The exclusion of oats in a gluten free diet is still advised by some. Although it is possible that a small minority of coeliac individuals will not tolerate oats, the weight of evidence supports the safety of oats obtained from gluten free manufacturers. The BSG (2010) advises that coeliac individuals can use labelled gluten free oats safely. It also recommends that adults avoid oats for the first 6–12 months after diagnosis with coeliac disease. This is a pragmatic approach to allow for full symptom improvement before oats are introduced. Children should first be established on a strict gluten free diet and introduced to oats once the diet is established, usually after a year. The inclusion of oats in the diet should be considered on an individual basis and progress reviewed regularly.

The addition of oats in the gluten free diet has benefits in terms of improving variety and as a valuable source of fibre, especially soluble fibre. Coeliac UK produces a list of oats and oat products that are free from contamination. It is essential the person with coeliac disease is aware of the contamination risk and only uses products that are known to be safe.

Dietary balance

Lifelong dietary restrictions and an adherence to a gluten free diet can be difficult to accept and follow (Sverker *et al.*, 2005). Nutrient intake may also be compromised due to the essential avoidance of bread and cereals, which are important sources of carbohydrate, fibre, vitamins and minerals. While gluten avoidance is the principal dietary objective, it should not be overlooked that, once optimal absorption is established on the gluten free diet, people with coeliac disease are just as likely as the general population to develop unrelated health problems such as hypertension, dyslipidaemia, obesity and type 2 diabetes, although the risk of vascular disease may be slightly less (West *et al.*, 2004b). As already mentioned, coeliac disease also conveys its own health risks such as osteoporosis. People therefore need to adopt diet and lifestyle measures that encompass all aspects of health.

Dietetic follow-up

The PCSG (2006) management guidelines recommend that after initial dietetic assessment patients are reviewed after 3 and 6 months, and thereafter annually if otherwise well. The BSG (2002) guidelines recommended regular follow up at 6–12-month intervals. The BSG (2010) guidelines recommend an annual full blood count, assessing vitamin and mineral status.

The follow-up care of patients ranges from patients being seen in specialist clinics (followed up by GPs, gastroenterologists, consultants, dietitians or nurse specialists) to being discharged back to the community without any provision for follow-up. Stucky *et al.*, (2009) concluded that a team approach was the ideal, with a clinician and dietitian being necessary to provide the best follow-up care. A dietitian should supervise treatment, including follow-up, because of the potential long term complications (BSG, 2010).

Patients usually return to a follow-up appointment with lots of questions about their diet, lifestyle and experiences of living with coeliac disease. Sverker *et al.* (2005) concluded that the lived experiences of patients with coeliac disease were more varied and profound than expected. It is important to take psychological and social aspects into account and how these may potentially impact on patient compliance.

The following topics should be discussed at a review appointment:

- Gluten content of the diet.
- Calcium intake.
- Dietary compliance.
- Symptomatic improvement.
- Nutritional status.
- Blood test results.
- Gluten free prescriptions.
- Membership of Coeliac UK and use of the food and drink directory.

Ongoing dietetic support is essential both at diagnosis and follow-up to assess and review nutritional status and to review possible nutritional issues or deficiencies. It is essential for good compliance, as well as promoting an overall healthy balanced diet for long term health. An annual dietetic review is important because even experienced coeliac patients may be inadvertently consuming gluten or having an unbalanced diet (McFarlane *et al.*, 1995). Compliance to a gluten free diet is improved by regular dietetic intervention (Pietzak, 2005; Wylie *et al.*, 2005) and patients prefer to see a dietitian for long term follow-up, with a doctor available if needed (Bebb *et al.*, 2006). Serology markers cannot replace a trained dietitian's evaluation in assessment of adherence to the gluten free diet (Leffler *et al.*, 2007).

In addition, weight gain after diagnosis is common and may contribute to morbidity in the long term. Patients may have additional medical conditions, such as diabetes, which also require dietetic input. It is important that the dietitian works collaboratively with a patient to ensure that dietary advice meets an individual's needs. This should be carried out on an ongoing basis in order to improve healthcare with patient centred information and to increase quality of life.

Diet related problems

Poor compliance

Evaluating compliance is a particularly important aspect of a dietary review as the difficulties in following a gluten free diet should not be underestimated. Many patients are tempted to deviate from the dietary constraints in some circumstances, especially if there are no obvious penalties (such as unpleasant symptoms) from doing so. Compliance is particularly likely to be a problem in people found to have silent coeliac disease where the benefits from gluten avoidance will be even less obvious (Westman *et al.*, 1999). Studies indicate that compliance varies greatly in adults, with between 45% and 94% of

patients adhering to the gluten free diet (Holmes & Catassi, 2000).

The dietitian and other healthcare professionals should actively support the individual in developing strategies to effectively manage their own behaviour, e.g. through the use of behaviour change techniques. Dietitians with skills in motivational interviewing can encourage behavioural change and help with dietary adherence (Stucky *et al.*, 2009). Such skills are particularly important in helping older patients, since many patients with coeliac disease are now being diagnosed at a later age. The attitude of healthcare professionals is important, as stated by Silvester & Rashid (2007) *'rather than condemn those individuals with coeliac disease, who struggle with the complete elimination of gluten from their diet, health care professionals must adopt a more enlightened view that looks beyond non compliance as an act of individual failure or defiance to consider social factors that render compliance difficult, even for the well informed and highly motivated patient'*.

