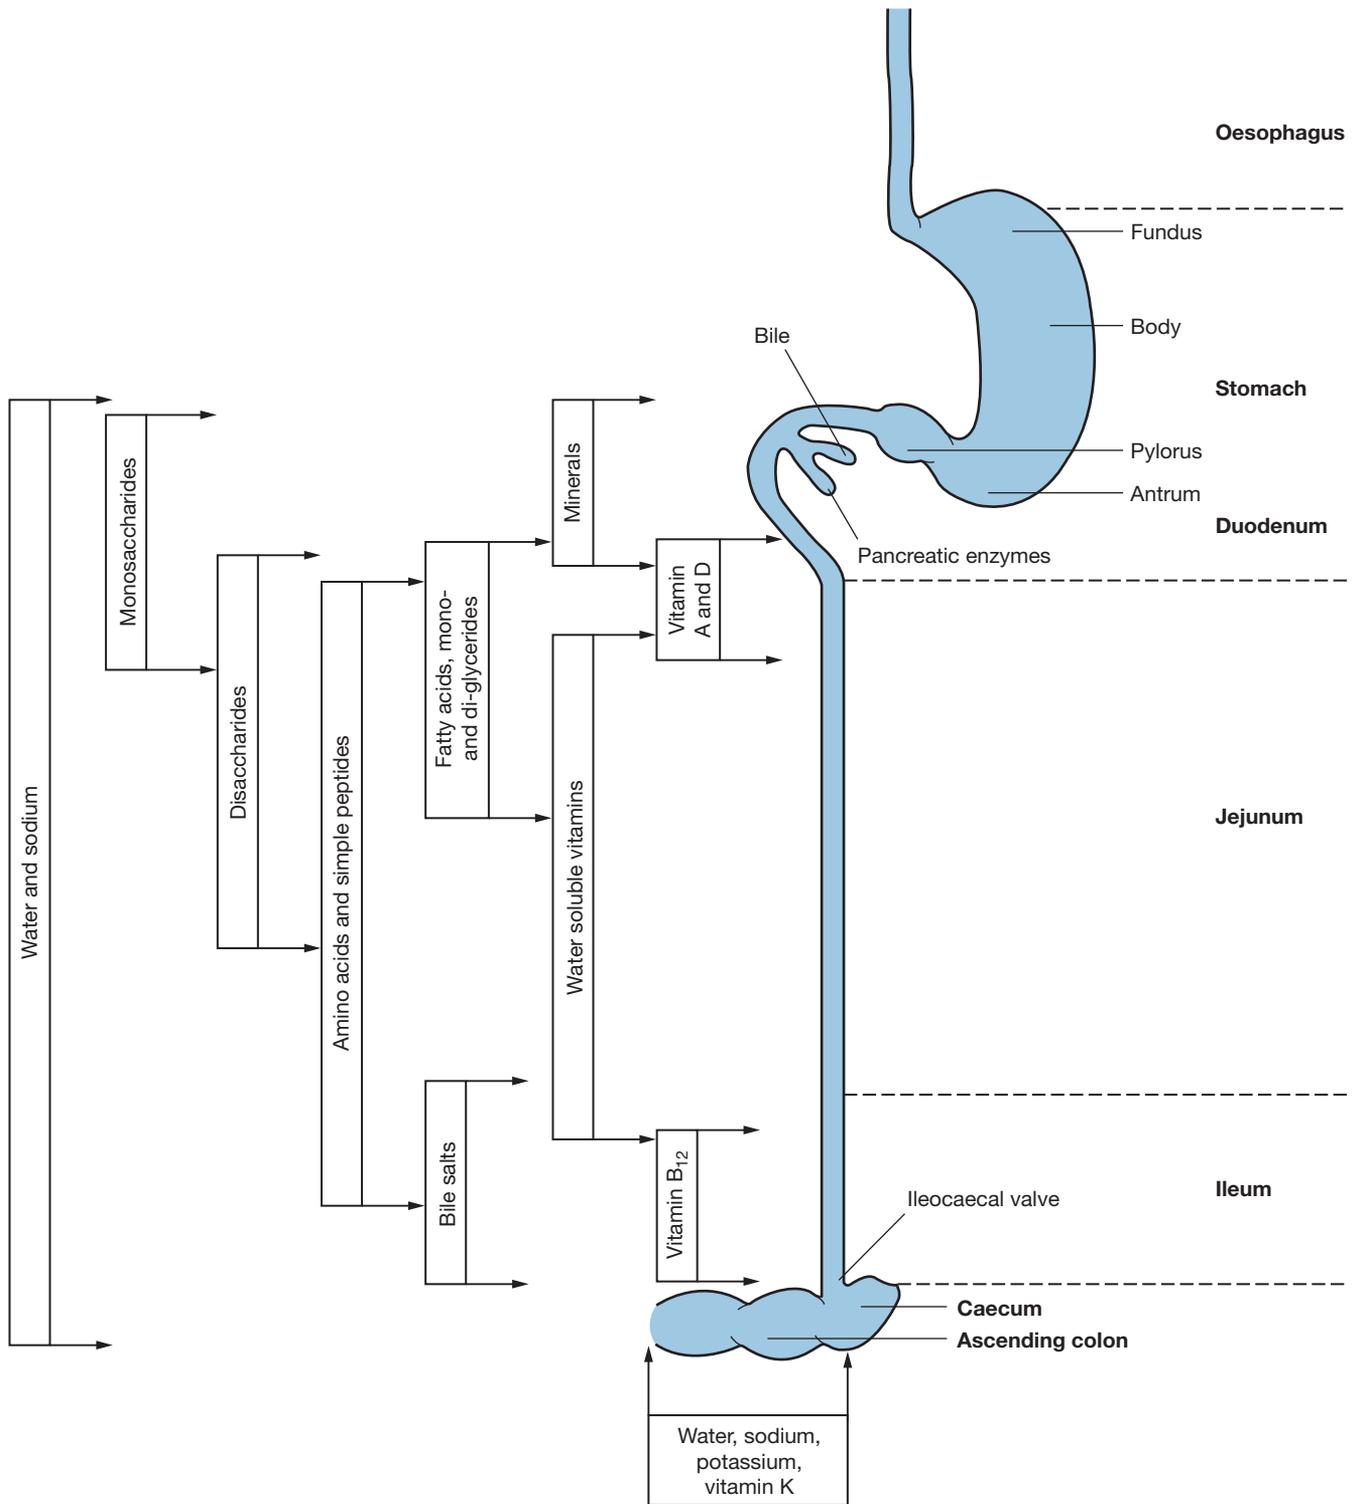

Figure 7.4.4 Principal absorption sites for nutrients

small bowel bacterial overgrowth has been identified. Cultures of small bowel aspirates are recommended, although less sensitive hydrogen breath tests are easier to perform and are more frequently employed. Non-invasive tests for pancreatic insufficiency are limited by the large reserve capacity of the pancreas, which means that 90%

tissue involvement may be required before reductions in pancreatic enzyme secretions are seen. Imaging techniques are used to investigate changes in pancreas structure in severe insufficiency, but faecal elastase remains the first line assessment for malabsorption of suspected pancreatic origin (Thomas *et al.*, 2003).

Dietary treatment

Whatever the cause of malabsorption, the principles of dietary therapy remain consistent:

- Daily replacement of large losses of fluid and electrolytes.
- Dietary treatment of the primary disorder, e.g. removal of gluten in coeliac disease.
- Dietary measures to provide symptom relief.
- Work towards restoring optimal nutritional status, with supplementation for micronutrients and/or trace elements as required.

Specific aspects of particular types of malabsorption are considered below.

Fat malabsorption

The main nutritional significance of the loss of fat is the associated loss of energy and fat soluble vitamins A, D, E and K. Unabsorbed fatty acids may also form complexes with minerals such as calcium and iron, thus inhibiting their absorption. This can increase the risk of long term complications such as iron deficiency anaemia or osteoporosis.

In those with proven chronic malabsorptive states, supplements of fat soluble vitamins will be required to restore losses and prevent further deficiency. In cases of persistent malabsorption, it may be necessary to administer these in a micelleised (water soluble) form or by injection. In children, deficiency of essential fatty acids can occur, necessitating supplementation. Zinc status can also be compromised and measurement of red blood cell zinc can guide the need for supplementation.

Steatorrhoea compromises nutritional status due to energy loss via the stool and may be exacerbated by self selection of low fat foods for symptom relief by the patient. Steatorrhoea due to pancreatic insufficiency can be treated with pancreatic enzymes and clinical practice guidelines exist for both the most common causes, namely cystic fibrosis (see Chapter 7.4.13) and pancreatitis (see Chapter 7.4.5). If despite additional drug therapy (options include the addition of a proton pump inhibitor or acid suppression with an H₂ blocker), the symptoms of steatorrhoea continue to be unacceptable, or are causing electrolyte disturbances or mineral deficiencies, dietary fat intake can be reduced (30% energy), replacing energy via modular carbohydrate supplementation (see Chapter 6.3). Alternatively or additionally, a proportion of long chain triglycerides (LCTs) can be substituted with medium chain triglycerides (MCTs). MCTs are more readily hydrolysed by pancreatic enzymes and about one-third of ingested MCTs can directly enter mucosal cells and be hydrolysed by a mucosal lipolytic system, the medium chain fatty acids then passing into the portal vein.

Intervention studies generally use MCT containing supplements and formulae as pure MCT supplements are often unpleasant and poorly tolerated. If used for cooking, the oil must not be heated above 150–160 °C or its palat-

ability is further impaired. Medium chain triglycerides can cause osmotic diarrhoea and so divided doses of 1 mL, four times a day [providing 1463–1672 kJ (350–400 kcal)] may be better tolerated.

There is good evidence that in acute pancreatitis, elemental or semi elemental feeds are effective when delivered via a tube placed past the ligament of Treitz; there is less evidence of effectiveness of this approach in mild or moderate pancreatitis, although this is accepted in practice (Pancreatitis Practice Guidance Summary www.pennutrition.com).

Carbohydrate malabsorption

Lactose malabsorption

The enzyme lactase is required for the breakdown of the disaccharide lactose into galactose and glucose, which are absorbed. Varying degrees of deficiency of lactase can lead to lactose remaining within the intestine, causing osmotic diarrhoea. Colonic bacteria further ferment the lactose, resulting in symptoms such as abdominal distension, flatulence and explosive watery diarrhoea, which is often acidic in nature and may cause perianal dermatitis. Lactose intolerance occurs in three main forms.

Congenital alactasia

This is a rare autosomal recessive disorder characterised by complete absence of lactase, and requires total and permanent lactose exclusion. The symptoms of profuse watery diarrhoea appear soon after initial feeding with a lactose containing milk. Breastfeeding is contraindicated and the use of lactose free infant formulae is essential. Paediatric dietetic expertise will be required to ensure that the diet remains lactose free but nutritionally adequate from weaning onwards.

Primary lactase deficiency

A gradual reduction in lactase production (lactase non-persistence) causes symptoms of lactose maldigestion in older children and adults (Enattah *et al.*, 2002). This autosomal recessive trait is particularly common in people whose genetic origins lie in countries where milk consumption after infancy is traditionally rare, i.e. South East Asia, India, the Middle East and parts of Africa. The prevalence may exceed 50% in South America, Africa and Asia, and reaching almost 100% in some Asian countries. Data from the USA suggest a prevalence of between 15% (in white people) and 80% (in black people), whilst European rates range from 2% in Scandinavia to about 70% in Sicily (Sahi, 1994).

In lactase non-persistence, undigested lactose and the products of its bacterial fermentation can cause the gastrointestinal symptoms described earlier, although not everyone with low lactase levels has physical symptoms of lactose intolerance (Iqbal *et al.*, 1996). The clinical effects are dose related and only become marked at high levels of intake, e.g. 50-g loads. Many malabsorbers can tolerate moderate intakes of milk products and complete avoidance of lactose is unnecessary and undesirable due to most dairy foods being nutrient dense. Instead,

symptoms should be stabilised at a low intake and lactose containing foods then reintroduced in gradually increasing amounts. The individual level of tolerance varies, but most people with low lactase levels can consume 6g/serving without discomfort (Johnson *et al.*, 1993). In some cases, up to 25g/day (spread throughout the day) or sufficient dairy products to provide 1500 mg of calcium/day may be well tolerated (Suarez *et al.*, 1997; 1998). Fermented milk products may be better tolerated with both delayed gastric emptying and increased transit time being cited as possible reasons, along with the positive effects of certain probiotic strains of bacteria. Yogurts that contain some microbial beta-galactosidase can result in the beneficial proliferation of colonic flora such as bifidobacteria, which can metabolise lactose, and regular lactose ingestion can actually improve tolerance over time (Hertzler & Savaiano, 1996, de Vrese *et al.*, 2001). Exogenous lactase via drops or tablets can be added to milk to reduce lactose load or ready to drink reduced lactose milks and reduced lactose yoghurts are available.

Symptoms may also be less likely to occur if lactose is consumed with food rather than in isolated liquid form such as a glass of milk between meals (Vesa *et al.*, 1996). There is some evidence that temperature may also be related to tolerance, with warm milk being less well tolerated, but there is individual variation (Peuhkuri *et al.*, 2000).

Since the clinical effects of lactose intolerance are similar to those of irritable bowel syndrome, the possibility of primary lactase deficiency should always be considered, particularly in genetically susceptible groups or in children complaining of recurrent abdominal pain, where more common organic causes have already been excluded. It should also be borne in mind that the prevalence of lactose intolerance may be overestimated, with similar gastrointestinal symptoms resulting from a range of other physiological and psychological factors, including milk aversion (McBean & Miller, 1998; Rosado, 1997; Suarez & Levitt, 1996). In those with irritable bowel syndrome (IBS), tolerance to fermentable carbohydrates (fructose and lactose in particular) may be worth investigating further as they have been demonstrated to elicit IBS symptoms in some individuals (Gibson & Shepherd, 2010). Quantification of fructans and other short chain carbohydrates in grains and cereals is available (Biesieki-erski *et al.*, 2011). A clinical pathway for IBS management can be found in Chapter 7.4.10.