The ubiquity of gluten in food may mean that some people inadvertently consume gluten, assuming a food to be gluten free or due to cross contamination within the home, e.g. using the same bread board to slice ordinary and gluten free bread, or eating out, e.g. frying gluten free foods in oil previously used to cook a flour coated product. These aspects should be explored during a dietetic consultation. Catassi *et al.* (2007) established that gluten contamination in gluten free products could not be completely avoided. They showed that changes in the height of the villous lining of the gut occurred at an intake of 50 mg of gluten/day.

Whilst dietitians should remind patients of the reasons for compliance with a gluten free diet, it is important that they also help foster a positive dietary outlook by emphasising the many foods that can be eaten, by encouraging appropriate use of prescribable gluten free foods and by suggesting ways in which particular difficulties can be overcome. Patients should also know where to obtain further advice on queries or problems so that they feel they have a constant source of support.

Some NHS trusts, e.g. Cumbria Partnership NHS Foundation Trust, support coeliac patients by employing coeliac lifestyle advisor–patient experts. Following an initial appointment with a dietitian, a referral can be made to the advisor via the dietitian. Depending on the individual's needs, the advisor may arrange a home visit or provide training to catering and healthcare staff at nursing homes. Topics such as cross contamination, how to obtain locally sourced gluten free products and advise on eating out are discussed.

Continuing symptoms

The most common cause of continuing symptoms or a poor response to the diet is gluten consumption due to contamination, non-compliance or a high level of sensitivity. Another reason for poor response may be secondary lactose intolerance, which is common in those newly diagnosed with coeliac disease. A trouble shooting

approach in dietetic management of coeliac patients is needed when patients present with ongoing symptoms. A focused dietary history is essential for the elimination of possible sources of gluten in the form of contamination, oats or foods containing malt extract. Patients who are found to be highly sensitive to gluten will need to use proprietary gluten free foods.

Non-responsive coeliac and refractory coeliac disease

Despite following a strict, gluten free diet, after 1 year an individual may remain clinically unwell; this is defined as refractory coeliac disease. Recent guidelines (Rubio-Tapia *et al.*, 2010) provide useful information on the classification and management of refractory coeliac disease.

Levels of sensitivity to gluten

Some people are more sensitive to the effects of gluten than others and react to levels of gluten that are tolerated by other people with coeliac disease. The revised Codex standard of gluten free foods of 20 ppm will provide safer limits overall. The term gluten free implies no gluten; however, even naturally gluten free cereals, e.g. rice, can contain up to 20 ppm or 20 mg/kg of gluten. This amount of gluten is not usually toxic to people with coeliac disease who can eat unlimited amounts of products with gluten at a level of <20 ppm.

Codex wheat starch

Codex wheat starch is highly processed, which improves the texture and taste of foods, and has a level of gluten within the Codex standard. Products containing this are mainly obtained on prescription (Table 7.4.6). They are labelled as gluten free (<20 ppm) and are suitable for all people with coeliac disease. This means that gluten free foods that contain Codex wheat starch should no longer cause a problem for sensitive patients. The previous level of 200 ppm of gluten in products had an additive effect, and eating large quantities may have led to ongoing symptoms in the more sensitive individuals. Further details of Codex wheat starch can be found at www.coeliac.org.uk/healthcare-professionals/diet-information/codex-wheat-starch.

Coexisting disorders requiring dietary intervention

The presence, or subsequent development, of other disorders, including type 1 diabetes or hyperlipidaemia, requires dietetic input. Weight reducing or vegetarian diets also require individual dietetic consultation to ensure nutritionally adequacy, especially in respect of calcium intake.

Constipation

The gluten free diet may lead to a reduction in the intake of fibre due to reduced consumption of cereals, resulting

in constipation. This may be alleviated by the following advice:

- Increasing fibre intake from fruit and vegetables, especially dried fruit, potato skins and pulses (peas, beans and lentils).
- Using higher fibre varieties of prescribable gluten free bread, mixes and crackers, and gluten free muesli.
- Increasing consumption of wholegrain gluten free cereals such as brown rice and buckwheat.
- Increasing fluid consumption.
- Increasing activity level.

Lactose intolerance

Newly diagnosed patients with coeliac disease may also suffer from secondary lactose intolerance as a result of gut inflammation, which results in a lactase deficiency. Lactase is found in the brush border of the small intestine. Symptoms of lactose intolerance are similar to some of the symptoms of coeliac disease, such as bloating, excess wind and diarrhoea. Once established on a gluten free diet, the inflammation subsides and lactose digestion returns to normal. Lactose intolerance is therefore usually temporary. However, it can take up to a couple of years for lactase production to return to. It is essential that during this time dietary advice is given to ensure adequate calcium intake from non-dairy sources (fortified gluten free bread or rolls, soya milk or yoghurt). Supplementation with calcium may be required to ensure adequate intake. Individuals should have their diet assessed and advice should be given on an individual basis. Lactose intolerance should be considered in patients with ongoing symptoms but who are known to be following a gluten free diet. A hydrogen breath test can diagnose lactose intolerance; this is a non-invasive test and has good sensitivity and specificity (Romagnuolo, 2002) (see Chapter 7.4.6).

Type 1 diabetes

Dietary management of the combined diseases requires professional guidance from a dietitian. The aim of dietary management is to improve blood glucose control as well as support people with the gluten free diet. Children with coeliac disease and type 1 diabetes mellitus should have their growth and development carefully monitored. Gluten free alternatives to bread, pasta, biscuits and flour have approximately the same glycaemic index (GI) as their gluten containing counterparts (Packer *et al.*, 2000) so should not compromise glycaemic control and can be incorporated into the diet in the same way as normal products. Patients should be encouraged to choose the higher fibre varieties where possible (see Chapter 7.12).