Secondary lactase deficiency

This is a common, usually temporary, consequence of damage to the intestinal brush border as a result of severe gastroenteritis, intestinal surgery, chemotherapy, HIV and AIDS, untreated coeliac disease or cow's milk protein intolerance. The condition is characterised by diarrhoea that persists after the primary disorder has been treated and is particularly likely to occur in infants and children. Severe secondary lactose intolerance is sometimes accompanied by secondary sucrose intolerance.

Although transient in nature, it may take weeks rather than days for lactase secretion to be adequately re-established. Most lactase production takes place in the older cells at the tips of the villi rather than in the newer cells at the base. Lactase production is therefore the first of the disaccharidases to be affected by damage to the villi and the last to be restored.

Management depends on the severity of symptoms. In adults and children, avoidance of lactose for a few days will cause symptoms to subside and it can then gradually be reintroduced into the diet with the use of foods such as lactose reduced milk, fermented milk products such as yogurt and hard cheeses. As tolerance improves, the range of lactose containing foods and their level of consumption can be increased. Because the condition is usually resolved within a relatively short timescale, the avoidance of milk and milk based foods, even by children, is unlikely to pose a nutritional problem. However, if lactose (and hence milk) restriction is required for >3–4 weeks, the question of nutritional adequacy in terms of calcium, protein and energy will need to be addressed.

Formula fed infants with secondary lactase deficiency may require a lactose free infant formula as a temporary substitute for cow's milk. Breast milk is usually tolerated but in severe cases, partial or total substitution by a lactose free formula may be necessary. If the secondary lactase intolerance has resulted from an intolerance to cow's milk protein, an alternative milk free, lactose free formula will be required (see Chapter 7.11.2).

Malabsorption of other disaccharides

Primary disaccharidase deficiencies

Congenital disorders such as sucrose–isomaltase deficiency can occur but are rare. Management requires total avoidance of the disaccharide substrate.

Secondary disaccharidase deficiency

Production of enzymes such as sucrase and maltase is less likely to be affected by intestinal damage than lactase, but severe enteropathies or infections, particularly in children, may result in malabsorption of disaccharides, such as sucrose coexisting alongside lactose malabsorption. Temporary avoidance of major sources of sucrose followed by its gradual reintroduction may be necessary.

Monosaccharide malabsorption

Fructose

A natural sweetener with a low glycaemic index, fructose occurs naturally in fruit, vegetables and honey in varying proportions either in the monosaccharide form or bound with sucrose as a disaccharide, such as in sugar cane and sugar beet. In processed foods, high fructose corn syrup (HFCS) has different properties as it is derived from hydrolysed corn starch. There is emerging evidence that excess consumption of fructose and HFCS in particular could be contributing to adiposity, dyslipidaemia, the metabolic syndrome and non-alcoholic fatty liver disease (Elliott *et al.*, 2002; Bantle *et al.*, 2000; Ouyang *et al.*, 2008).

Fructolysis occurs in the small intestine, with fructose being transported to the liver via the GLUT5 mechanism, which does not require insulin. Unabsorbed fructose enters the colon where it is a substrate for bacteria, which produce short chain fatty acids, organic acids and gases. A range of gastrointestinal disturbances such as bloating, abdominal pain, loose stools and flatulence are symptomatic consequences of colonic fermentation byproducts and may become more common in adults as dietary fructose consumption increases (Beyer *et al.*, 2005).

In very young children, apple and pear juices that contain a large proportion of free fructose have been linked to toddler diarrhoea, which resolves when dietary fructose is limited (see Chapter 3.8.12). The breath hydrogen test can be used alongside diet and symptom diaries to gauge individual tolerance to fructose.

Secondary malabsorption of monosaccharides

This may occur in infants following surgery, protein energy malnutrition or gastroenteritis. An initial period of intravenous fluids is often necessary to correct water and electrolyte imbalances. This will be followed by the use of a carbohydrate free formula, during which time there should be careful monitoring for signs of hypoglycaemia. The problem is thought to be one of monosaccharide malabsorption, since disaccharidase activity is normal. The ability to tolerate carbohydrates slowly improves and a monosaccharide such as glucose or fructose may be added to the diet in increasing increments of 1% of normal carbohydrate intake. These children are often underweight and gravely ill, and parenteral nutrition may be life saving if resumption of adequate oral nutrition is delayed. The detailed dietary management of carbohydrate malabsorption in infants and children should be sought in paediatric dietetic textbooks (see Chapter 3.8).

Protein malabsorption

Malabsorption states in which there is a deficiency of enzymes or proenzymes involved in protein digestion, e.g. enterokinase or trypsinogen, are not indications for the dietary restriction of protein. When increased protein losses occur due to an enteropathy or malabsorption, a high protein intake (0.5–1.5 g/kg/day) should be prescribed to allow for the decreased efficiency of absorption. If fat malabsorption is present, foods with a high protein content but which are also low in fat must be selected. Modular protein supplements can be used in conjunction with glucose polymers (Chapter 6.3 and Appendix A10).

Pancreatic enzyme replacement therapy is often a central aspect of management of such malabsorption and maldigestion states that lead to pancreatic insufficiency (Toouli *et al.*, 2010) and more specifically in cystic fibrosis (see Chapter 7.4.13).

7.4.7 Coeliac disease

Helen Fraser-Mayall

Key points

- The prevalence of coeliac disease is 1 in 100. It affects people of all ages, although the average age of diagnosis is between 40 and 60 years.
- It is a multisystem disease that affects many organs, not just the gastrointestinal tract.
- Treatment is a lifelong gluten free diet that avoids wheat, rye and barley and their derivatives. Some patients may also be sensitive to oats.
- Dietetic management aims to optimise absorption of nutrients and help prevent or treat complications, e.g. osteoporosis.
- Dietetic advice needs to be tailored to individual needs due to varying degrees of sensitivity to gluten.
- The prevalence of type 1 diabetes and autoimmune thyroid disease is increased in patients with coeliac disease.

Coeliac disease is an inflammatory condition of the small intestinal mucosa that is induced by the ingestion of gluten and which improves clinically and histologically when gluten is excluded from the diet. It is alternatively termed coeliac sprue or gluten sensitive enteropathy. Gluten is often used as a generic term to collectively describe all the cereal proteins that are toxic to individuals with coeliac disease. Wheat, barley and rye have all been shown to cause intestinal inflammation in coeliac patients, but the possible toxicity of oats continues to be debated (British Society of Gastroenterology (BSG), 2010). Coeliac disease can present at any age and has a wide range of clinical manifestations. The average age of diagnosis has risen in the UK to 40–60 years (BSG, 2010).

Traditionally, coeliac disease has been associated mainly with gastrointestinal symptoms, e.g. diarrhoea, abdominal pain and bloating, as chronic inflammation of the small intestine is a feature of the immune response to gluten. However, increasingly non-gastrointestinal features of coeliac disease have been recognised in people presenting with the disease. Some people with coeliac disease have no obvious symptoms (NICE, 2009). Coeliac disease is a multisystem disorder that can affect a variety of organs and can present with non-specific symptoms that may be overlooked in diagnosis (Johnston *et al.*, 1998).

Intolerance to gluten is permanent; the key treatment is lifelong adherence to a gluten free diet that can be difficult to accept and follow. Dietary compliance is associated with severity of symptoms and the more symptomatic, the greater the need for compliance with the gluten free

diet (Westman *et al.*, 1999). Persistent problems are most often due to non-compliance, but other reasons are lactose intolerance, pancreatic insufficiency and microscopic colitis (Ahmad *et al.*, 2002). Gluten intolerance can also manifest itself as dermatitis herpetiformis, which appears as a cutaneous rash and may be associated with gastrointestinal symptoms.

Coeliac disease is more prevalent in people with autoimmune conditions such as type 1 diabetes or autoimmune thyroid disease, and in first degree relatives of people with coeliac disease (NICE, 2009). Primary complications of coeliac disease are osteoporosis and malignancy; however, recent work has indicated that the risk of malignancy is not as significant as previously thought (BSG, 2010).

Coeliac disease results from an immune reaction to antigenic fractions within gluten. The responsible fraction of gluten in wheat is gliadin, an alcohol soluble prolamin that is a mixture of proteins, and the different gluten peptides are involved in different ways. Some peptides cause mucosal damage by triggering an immunological pathway that has a rapid effect (innate immune response), whereas others stimulate a different immunological response (adaptive immune response) (Ciccocioppo *et al.*, 2005).

As well as gliadin in wheat, prolamins found in other cereals, e.g. secalin in rye and hordein in barley, also trigger the immunological response leading to coeliac disease. Similar proteins (avenins) are found in oats, but these are not thought to be harmful to the majority people with coeliac disease (see Oats section).

Onset and prevalence

Coeliac disease can develop and be diagnosed at any age. It was historically only associated with childhood, but now only 9% of all coeliac patients are diagnosed under the age of 16 years. This is partly due to the exclusion of gluten in infant formula and partly the increase in diagnosis rate in the adult population (BSG, 2010). Recent evidence suggests introducing gluten between 4 and 7 months while breastfeeding may reduce the risk of coeliac disease and wheat allergy (ESPGHAN, 2008). Current weaning guidelines recommend that the age range at which to begin weaning should not change unless there is strong scientific evidence (BDA, 2013).

The prevalence of coeliac disease has historically been difficult to determine because many cases with coeliac disease do not have specific signs and symptoms. Therefore, the prevalence has been considerably underestimated. In national studies in the UK, the prevalence ranges between 0.8% and 1.9%. This is broadly similar to the prevalences found in other international studies (NICE, 2009). Recognition of this higher prevalence demonstrates the clinical variability of coeliac disease (Leeds *et al.*, 2008). It affects 1 in 100 people in the UK, making it much more common than previously thought. Delayed diagnosis is common, with 13 years being the average time from first reporting of symptoms to diagnosis. Under diagnosis is a big problem and as many as 500 000 people remain undiagnosed in the UK.

The prevalence of coeliac disease is at least 10% in first degree relatives and approximately 2% in second degree relatives (Hogberg *et al.*, 2003). When coeliac disease is inherent in a family, there is a 1 in 10 chance that a new baby will develop the condition. There is limited evidence that the prevalence of coeliac disease is twice as high in females as in males (NICE, 2009). Coeliac disease is associated with a particular HLA genotype, with the HLA DQ heterodimer appearing to confer disease susceptibility. Approximately 95% of people with coeliac disease have been shown to have HLA DQ antigen and studies looking at identical twins have found concordance levels of 75–90% (Greco *et al.*, 2002) (see Chapter 5.1).

Clinical presentation

In children and adults, coeliac disease can present with a broad range of signs and symptoms, the most frequent being:

- Abdominal pain, cramping or distension.
- Chronic or intermittent diarrhoea.
- Faltering growth in children.
- Fatigue.
- Iron deficiency anaemia.
- Nausea or vomiting.
- Weight loss.

Symptoms in children with coeliac disease depend on the age at presentation, and can develop following weaning and the introduction of foods that contain gluten at between 6 months and 2 years (Fasano, 2005). Under

the age of 2 years the clinical picture is characterised by a lethargic or irritable child, with loose, pale, offensive smelling stools and a bloated abdomen. In infants, vomiting, anorexia and constipation may be seen. Between the ages of 2 and 16 years coeliac disease presents with gastrointestinal symptoms, nutritional deficiencies, impaired growth and generally failing to thrive. Short stature or growth delay may be picked up during weight and height assessment. Typically a child presents with:

- Loss of appetite.
- Faltering growth.
- Unhappy or clingy behaviour.
- Abnormal stools.
- Abdominal distension.
- Small stature.
- Muscle wasting.

In children with coeliac disease stools become pale, frequent and bulky. Constipation and diarrhoea may be seen and can alternate, and vomiting may also occur. Atypical symptoms may include dental enamel defects, recurrent mouth ulcers, muscle pain and stiffness. Symptoms such as anaemia and short stature are often common and it is therefore important that children are carefully monitored to ensure early diagnosis. In older children, an atypical presentation is more common, with failure to achieve normal growth.

The traditional view of a patient presenting with coeliac disease is one of being underweight. In adults, the clinical picture is very variable (Emami, 2008; Green *et al.*, 2001; Tursi *et al.*, 2001; Gillett *et al.*, 2003; Lo *et al.*, 2003; Vilppula *et al.*, 2008). Although the onset can be acute and cause severe diarrhoea and rapid weight loss, it is usually more insidious with less obvious symptoms resulting from chronic malabsorption such as:

- Tiredness.
- Irritability.
- Depression.
- Breathlessness.
- Anaemia.
- Oedema.
- Abdominal discomfort.
- Mild gastrointestinal upsets.
- Unexplained weight loss.
- Recurrent mouth ulcers.
- Bone and joint disorders, arthralgia or osteoporotic fracture.
- Infertility.
- Dental enamel defects.
- Neurological symptoms.

The nature of these symptoms explains why the condition is not always recognised. Studies of newly diagnosed adult patients have found that fewer than half have symptoms of diarrhoea, and even fewer show signs of weight loss (Green & Jabri, 2003). Dickey & Kearney (2006) suggested that patients with coeliac disease can be of normal weight or overweight at diagnosis. Valletta *et al.* (2010) found that coeliac disease and obesity could coexist both in children and adolescents.

The absence of signs of malabsorption can be explained by coeliac disease affecting mainly the proximal small bowel, so there is considerable functional reserve. In the absence of obvious signs of malabsorption, symptoms such as tiredness and anaemia may be attributed to other causes (Hin *et al.*, 1999). Diagnosis is therefore often missed or delayed, particularly in elderly people (Hankey & Holmes, 1994). A common misdiagnosis is irritable bowel syndrome (Shahbazkhani *et al.*, 2003). In adults, anaemia may be a particularly important indicator of coeliac disease. In coeliac patients identified by serological screening (with subsequent confirmatory biopsy), over 80% did not have gastrointestinal symptoms, but over half did have anaemia (Hin *et al.*, 1999). Coeliac disease should therefore be considered in any patient with anaemia or symptoms of tiredness, especially when there is a family history of the disease.

Diagnosis

Biochemistry

Specific circulating antibodies are present in coeliac disease and titres decrease when a gluten free diet is commenced. The National Institute for Health and Care Excellence (NICE, (2009) recommends the use of serological tests for endomysial antibodies (EMAs) and tissue transglutaminase antibodies (TTGAs) in the diagnostic process for coeliac disease. It is essential for patients to continue having a normal gluten containing diet before considering diagnostic tests for coeliac disease. The NICE (2009) guidelines recommend that if the diet has been changed, foods that contain gluten should be eaten in at least one meal every day for at least 6 weeks before testing.