Dietary considerations in particular groups

Weaning

Breastfeeding may be protective and may delay onset of coeliac disease (Kramer & Kakuma, 2002; Hill *et al.*, 2005). A group of researchers in Sweden has suggested

that the risk of coeliac disease is reduced in children who are breastfed whilst gluten is gradually introduced into the diet (Ivarsson *et al.*, 2000; 2002). Introducing gluten containing cereals during the first 3 months of life to at risk groups of children has been found to increase the risk of coeliac disease by five times compared to when gluten is introduced between 4 and 6 months (Norris *et al.*, 2005). This study also showed that there was no benefit in delaying the introduction of gluten beyond 6 months. Guidelines regarding the age of introduction of gluten into the diet are the same regardless of family history of coeliac disease. The Food Allergy and Intolerance Specialist Group (FAISG, 2005) advice for infants with an increased risk of coeliac disease is therefore to continue breastfeeding (if possible) until the introduction of solids. Solids should not be introduced before the age of 4 months (preferably 6 months) and gluten should not be included before the age of 6 months.

Children

The North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) has produced guidelines on diagnosis and management in children (Hill *et al.*, 2005). It is recommended that children with coeliac disease be monitored with periodic assessments of symptoms, growth (with signs of poor growth investigated), physical examination and adherence to a gluten free diet.

A paediatrician and paediatric dietitian should see children with coeliac disease at least once a year (ideally 6-monthly), with an initial follow-up within the first 3 months of diagnosis. An annual assessment should also be offered that should include a detailed dietary assessment to look for possible nutrient deficiencies, compliance with the diet and the need for any nutritional supplementation. If symptoms recur, then urgent clinical review is required.

In preschool children, it is generally easier if the whole family eats gluten free foods; difficulties at meal times are more likely if a young child sees that everyone else has different foods on their plate. Other children's parties need not be a problem if the situation is discussed with the host parent beforehand and a supply of gluten free food provided (although its consumption by the right child may be harder to police). Food at their own parties should be gluten free. Preschool groups present few problems since the children are usually only allowed to eat food under supervision. Play dough used in such groups is sometimes made from ordinary flour and, although flavourings are usually added to give an unpleasant taste, can occasionally be a source of gluten consumption.

It is important that a coeliac child is not excluded from school activities as well as social events, such as eating out, parties and holidays. Most children adapt surprisingly quickly to the idea that they cannot eat certain foods and are willing to take their own supply of suitable items to eat outside the home. There may however be some situations that pose temptations, e.g. the common practice of swapping snacks in the playground.

Teenagers

Rebellion against the dietary constraints of a gluten free diet is common in adolescence (Fabiani *et al.*, 1996). Studies in teenagers with coeliac disease show that only about 50–65% follow a gluten free diet (Mayer *et al.*, 1991; Kumar *et al.*, 1988). Peer group pressure may lead to consumption of takeaway or fast foods, such as fish and chips, pies, hamburgers or pizzas. Those who become ill after doing so are usually wary of future indiscretions, but others with a higher degree of gluten tolerance may not suffer any immediate symptoms. Teenagers should be reminded that damage to the intestinal mucosa will still occur, but also offered as much positive advice as possible regarding what foods can suitably be eaten when eating out with friends. Parents should also consider that the appetites of teenagers, particularly boys, can be voracious and that dietary indiscretions are more likely to occur when they are hungry; providing plenty of gluten free snacks may help.

Transition to adult services is obviously a critical period and should be addressed in a timely and sympathetic manner to meet the needs of the young person and according to the best practice guidance (Maki & Collin, 1997; Ljungman & Myrdal, 1993).

Adults

The greatest difficulties usually arise when eating away from home, but can be averted to some extent by advance planning. At work, some canteens will, with notice, provide gluten free meals and others will be willing to microwave a preprepared meal supplied by the person with coeliac disease. Hotels and restaurants can be scoped in advance and if necessary sent information about the diet. Many airlines will provide gluten free meals on long distance (not always short haul) flights if sufficient notice is given. Nevertheless, carrying a supply of gluten free rolls, crackers or similar foods is a wise precaution when travelling, on holiday or going to social functions, so that suitable foods are always available.

Pregnancy

Undiagnosed coeliac disease has been associated with reduced fertility and unfavourable pregnancy outcomes, such as an increased risk of miscarriage (Ciacci *et al.*, 1996). However, compliance with a gluten free diet reduces these risks to those of the general population. There are no specific guidelines for pregnant women with coeliac disease. Those who are diagnosed and adhering to a gluten free diet prior to conception should follow the same advice as non-coeliac pregnant women (see Chapter 3.2).

Older people

Older patients will always find it difficult to change the eating habits of a lifetime overnight, but many will do so successfully if given sufficient help in making suitable dietary substitutions. Some will also welcome feeling

fitter on a gluten free diet after perhaps years of having had undiagnosed coeliac disease with consequent chronic tiredness and feeling below par.

Gluten avoidance may be more difficult in those dependent on others for meals. Meals on wheels services may not provide gluten free diets, although most will endeavour to provide suitable food choices, e.g. a piece of fruit instead of a pudding, once they understand the nature of the diet. Since the prevalence of coeliac disease among elderly people is increasing as awareness and diagnosis of the condition improves, educating residential and care homes regarding the needs of coeliac patients is particularly important.