However, immunoglobulin A (IgA) deficiency will produce a false negative result and people with coeliac disease are more likely to be IgA deficient: 2.5% in coeliac disease compared with 0.25% in the general population (Lenhardt *et al.*, 2004). The use of IgG antibody testing is recommended in those deficient in IgA (NICE, 2009). Therefore, a combination of TTG and EMA testing is used. Blood samples are initially tested for IgA TTG antibodies and positive results are then tested using an EMA test. Positive EMA individuals should be referred for duodenal biopsy. Those with only TTG positive results need to be considered for further evaluation, but the majority of these have antibody titres at the lower range compared with those who are also EMA positive (BSG, 2010). While these tests are useful, especially in primary care, a duodenal biopsy is necessary to confirm diagnosis. Where suspicion of coeliac disease is high, a patient should proceed to biopsy regardless of serological test results. They can also be useful as a screening tool to identify silent or undiagnosed cases of coeliac disease in high risk groups, e.g. family history of the disease, type 1 diabetes or autoimmune thyroid disease.

Small bowel histology

Duodenal biopsy should be performed in all patients suspected of having coeliac disease and all those who

merit exclusion of coeliac disease (BSG, 2010). Duodenal biopsy carries minimal risk, and has high positive and negative predictive values. Duodenal biopsies should be taken in those with:

- Positive coeliac antibodies.
- Iron deficiency anaemia.
- Folate deficiency.
- Osteomalacia.
- Malabsorption.
- Abnormal duodenal appearances.
- Significant unexplained weight loss.

Negative coeliac serology should not preclude duodenal biopsy in those who have other indications (Hopper *et al.*, 2007). Visible abnormalities at endoscopy include mucosal pallor, visible vessels, mosaic pattern, micronodular appearance, scalloping and reduction in duodenal folds. These changes have been shown to correlate with degrees of villous atrophy (Niveloni *et al.*, 1998). As with serological testing, it is essential that a gluten containing diet be maintained before a biopsy is carried out.

Marsh classification

The stages of damage to the small bowel seen in coeliac disease are graded by the Marsh (1992) classification:

- Marsh 0: normal mucosa.
- Marsh 1: increased number of intraepithelial lymphocytes.
- Marsh 2: increased lymphocytes and crypt depth.
- Marsh 3: partial or complete villous atrophy – classic coeliac lesion.
- Marsh 4: villous atrophy without lymphocytes: rare and typically unresponsive to diet.

Long term consequences

Malignancy

Coeliac disease is associated with a small increase in the risk of malignant small intestinal lymphomas, mainly non-Hodgkin's lymphoma (West *et al.*, 2004a; Catassi *et al.*, 2005). The risk of lymphoma is reduced by adherence to a strict gluten free diet and after approximately 5 years the risk is likely to have been reduced to the level of the general population (Holmes *et al.*, 1989; Askling *et al.*, 2002). Coeliac disease also increases the risk of small bowel adenocarcinoma (Holmes *et al.*, 1989; Howdle *et al.*, 2003). However, research by Van Heel & West (2006) has suggested a decrease in the risk of breast cancer in people with coeliac disease, although the reasons for this are unclear.

Osteoporosis

Undiagnosed coeliac disease is related to low bone mineral density, osteoporosis and increased risk of fractures (NICE, 2009). Bone metabolism is disturbed and both treated and untreated people with coeliac disease appear to have an increased risk of osteoporosis. Approximately 75% of adults with untreated coeliac disease suffer

from osteopenia or osteoporosis (Corazza *et al.*, 2005). Even in people with few symptoms of coeliac disease, bone mineral density can be significantly lower than in the general population. There is reduced bone mineral density, osteopenia or osteoporosis in 20–50% of patients newly diagnosed with coeliac disease, making it the most common complication of coeliac disease (Bianchi & Bardella, 2002). Risk factors, specifically related to coeliac disease that may reduce bone mineral density and increase the risk of osteoporosis include:

- Late or delayed diagnosis of coeliac disease in adult life.
- Chronic malabsorption of calcium prior to diagnosis.
- Reduced intake of calcium following diagnosis; bread and cereal foods contribute to about 30% of daily calcium intake (Henderson *et al.*, 2003).
- Lapses from the gluten free diet.
- Persistent villous atrophy.
- Lactose intolerance.
- Low BMI.

Many of these may result in chronic malabsorption of foods, with calcium malabsorption leading to greater bone loss. There is a moderate risk of fracture in coeliac disease (Thomason *et al.*, 2003, Ludvigsson *et al.*, 2007). Following a gluten free diet helps to optimise calcium absorption and improve bone mineral density, although it may not restore this to the level found in a non-coeliac population (Corazza *et al.*, 1995, McFarlane *et al.*, 1995; Pazianas *et al.*, 2005). The prevalence of reduced bone density after 1 year of following a gluten free diet is similar to that after 3 years. This suggests that the extent of bone mass gain in the first year of dietary treatment is indicative of overall bone mineral density improvement (Corazza *et al.*, 2005). A calcium rich gluten free diet can achieve better remineralisation (Ciacci *et al.*, 1996) (see Chapter 7.9.1).

Calcium requirements in adults

The BSG (2007) guidelines for osteoporosis in inflammatory bowel disease and coeliac disease recommend 1000–1500 mg of calcium/day for adults with coeliac disease.

Calcium requirements in children

There are no guidelines recommending a higher requirement for calcium in children with coeliac disease. It is recommended that an individualised calcium rich, gluten free diet is followed that uses reference nutrient intake values (Department of Health, 1991) as a guide (see Appendix A2).

Associated conditions

Type 1 diabetes

The association between coeliac disease and type 1 diabetes mellitus is probably due to a common genetic predisposition. The gene *HLA DQB1* is present in the majority of people with both coeliac disease and type 1 diabetes (Hervonen *et al.*, 2004; Antonio & Gino, 2009). Approxi-

mately 2–10% of people with coeliac disease will also have type 1 diabetes mellitus. Coeliac disease should therefore be suspected in any patient who has type 1 diabetes with gastrointestinal symptoms or unexplained anaemia. Presentation of coeliac disease is often silent in type 1 diabetes and many diabetes centres screen patients for coeliac disease (Saukkonen *et al.*, 1996). There is also evidence to suggest that screening of siblings should be carried out as the incidence of coeliac disease in this group has been found to be 1.3–3.8% (Sumnik *et al.*, 2005). Adherence to the gluten free diet can improve growth parameters in children and long term blood glucose control in people with type 1 diabetes (Saadah *et al.*, 2004).

Autoimmune disorders

The link between coeliac disease and autoimmune thyroid disease is well recognised, with a prevalence of autoimmune thyroid disease of 7% in coeliac disease. Graves' disease (hyperthyroidism) and Hashimoto's thyroiditis (hypothyroidism) are the most common conditions (Ch'ng *et al.*, 2005; Valentino *et al.*, 2002). Screening patients with these thyroid disorders for coeliac disease is strongly recommended (NICE, 2009). Sjögren's syndrome is an autoimmune disorder with a coeliac disease prevalence of 4.5–15% (Luft *et al.*, 2003; Rutherford, 2004).