Future developments

Despite improvements in the quality of gluten free foods, some patients still find elements of the diet difficult. Therefore, there is interest in dietary supplements (peptidases) that digest gluten in the food prior to its entry into the small intestine; however, further research is required (Tennyson *et al.*, 2009).

7.4.8 Inflammatory bowel disease

Derbhla O'Sullivan

Key points

- Malnutrition is common in inflammatory bowel disease (IBD) and good nutrition is crucial for optimal clinical outcome.
- Enteral nutrition (elemental, peptide or polymeric) can be used as a primary treatment or adjunctive treatment to medical and surgical therapies for the treatment of active Crohn's disease or for nutritional support.
- Dietary treatment of Crohn's disease is especially useful in children and in cases where medical therapy is contraindicated.
- People with IBD need considerable dietetic support during relapse of disease and ongoing support during remission.
- Multidisciplinary team work is invaluable for caring for this lifelong relapsing–remitting condition.

Inflammatory bowel disease (IBD) is the collective term to describe Crohn's disease, ulcerative colitis and IBD, including type unclassified (IBDU) (Silverberg *et al.*, 2005). Although these are distinct disorders with differences in their presentation and management, they share a number of common features. Inflammatory bowel disease is a relapsing–remitting inflammatory disorder of unknown aetiology, which can significantly impair quality of life. The lifetime medical costs associated with the care of IBD can be comparable to major chronic diseases such as diabetes mellitus or cancer (IBD Standards, 2009). Nutrition therapy is pivotal in IBD, whether as the primary treatment or in a supportive role.

Prevalence

Both ulcerative colitis and Crohn's disease are diseases of young people with a peak incidence between the ages of 20 and 40 years (Marshall & Hilsden, 2003). With a reported prevalence of 400 per 100 000 (Rubin *et al.*, 2000) there are approximately 240 000 patients with IBD in the UK [ulcerative colitis 243 per 100 000 (146 000 people) in the UK population of 60 million and Crohn's disease 145 per 100 000 (87 000 people)]. There is a South–North gradient to the incidence of IBD in the UK, with rates being highest in Scotland. Compared with the non-Jewish Caucasian population, IBD occurs more frequently in Ashkenazi Jews and at about the same level in families originating from Africa or the Caribbean. For second generation Indian and Pakistani families, the incidence of Crohn's disease is about the same, but is higher for ulcerative colitis (Silverberg *et al.*, 2005).

Causation and risk factors

While there is no evidence that specific immune mediated reactions to food play a role in most patients with either Crohn's disease or ulcerative colitis (Bischoff *et al.*, 2000), it is commonplace for patients with gastrointestinal disorders to believe that something in their diet has caused their condition (Jones *et al.*, 1985). The cause of both Crohn's disease and ulcerative colitis remains unknown, yet is likely to be multifactorial; a combination of genetic predisposition and environmental triggers. There is a genetic predisposition that increases the risk of IBD about 10-fold in first degree relatives of an IBD patient and which probably determines the pattern and severity of the disease in any individual patient. Much research is focused on understanding the role of bacteria in the gut and the many different parts of the immune system's response to external triggers. It seems quite likely that the trigger for the disease varies between individuals (IBD Standards, 2009; NACC, 2007; Stange *et al.*, 2006; 2008).

Smoking is consistently documented to be associated with IBD. Current smokers are more likely to develop Crohn's disease and, following diagnosis, have a poorer prognosis with a significantly higher chance of surgical resection, and (if smoking continues) a greater chance of recurrence at the surgical anastomosis (Mahid *et al.*, 2006; Mowat *et al.*, 2011). Smoking cessation is associated with a 65% reduction in the risk of a relapse in Crohn's disease as compared with continued smokers (Johnson *et al.*, 2005). In contrast, smoking decreases the risk of ulcerative colitis (Mahid *et al.* 2006).

Clinical features

Inflammatory bowel disease results in an uncontrolled inflammatory response in the bowel wall. Crohn's disease most commonly affects the small bowel, often the terminal ileum, although any part of the gastrointestinal tract from the mouth to the anus can be affected. All layers of the intestine are affected and the rectum is often spared. It is characterised by distinct areas of inflammation, often associated with granulomas and deep fissuring ulceration, interspersed with areas of unaffected bowel tissue. Crohn's disease can follow either of two patterns; stricturing disease (narrowing of the intestine causing obstruction) or fistulising disease (where the disease creates holes in the bowel wall that allow the faecal contents to leak out) (IBD Standards, 2009).

Ulcerative colitis causes an area of continuously inflamed mucosa, starting in the rectum and extending up the colon to varying degrees. The intestinal lining becomes red and inflamed, and bleeds readily. It also follows a relapsing–remitting course, although the first presentation is often the most severe.

Both ulcerative colitis and Crohn's disease are associated with an equivalent increased risk of colonic carcinoma (Ekbom *et al.*, 1990a,b; Friedman *et al.*, 2008; Softley *et al.*, 1988). About 5% of patients with IBD affecting the colon are unclassifiable because they have some features of both Crohn's disease and ulcerative colitis. This is now termed as IBDU (Silverberg *et al.*, 2005).

Symptoms and diagnosis

The main presenting symptoms of IBD are abdominal pain, diarrhoea, sometimes with blood and mucus in the stool, and weight loss. Both Crohn's disease and ulcerative colitis can produce symptoms of urgency, profound fatigue and anaemia, with, for some patients, associated inflammation of the joints, skin, liver or eyes. Malnutrition and weight loss are common with patients often altering their eating habits to alleviate symptoms (IBD Standards, 2009). When diagnosed in childhood (about 25% of all cases) the disease is often more severe than if presenting in adulthood, with major consequences on life long morbidity (Van Limbergen *et al.*, 2008). Symptoms can severely affect self esteem and social functioning, particularly among the young and newly diagnosed.

The diagnosis of IBD is confirmed by clinical evaluation and a combination of haematological, endoscopic, histological or imaging based investigations (Mowat *et al.*, 2011; Stange *et al.* 2006; 2008). Laboratory investigations should include full blood count, urea and electrolytes, liver function tests, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), ferritin, transferrin saturation, vitamin B₁₂ and folate (Mowat *et al.*, 2011). The most frequent test used to diagnose IBD is a colonoscopy with multiple biopsies. Imaging, e.g. ultrasound, magnetic resonance imaging, computed tomography scanning and barium fluoroscopy, can be helpful in diagnosis and the assessment of disease extent. Faecal calprotectin

is also used in some centres to detect colonic inflammation and to help identify functional diarrhoea. Other causes of diarrhoea include irritable bowel syndrome (IBS) and infection and may be present alongside IBD, e.g. after travel abroad.

Several disease indices are available to describe the severity of Crohn's disease and ulcerative colitis. However, the most suitable indices to use in dietetic assessments are ones that include factors that are obtainable by a dietitian and are known locally such as the Harvey Bradshaw Index (HBI) (Harvey & Bradshaw, 1980) and The Simple Clinical Colitis Activity Index (Walmsley *et al.*, 1998). These can be useful in combination with other clinical measures such as blood results to help indicate remission versus active disease.

The HBI is a validated clinical index used for Crohn's disease that is also called the simple index. It is based on five items:

1. General wellbeing (0 = very well, 1 = slightly below par, 2 = poor, 3 = very poor, 4 = terrible).
2. Abdominal pain (0 = none, 1 = mild, 2 = moderate, 3 = severe).
3. Number of stools per day.
4. Abdominal mass (0 = none, 1 = dubious, 2 = definite, 3 = definite and tender).
5. Complications: arthralgia, uveitis, erythema nodosum, aphthous ulcers, pyoderma gangrenosum, anal fissure, new fistula, abscess (score 1 per item).

The first three items are scored for the previous day. A score of 3 or less indicates the disease is in remission. A score of >6 indicates the disease is active and the patient has relapsed.

The Simple Clinical Colitis Activity Index is based on six parameters:

1. Bowel frequency during day (0 = 1–3/day, 1 = 4–6/day, 2 = 7–9/day, 3 = >9/day).
2. Bowel frequency during night (1 = 1–3/night, 2 = 4–6/night).
3. Urgency of defecation (1 = hurry, 2 = immediately, 3 = incontinence).
4. Blood in stool (1 = trace, 2 = occasionally frank, 3 = usually frank).
5. General wellbeing (0 = very well, 1 = slightly below par, 2 = poor, 3 = very poor, 4 = terrible).
6. Extracolonic features (score 1 per manifestation): arthritis, pyoderma gangrenosum, erythema nodosum, uveitis.

A score of <2.5 defines remission (Higgins *et al.*, 2005) and a score of 5 or more defines relapse.

Management

Drug treatment

Drug therapy for IBD is a rapidly evolving field. Antibiotics such as metronidazole and ciprofloxacin have an important role in treating secondary complications in

Table 7.4.8 Common nutritional deficiencies in patients with inflammatory bowel disease (IBD)

Nutritional deficiency	Common causes
Dietary energy	Poor appetite as a result of symptoms or drug side effects Catabolic effects of chronic inflammation Malabsorption (as a result of ileal IBD or following ileal resection)
Protein	Increased nitrogen losses High requirements for tissue repair
Vitamins D and K	Bile salt deficiency
Iron	Poor intake Poor absorption Chronic blood loss (especially in ulcerative colitis)
Folate	Impaired absorption Use of sulphasalazine
Vitamin C	Low consumption of fruit and vegetables
Vitamin B ₁₂	Ileal resection Small bowel overgrowth
Calcium	Use of corticosteroids Malabsorption and chronic diarrhoea Avoidance of dairy food
Magnesium and zinc	Malabsorption and chronic diarrhoea Short bowel syndrome
Sodium and potassium	Avoidance of dairy foods Persistent diarrhoea and vomiting

IBD, such as abscess and bacterial overgrowth (Castiglione *et al.*, 2003). However, corticosteroids such as prednisolone, 5-aminosalicylates (e.g. sulfasalazine, mesalazine and osalazine), and immunosuppressive drugs such as azathioprine and mercaptopurine are the mainstay of medical management for inducing and maintaining remission; they suppress the symptomatic effects of IBD. Corticosteroids are the biggest risk factors in postoperative complications (Dignass *et al.*, 2010). Thirty per cent of patients will fail to respond to these drugs or be intolerant of them, and these patients may then be considered for antitumour necrosis factor-alpha biological therapies such as infliximab, or surgery (IBD Standards, 2009).