Abnormal liver function

Elevated transaminase levels can be associated with coeliac disease, with 42% of patients newly diagnosed with coeliac disease found to have raised levels (Duggan & Duggan, 2005), the majority returning to having normal levels after commencement of a gluten free diet. Biliary cirrhosis has been linked with coeliac disease in some (Floreani *et al.*, 2002), but not all, populations (Habior *et al.*, 2003). It is recommended that people with autoimmune liver conditions should be considered for screening of coeliac disease (NICE, 2009).

Down's syndrome

The high prevalence of coeliac disease in people with Down's syndrome (5–6%) (Goldacre *et al.*, 2004; Carnicer *et al.*, 2001) is possibly explained by genetic factors, although the nature of the linkage remains to be determined (Morris *et al.*, 2000).

Dermatitis herpetiformis

Dermatitis herpetiformis is the skin presentation of coeliac disease. It is characterised by a persistent, itchy blistering rash that usually occurs on the knees, elbows, buttocks and back, although it can affect any area of skin. Intestinal biopsy nearly always shows the characteristic flattening of intestinal villi. Gastrointestinal symptoms may be mild and absent; fewer than 10% of people with dermatitis herpetiformis have gastrointestinal symptoms characteristic of coeliac disease (Caproni *et al.*, 2009).

Another 20% have atypical symptoms, but >60% will have undiagnosed coeliac disease (Coeliac UK). Diagnosis of dermatitis herpetiformis is by biopsy of an unaffected area of skin. The NICE (2009) recommends that people with dermatitis herpetiformis should be screened for coeliac disease.

Dermatitis herpetiformis is less common than coeliac disease, with a UK incidence of about 1 in 10 000; it is more common in men and usually presents at 15–40 years of age, being rare in children. As with coeliac disease, there is an inherited tendency to develop the disease, and there are links with autoimmune thyroid disease and type 1 diabetes (Reunala & Collin, 1997), with both patients with dermatitis herpetiformis and family members being at increased risk of developing these disorders (Hervonen *et al.*, 2004).

The condition is managed by a gluten free diet, but as it can often take several months before the rash improves and nearly 2 years before it disappears completely, a range of medications may need to be prescribed to control the rash, including dapsone.

Patients with dermatitis herpetiformis are affected by the same long term complications as those with coeliac disease, including lymphoma (Hervonen *et al.*, 2005). There is a high prevalence of anaemia, which may be exacerbated if dapsone treatment is used. There is also increased of osteoporosis (Reunala & Collin, 1997). It is therefore important that attention is paid to the overall nutritional content of the diet, particularly in respect of micronutrients, as well as gluten avoidance.

Management

Guidelines for the diagnosis and management of CD are available, including:

- *Children:*
 - British Society of Paediatric Gastroenterology, Hepatology and Nutrition (BSPGHAN, 2006) <http://bspghan.org.uk>.
- *Adults:*
 - British Society of Gastroenterology (BSG, 2010) www.bsg.org.uk.
 - Primary Care Society of Gastroenterology (PCSG, 2006) www.pcsog.org.uk.
 - Clinical Resource Efficiency Support Team (CREST, 2006) www.gain-ni.org.uk.

The dietitian has a key role to play in supporting patients in the effective management of coeliac disease both in terms of optimising nutrient intake and maintaining quality of life. Diet therapy is essential in the management of patients with coeliac disease.

Dietary management

All newly diagnosed coeliac patients should have a nutritional assessment with a dietitian to establish overall dietary adequacy and associated goals. Following a gluten free diet requires specific education, which should be

provided by a dietitian with experience in coeliac disease (BSG, 2010).

Dietary objectives

The dietary objectives are to ensure that people with coeliac disease:

- Exclude all dietary sources of gluten.
- Know which foods and ingredients are naturally free from gluten.
- Substitute gluten containing foods and ingredients with gluten free alternatives to improve dietary acceptability, nutritional adequacy and compliance.
- Consume a balanced diet which helps maintain health and prevent or manage associated diseases, particularly osteoporosis.

The dietitian needs to ensure that the diet is sufficiently energy and nutrient dense to meet increased needs and help restore losses. At diagnosis, iron deficiency is common as well as subclinical deficiencies of other vitamins and minerals, especially folate, vitamin D and calcium. Additional vitamin and mineral supplementation, particularly of iron, may be required for a period of weeks or months in those shown to have deficiencies.

The limited period (typically 20–30 minutes) allocated to an outpatient appointment for a newly diagnosed coeliac patient rarely allows all topics to be discussed. A survey of provision of dietetic services in the UK showed that a quarter of dietetic departments in the UK allocated 1 hour a month per 100 000 per population (Nelson *et al.*, 2007) despite the minimum recommended level of provision of 8 hours per month per 100 000. More hours were allocated where a multidisciplinary team undertook care either in a gastroenterology or specialist coeliac clinic setting. Coeliac review clinics take place both in primary and secondary care, with different healthcare professionals (HCPs) taking the lead. Dietitian led coeliac clinics are evolving in the management of patients with coeliac disease (Wylie *et al.*, 2005), although dietitian led clinics should have support from gastrointestinal physicians (Leeds *et al.*, 2008).

A new patient appointment check list is available from Coeliac UK to assist dietitians in covering the most important issues, such as a simple explanation of the principles of a gluten free diet, provision of written information on gluten containing foods, obtaining gluten free products, symptoms, cross contamination and eating out. Individuals should be encouraged to join Coeliac UK to gain access to the annually updated food and drink directory, gluten free products and manufacturers. Coeliac UK also provides a nationwide support group network and a wide range of information leaflets.

Symptoms of coeliac disease such as bloating and diarrhoea usually improve within a few weeks of commencing a gluten free diet. It often takes >12 months for mucosal damage to the small bowel to be completely repaired and villi return to normal (Dickey *et al.*, 2000), so other symptoms such as anaemia may take longer to improve. A dramatic drop in antibody levels will be seen in the first month following commencement of the diet, but antibod-

ies may still be present 12 months after commencement of the diet. For this reason, positive antibodies or a degree of villous atrophy in the first 12 months following diagnosis do not necessarily suggest that the patient is not adhering to the diet (Midhagen *et al.*, 2004).

Dietary sources of gluten

A typical daily diet contains an estimated 10–20 g of gluten derived from multiple sources and a gluten free diet therefore necessitates the calculated avoidance of many foods (BSG, 2010). Gluten is used here as a generic term to encompass all the proteins derived from wheat (gliadins), rye (secalins) and barley (hordeins). Oats contain the gluten like protein avenins and their place in the gluten free diet is not uniform. Some people may be sensitive to avenins and individual tolerance should be assessed. Wheat flour is a particularly ubiquitous constituent of a modern diet being contained in bread, breakfast cereals, pasta, pizza, pastry, biscuits, cakes and sauces. The presence of gluten in foods made from wheat flour, such as bread, cakes, biscuits, pasta and pastry, is easy to identify. However, gluten is also a hidden component of many manufactured foods and can be present in almost any type of product, e.g. vending machine drinks. These sources are much less apparent and are also difficult to predict since some brands in a product range may contain gluten while others do not. Under European law food labels must now show the presence, or possible presence, of gluten (see Chapter 4.5).