Surgery

Between 50% and 70% of patients with Crohn's disease will undergo surgery within 5 years of diagnosis. In total ulcerative colitis, lifetime surgery rates are about 20–30%. Of patients who have chronic relapsing ulcerative colitis, about 50% need a colectomy, though rates vary between countries and regions (Carter *et al.*, 2004; IBD Standards, 2009; Oresland, 2006; Roberts, 2007).

The most common forms of surgery for Crohn's disease are removal of the diseased part of the small bowel, with or without part of the colon; and partial or total removal of the colon and/or rectum (proctocolectomy) with formation of a stoma, which may be permanent. For people who have ulcerative colitis, restorative proctocolectomy is the most common operation. This involves removal of the colon and rectum, combined with the fashioning of an ileal pouch. This is made from the terminal ileum and

joined to the anus to form a reservoir, which replaces the rectum, thus avoiding a permanent ileostomy (IBD Standards, 2009; Stange *et al.* 2006; 2008; Travis *et al.*, 2008; Parks & Nicholls, 1978).

Nutritional implications

In cases where diarrhoea is prolonged, or bloody and severe, water and salt loss and poor absorption of nutrients may occur, leading to anaemia, dehydration, severe weight loss and nutritional depletion (Table 7.4.8).

Drug treatment may also impact on nutritional status. Prolonged use of corticosteroids may cause growth retardation in children, muscle wasting, diabetes, peptic ulcer, osteoporosis, liver and renal damage. Nausea and diarrhoea are common side effects of aminosalicylates and immunosuppressant drugs. Sulfasalazine is a folic acid antagonist and its long term use can cause megaloblastic anaemia. Folate deficiency is also associated with hyperhomocysteinaemia, which increases the risk of thromboembolic disease in IBD.

Dietary management

The aims of dietary management in IBD include:

- Achieving and maintaining good nutritional status during both active disease and remission.
- Helping to alleviate clinical symptoms in combination with medical and/or surgical treatment.
- Helping to treat clinical complications in combination with medical treatment.

- Achieving remission in Crohn's disease patients, when enteral nutrition is used as a primary treatment or in combination with medical treatment.

Patients report that access to a dietitian is vital (Jones *et al.*, 2009; Prince *et al.*, 2010) and the need for increased dietetic access is recommended (IBD Standards Standard A5, 2009). Malnutrition is present in up to 85% of patients with IBD, and weight loss occurs in up to 80% of patients with Crohn's disease and 18–62% of patients with ulcerative colitis (Gassull & Cabre, 2001; Geerling *et al.*, 1999). All IBD patients should be weighed and their nutritional needs assessed (IBD Standards Standard A10, 2009). Therefore, nutritional intake and dietary advice are important when patients are admitted, when they relapse and during periods of remission. Osteoporosis is common in IBD (Tilg *et al.*, 2007) and the daily recommendation for calcium intake in patients with IBD is 1000 mg (Lewis & Scott, 2007).

Patients should be encouraged to follow as normal a diet as is possible for their clinical state, and which is balanced in terms of overall composition. Most will benefit from relatively small meals of high energy and nutrient density consumed at fairly frequent intervals. At times when appetite is poor, food fortification strategies or supplement use may be necessary (see Chapter 6.3). The importance of adequate fluid intake in the presence of diarrhoea, pyrexia or fistulae should be stressed. Nutritional status should be assessed at regular intervals and the growth of children and young people closely monitored.

Additional dietary manipulations may be needed to help to alleviate the effects of the disease or the consequences of intestinal resection, or to achieve remission in Crohn's disease patients. Some IBD patients may need to avoid specific foods that appear to exacerbate symptoms, but unnecessary food avoidance should be discouraged; the justification for excluding specific foods to help to alleviate symptoms should always be carefully considered. In many patients with IBD, functional symptoms, e.g. abdominal pain, bloating, flatulence and diarrhoea, are more problematic than symptoms due to inflammation that may be attributed to IBS (Camilleri, 2011).

Specific aspects of dietary management of crohn's disease

People with Crohn's disease are at particular risk of nutritional deficiencies because this form of IBD is more likely to:

- Occur in children or young adults whose energy needs are high.
- Result in malabsorption as a result of ileal inflammation or resection.
- Necessitate repeated surgery to treat complications such as strictures or fistulae.

Restoring and maintaining good nutritional status is a treatment priority at all stages of the illness. As far as possible, this should be achieved by means of a diet comprised of ordinary foods which minimises disruption to normal life.

Since appetite tends to be poor in active disease, the diet needs to be of high energy and nutrient density, and various strategies can be deployed to help to achieve this (see Chapter 6.3). Many patients will avoid greasy, spicy or irritant foods in an attempt to minimise symptoms, but the nutritional impact of any food restrictions imposed by the patient should be carefully explored with the patient. If fat malabsorption is resulting in problematic symptoms, fat restriction to tolerance levels may be necessary, but care must be taken to avoid compromising energy intake. Substitution of some long chain triglycerides (LCTs) with medium chain triglycerides (MCTs), or dietary fortification with carbohydrate polymers may be necessary. Additional fat soluble vitamins are also likely to be required and a daily multivitamin supplement may be advisable if food intake remains inadequate or malabsorption is pronounced.

In specific circumstances, protein and energy support is indicated, such as when the absorptive capacity of the gut is reduced in short bowel syndrome or in the perioperative care of patients with significant (>15%) weight loss or low body mass index (National Collaborating Centre for Acute Care, 2006). This may mean parenteral nutrition (PN) including home PN in a minority of Crohn's disease patients with intestinal failure. Approximately 20% of home PN patients in Europe have underlying Crohn's disease, which is about one case per 1.5 million population (Bakker *et al.*, 1999).