Food labelling

If a food has a gluten containing cereal as an ingredient, this must be stated on the label. Some ingredients that are derived from gluten containing cereals, such as glucose syrup and maltodextrin, are exempt from this labelling as the level of gluten contained in them is below the level that is toxic in coeliac disease (EC 2000; EC 2003; EC 2005). Previously, the standard for gluten free was <200 parts per million (ppm) of gluten. Legislation for labelling of gluten free foods is based on the Codex standard (2008) (used in the UK and Europe); foods labelled as gluten free must contain <20 ppm of gluten, or if labelled as very low gluten, 20–100 ppm (see Chapter 4.5).

Manufactured foods may contain gluten as a result of wheat flour being added as an ingredient, processing aid, binder, filler or a carrier for flavourings and spices. Although wheat flour may only be present in small amounts, this can still be significant in terms of gluten content. Since February 2000, manufacturers are required to state in the ingredients listing the origin of starch or modified starch if this is likely to contain gluten. Other substances derived from wheat, rye, barley (or oats) may be used as an ingredient, e.g. barley malt extract.

Coeliac UK licenses the Crossed Grain symbol (Figure 7.4.5) to a growing number of manufacturers who produce gluten free foods and drinks. It is an internationally recognised symbol and registered trademark. Many food manufacturers and supermarkets use their own symbol to flag up gluten free foods. It is essential that

Figure 7.4.5 The Coeliac UK Crossed Grain symbol licensed to manufacturers to indicate a gluten food produce [source: Coeliac UK. Reproduced with permission of Coeliac UK (www.coeliac.org.uk)]

patients check the ingredients list on foods and not just the allergy advice box on the food label.

Contamination

Gluten may also be present due to cross contamination during production but this may not be flagged up on the label (Collin *et al.*, 2004). Contamination with wheat, rye, barley (or oats) can occur during food production or storage. For example, flour particles from foods being made in one area can be suspended in the atmosphere and cross contaminate supposedly gluten free foods being produced in another. Traceability of ingredients and minimising risk of contamination are essential components of quality control on the food industry and the food service sector. It is important that gluten free foods are not contaminated with gluten during storage and preparation.

In the home, practical measures that patients can take to reduce the risk of contamination include:

- Wash surfaces, chopping boards or utensils thoroughly before preparing food or use a separate set of utensils.
- Use a separate toaster for gluten free breads or toaster bags, or foil on a clean grill to make gluten free toast.
- Cook gluten free food in separate dishes.
- Wash hands after handling gluten containing food.
- Serve gluten free food with separate utensils.
- Use separate containers for butter, jams, chutneys, etc., or ensure that a clean knife or spoon is always used to serve them.
- Ensure that gluten free food is not prepared in a floury atmosphere.

Foods and ingredients naturally free from gluten

Most foods that have not been processed, such as fresh meat, fish, eggs, cheese, milk, fruit and vegetables, can be safely included in a gluten free diet (see Table 7.4.5).

Prescription of gluten free products

Gluten free prescribing guidelines were produced for healthcare professionals by the collaboration of Coeliac UK, BDA, BSPGHAN and PCSG (2011). The national

Table 7.4.5 Gluten content categorisation of some foods

	Gluten free	May contain gluten	Gluten containing
Cereals and flours	Manufactured gluten free products Rice (white, brown, wild, rice flour, ground rice) Maize (corn), maize starch, cornmeal, popping corn Polenta Potato flour, potato starch Soya, soya flour Bean flours (chick pea flour, split pea flour) Sago, tapioca, cassava Arrowroot Amaranth Buckwheat Millet Quinoa Sorghum Teff Cornflour	Oats (contain gluten like protein; may cause symptoms in some patients – see text)	Wheat, rye, barley Bulgar wheat, durum wheat Spelt, triticale, kamut Wheat flour (e.g. plain/self raising/strong flour) and other flours derived from rye, barley, spelt, triticale and oats Wheat starch Wheatgerm Wheat bran, oat bran Semolina, couscous Malt and malted barley
Bread, cakes and biscuits	Manufactured gluten free products, e.g. bread, rolls, crispbread, biscuits Pastry, cakes biscuits made with gluten free flours or mixes Rice cakes Cakes made without flour (e.g. macarons) Gluten free pizza bases		Bread and bread products containing wheat, rye, barley, including croissants, brioche, naan bread, pitta bread, chapattis, parathas, ciabatta, ryebread Ordinary biscuits, crispbread, crackers, matzos, rusks Ordinary cakes and pastries, muffins and scones Pizza, pastry, croutons Batter, pancakes, Yorkshire pudding Fresh, dried or canned pasta and noodles
Pasta	Manufactured gluten free pasta Corn pasta; rice pasta	Rice noodles	
Breakfast cereals	Manufactured gluten free muesli Buckwheat flakes	Cornflakes Rice cereals Porridge oats and oatmeal	Wheat based breakfast cereals Muesli
Fruit, vegetables, pulses and nuts	Fresh, frozen, canned, dried whole or sliced fruit Fresh, frozen, canned vegetables Peas, beans, lentils Plain, roasted, salted nuts	Chips Instant mashed potato Vegetables in sauce Canned fruit pie fillings Canned baked beans Dry roasted nuts	Vegetables and potatoes coated with batter, breadcrumbs or flour Fruit pies, pasties or fruit coated with batter or flour
Milk and dairy products	Whole, semi skimmed, skimmed milk Dried skimmed milk Evaporated and condensed milk Sterilised and UHT milk Soya milk Goat's milk Cream Cheese including cheese spreads and processed cheese	Yogurts and fromage frais Coffee and tea whiteners Artificial cream	Milk with added fibre Yogurt and fromage frais containing muesli or cereals
Meat and meat products	Fresh red meat, poultry, game and offal Meat canned or prepacked in its own juices of jelly Smoked or cured pure meat such as bacon or ham Gluten free sausages Continental sausages that are 100% meat	Beefburgers Canned meat products Meat pastes, pâtés	Any type of meat coated in breadcrumbs or batter Meat pies and puddings Haggis Ordinary sausages and sausage meat Faggots and rissoles
Fish and shellfish	All fresh fish and other seafood Smoked, kippered and dried fish Fish canned in oil or brine Gluten free fish fingers	Fish in sauce Fish pastes and pâtés	Fish/shellfish in batter or breadcrumbs Fish cakes Fish fingers Taramasalata

Table 7.4.5 (Continued)

	Gluten free	May contain gluten	Gluten containing
Eggs	Whole eggs Egg yolk Egg white Meringue (free from flour)	Egg substitutes	Scotch eggs
Desserts and puddings	Jelly Sorbets Milk puddings made with gluten free ingredients Custard powders	Ice cream Instant dessert Mousses	Semolina and macaroni milk puddings Trifle Sponge and suet puddings
Fats and oils	Butter Lard Vegetable oils, margarines and fat spreads Reduced and low fat spreads		Suet
Soups, sauces and seasonings	Salt, peppercorns Tomato purée Garlic, herbs and spices Wine and cider vinegars Pickled vegetables in vinegar Gluten free stuffing mix	Canned and packet soups Packet sauces and sauce mixes 'Cook-in' sauces Bottled sauces and ketchups Stock and stock cubes Gravy browning and mixes Mustard powder Curry powder Mayonnaise, salad cream, salad dressings Pickles and chutneys Tamari (Japanese soy sauce)	Soyu (Chinese soy sauce) Mixed seasonings and spices that specify flour on the label Stuffing and stuffing mixes
Savoury snack foods	Plain potato crisps Home made popcorn Prawn crackers Pappadums	Flavoured crisps and snacks	Snack products made from wheat, rye, barley Pretzels
Preserves and spreads	Sugar, glucose, golden syrup, treacle, molasses Jam, conserves, honey, marmalade Peanut and other nut butters	Mincemeat Lemon curds and cheeses Chocolate or other sweet spreads	
Confectionery	Boiled sweets/jellies	Sweets, chocolate, toffees, etc. Iced lollies Chewing gum	
Beverages	Tea, coffee Fruit juices, fruit squash Mineral water Clear fizzy drinks Cocoa Milk Spirits, wines, liqueurs, cider, sherry, port Complan, Build-up Specialist gluten free beers	Herbal teas Chocolate powders and drinks Milk shakes and mixes Sports and health drinks	Vending machine chocolate drinks Barley waters Cloudy fizzy drinks Malted milk drinks Beer, lager, ale and stout, home brewed beers, low alcohol beers and lagers.
Miscellaneous	Gelatine Bicarbonate of soda, cream of tartar Fresh and dried yeast Tofu Food colourings, essences and flavourings Cake coverings and decorations Marzipan Meat, vegetable and yeast extracts	Baking powder	Ice cream cones and wafers Communion wafers Quorn

guidelines were based on a review of data from the National Diet and Nutrition Survey (NDNS) (Henderson *et al.*, 2003) and provide recommendations that suggest reasonable amounts of gluten free foods that should be prescribed as part of a balanced diet. These guidelines are based on the consumption of 50% of total energy as carbohydrate, with gluten free prescribable foods providing 15% of total energy. Gluten free sources of carbohydrate such as potatoes, rice and breakfast cereals make up the remaining 35% of total energy. Energy requirements of the different sexes and ages are taken into account, as well as variables such as a high activity level, pregnancy and breastfeeding (Holmes *et al.*, 2004). The guidance provides a minimum monthly requirement in unit values that are based on carbohydrate content and cost. The guidance is not mandatory and products are prescribed at the discretion of the general practitioner (GP).

In principle, prescriptions provide equal access to gluten free products. Although, increasingly, gluten free

staple products are available in supermarkets, they continue to be significantly more expensive than standard staple foods (Carr, 2011). Gluten free specialist foods have been available on prescription since the late 1960s. In this time the range of products on prescription has increased and the prescribing practices have also become variable, with some people receiving more gluten free food on prescription than others. However, prescriptions may help patient adherence to a gluten free diet.

Products available on prescription

Foods such as gluten free bread, plain biscuits and crackers, pasta and pizza bases are prescribable according to the Advisory Committee on Borderline Substances (ACBS) for people medically diagnosed with coeliac disease or dermatitis herpetiformis. Prescribable gluten free flours and flour mixes are also available for home baking. The types of gluten free foods available are summarised in Table 7.4.6. Further details can be found in the *British National Formulary*, the *Monthly Index of Medical Spe-*

Table 7.4.6 Prescribable and non-prescribable gluten free foods

Type of product	Gluten free products available	Notes
Prescribable gluten free foods		
Bread and rolls	White, brown, wholemeal bread (sliced/unsliced), rolls, baguettes High fibre bread Bread mixes	Some breads and rolls are vacuum packed either fully or partially baked; a few products are available fresh (and can be frozen)
Flour substitutes	Flour mixes (white, brown, high fibre)	Can be used for home baking
Biscuits	Digestives, tea biscuits Crackers/savoury biscuits Crispbread	
Pasta	Fusilli, lasagne, macaroni, penne, rigati, spaghetti, spirals, tagliatelle	
Convenience foods	Pizza bases	
Non-prescribable gluten free foods		
Available from supermarkets, health food stores and by mail order		
Breakfast cereals	Muesli Hot breakfast cereal	
Bread products	Breadsticks Naan bread	
Biscuits	Wafers Pretzels	
Cakes	Madeira cake Ginger cake Fruit cake Rich fruit cake Cake mixes	
Seasonal fare	Mince pies Christmas pudding	
Confectionery	Chocolate bars Cereal bars Ice cream cones	
Convenience	Pizza – frozen and chilled Fish fingers Chicken nuggets Fish cakes	
Miscellaneous	Yorkshire puddings Stuffing mix	

Table 7.4.7 Manufacturers of branded gluten free foods

Manufacturer	Brand names
Bakers Delight Ltd	Bakers Delight
Community Foods	Orgran
General Dietary Ltd	Ener-G
Gluten Free Foods Ltd	Barkat, Glutano, Tritamyl, Warburtons
Heron Quality Foods Ltd	Heron Foods
Innovative Solutions	Pure
Novartis Consumer Health	Bi-Aglut
Nutrition Point Limited	Dietary Specials, Glutafin, Trufree

NB: Manufacturers and product names are liable to change. A full list of all currently available proprietary gluten free foods can be obtained from Coeliac UK.

cialities (MIMS), the Drug Tariff, or obtained directly from the manufacturers (Table 7.4.7). It should be noted that the names of both the producers and products are liable to change. A full list of all currently available proprietary gluten free foods can be obtained from Coeliac UK.

The supply of gluten free foods on prescription by prescribing schemes led by community pharmacists has been demonstrated to reduce costs by 20% (Carr, 2011) due to improved product controls, e.g. the scheme did not recommend prescribing gluten free cake mix or sweet biscuits. These are widely available in supermarkets and are not essential to the gluten free diet, although they may serve an important role in the social aspects of food and quality of life. The scheme also was able to show a considerable saving in GPs time and was preferred by patients. People with coeliac disease and dermatitis herpetiformis are not classified as chronically sick and hence not entitled to free NHS prescriptions (although the usual exemptions apply). A prepayment facility can represent a significant saving.

Gluten free cakes, fancy biscuits, cereal bars, breakfast cereals, chilled and frozen pizzas, chicken nuggets, fish fingers and fish cakes are also available for purchase but not prescribable (Table 7.4.6). They are usually more expensive than standard products, but their use may make the diet more appealing, inclusive and socially acceptable.

Oats

It was initially assumed that oats were toxic due to the observation that patients had continued symptoms whilst ingesting oats. However, many sources of oats are significantly contaminated with wheat flour during processing. Oats can be included in the diet of adults (Janatuinen *et al.*, 2002) and children with coeliac disease (Hogberg *et al.*, 2004) without causing damage to the gastrointestinal tract. In practice however, recommendations on the inclusion of oats in the diet are variable. Hernando *et al.* (2008) suggests uncontaminated oats are tolerated by most people with coeliac disease, while Lundin *et al.* (2003) found that 1 in 20 people were sensitive to uncon-

taminated oats. Further systematic reviews confirmed this (Garsed *et al.*, 2007; Haboubi *et al.*, 2006).