Use of enteral nutrition

In Crohn's disease, withdrawal of normal food and replacement with enteral nutrition (EN) or PN can be used to induce remission in some patients (King *et al.*, 1997; Griffiths, 1998; Seo *et al.*, 1999; Goh & O'Morain, 2003). The enteral route has been considered more appropriate if it is working and accessible, as PN is invasive, carries more risks of serious complications and leads to gut atrophy arising from complete bowel rest (Lomer, 2011). The reason why EN is efficacious in treating active CD is unknown. Proposed mechanisms have included improved nutritional status, bowel rest, reduced dietary antigens, a direct immunomodulatory effect via alterations in fat content and reduced gastrointestinal microbial activity (Bannerjee *et al.*, 2004; Gassull, 2004; Lomer *et al.*, 2005; Tsujikawa *et al.*, 2003; Zachos *et al.*, 2007). Enteral nutrition has a role in primary treatment and as adjunctive treatment to medical and surgical therapies for treatment of active Crohn's disease or for nutritional support (Akobeng & Thomas, 2007; Zachos *et al.*, 2007; Mowat *et al.*, 2011). It is used as a primary treatment for active Crohn's disease in children and adolescents (Griffiths *et al.*, 1995; Lochs *et al.*, 2006; Zachos *et al.*, 2007). Enteral nutrition induces disease remission, but also ensures adequate growth and development and avoids side effects from drug therapy (Sandhu *et al.*, 2010). It has been shown to improve mucosal healing in paediatric patients (Beattie *et al.*, 1994; Borrelli *et al.*, 2006; Fell *et al.*, 2000).

In adults with Crohn's disease, the evidence for using EN to induce disease remission is not so strong, and it is

less effective than corticosteroids (Griffiths *et al.*, 1995; Zachos *et al.*, 2007). However, it is an alternative therapy to corticosteroids (Lochs *et al.*, 2006) and can be particularly useful where medical therapy is contraindicated, where patients or physicians choose this treatment option (Mowat *et al.*, 2011), or in young adults and in patients with or at risk of malnutrition. There are no known long term health consequences associated with EN.

The different types of EN used in Crohn's disease include elemental (amino acid) formula, peptide (semi elemental) formula and polymeric (whole protein) formula. There is no difference in efficacy between elemental and polymeric diets when used to induce remission in Crohn's disease (Zachos *et al.*, 2007). Palatability and social inconvenience can be limiting; however, their impact can be offset by close support from a dedicated dietetic service (King *et al.*, 1997). Choice of EN can depend on patient preference and local policy; EN is usually prescribed for 2–8 weeks. While the patient is taking exclusive EN, it is normal to exclude all other foods or drink except still water. Close dietetic monitoring is essential and some of the problems that may occur and strategies for dealing with them are summarised in Table 7.4.9. By 10 days there should be a clinical response and patients may even go into disease remission (Giaffer *et al.*, 1990), but longer studies indicate that mucosal healing does not occur until later on and 8 weeks or more may be required (Fell *et al.*, 2000; Lomer, 2011; Yamamoto *et al.*, 2007) (see Chapter 6.4).

Use of diet to maintain remission

Supplementary EN providing 35–50% of energy requirements using either an elemental or polymeric formula has

been shown to help in the maintenance of disease remission if provided for up to 12 months (Akobeng & Thomas, 2007). Following a period of food withdrawal with EN, transition to normal foods needs to be made with care. Patients are often apprehensive about which foods to eat and may eliminate certain foods, fearing that they may worsen symptoms and cause a relapse. High fibre diets are not normally indicated as food reintroduction diets (Jones *et al.*, 1985). Exclusion diets are not recognised in national guidelines for Crohn's disease in maintenance of remission. However, diets such as an elimination or LOFFLEX (low fat fibre limited exclusion) diet can be useful following a period of EN (Riordan *et al.*, 1993; Woolner *et al.*, 1998) and can be used as a starting point for food reintroduction by patients who, without dietetic support, may exclude random foods, which may lead to possible nutritional inadequacy.

Riordan *et al.* (1993) reported that following a period of exclusive EN, most patients would relapse shortly after resumption of a normal diet. The elimination diet involved reintroducing a single food each day, and excluding any food that provoked symptoms. The elimination diet was compared against tapered steroids and usual diets/general dietary advice for efficacy of prolonging remission (Riordan *et al.* 1993).

The LOFFLEX diet was developed by Woolner *et al.* (1998) as a method of food reintroduction that was easier and less time consuming than the elimination diet. The LOFFLEX diet was found to have the same efficacy for maintaining remission as the elimination diet. Foods that have been reported by >5% of Crohn's disease patients to cause symptoms are excluded. Patients follow a basic diet for 2–4 weeks and, provided that the patient is still in a state of remission, further food reintroduction

Table 7.4.9 Problems associated with use of formula diets in patients with Crohn's disease

Problem	Cause and/or solution
Loss of weight	May be due to not meeting nutritional requirements in the first few days If weight loss continues into the second week, increase the prescribed quantity of feed Monitor symptoms
Tiredness	Ensure the patient is meeting their requirements for feed and fluid Encourage the patient to rest
Postural hypotension	This often occurs in first few days if fluid intake is inadequate
Hunger	This seldom occurs if an adequate amount of feed is prescribed and consumed Try increasing the frequency and quantity of drinks
Headache	This may be due to caffeine withdrawal or to an inadequate fluid intake
Bad breath	Ensure good oral hygiene Brushing teeth three times a day may help, as may using mouth wash and consuming water after each drink
Green liquid stools	An infrequent, mild side effect
Diarrhoea	This may be osmotic, advise drinking the product slowly or perhaps diluting it with water If given nasogastrically, slow the rate of administration Suggest trying different flavours, consuming from a covered glass with ice and a straw or freezing/warming the drinks
Dislike of drink	Many people will become accustomed to the taste in time

follows. A list of 25 specific foods is given in the LOFFLEX and each food is tested for 4 days. After gradual cessation of the liquid diet, additional drinks are useful throughout the LOFFLEX diet period as snacks or supplements.

Low or reduced fibre diets are often also used in clinical practice because patients find them easier to follow, and they are less limiting and more nutritionally adequate than exclusion or elimination diets. Whatever method is used for food reintroduction, it is important that each patient is given the support they need to make a safe return to normal eating, and if food intolerance is found, that they are given structured advice to ensure that a balanced diet can be consumed.

Use of diet in stricturing Crohn's disease

Patients with stricturing Crohn's disease should be advised to alter and reduce their fibre intake to help prevent the risk of bowel obstruction and reduce associated symptoms (Meier & Gassull, 2004; Woolner *et al.*, 1998). The degree of dietary stricture will be dependent on the nature (inflammatory and/or fibrotic) and extent (tightness and length) of the stricture (Lomer, 2011). Typically, high fibre foods (wholegrains, skins and pips in fruit and vegetables, nuts and seeds) and foods that are difficult to mechanically break down, e.g. gristle, skin on meat or fish, are avoided (Lomer, 2011).

Specific aspects of dietary management of ulcerative colitis

There is no indication for the use of EN to treat ulcerative colitis; however, nutrition is still of primary importance in preventing the detrimental effects of malnutrition (Burke *et al.*, 1997; Gonzalez-Huix *et al.*, 1993).

Management of an acute relapse

Severe attacks can be fatal and require emergency hospital admission with intravenous fluid and electrolyte support, possibly blood transfusion, and steroid administration to induce remission as quickly as possible. If symptoms fail to improve or complications such as haemorrhage or toxic megacolon occur, or if precancerous changes are detected, surgery will be needed; a colectomy is curative.

Low fibre diets are often used for symptom relief while waiting for medical treatment to take effect. If time permits, preoperative nutritional support may be indicated. Peri- and post-operative support to maintain an adequate nutritional state is also very important. In the absence of massive bleeding, perforation, toxic megacolon or obstruction, EN rather than PN should be the mode of choice. Dietary measures to alleviate the effects of colonic resection may be needed.

Patients suffering from a mild or moderate attack, or recovering from a more severe attack, will usually have lost weight and need to increase dietary energy and protein intake. Oral energy supplements may be necessary if this cannot be achieved by use of normal foods alone. Particular attention should be paid to micronutrient requirements and supplements should be given if needed.

Management during remission

Patients in remission should be encouraged to consume a varied, well balanced diet, and unnecessary food exclusions discouraged.

Other aspects of nutrition

Probiotics

Bacteria or yeast generally ingested orally as therapy are termed probiotics. They may be administered as a single organism or a defined mixture, aiming to beneficially alter the microbial ecology of the gut. The agents most studied in IBD are *Escherichia coli* Nissle 1917, VSL#3, *Lactobacillus rhamnosus* GC, *Bifidobacterium* and *Saccharomyces boulardii* (Mowat *et al.*, 2011; Pham *et al.*, 2008). There is evidence for the effectiveness of VSL#3 in preventing pouchitis (Mimura *et al.*, 2004; Gionchetti *et al.*, 2003) and some evidence of benefit in maintenance and treatment of ulcerative colitis (Bibiloni *et al.*, 2005; Miele *et al.*, 2009). Three randomised placebo controlled studies have shown that *E. coli* Nissle 1917 (Mutaflor®) 200 mg daily is equivalent to standard doses of mesalazine in maintaining remission in ulcerative colitis (Schultz, 2008) and therefore may be an option for patients who are unable or unwilling to take mesalazine (Mowat *et al.*, 2011). There is no clear evidence to support any role for probiotics in the maintenance of Crohn's disease either after surgical or medically induced remission (Rolfe *et al.*, 2006).

Food intolerance

The prevalence of IBS-like symptoms in ulcerative colitis patients in remission is about three times higher than in hospital controls (Ansari *et al.*, 2008). Thirty-three per cent of ulcerative colitis patients and 57% of Crohn's disease patients have been reported to have IBS symptoms and IBS-like symptoms. Irritable bowel-like symptoms in IBD patients in long standing remission are two to three times higher than that in the normal population (Simren *et al.*, 2002). The association between symptoms of IBD and diet has received much attention (Crowe, 2001; Jones *et al.*, 1985; Riordan *et al.*, 1993). However, the tools available for measuring and predicting food intolerances remain suboptimal. Traditional allergy testing concentrated on the measurement of IgE mediated responses, but this approach has not proven useful in gastrointestinal food sensitivity (Bruijnzeel-Koomen *et al.*, 1995; Crowe, 2001; Shanahan, 1993). While the role of IgG based testing for food specific antibodies has shown some promise in IBS, research is ongoing (Atkinson *et al.*, 2004; Zar *et al.*, 2005a,b) (see Chapter 7.11.2).

Lactose intolerance

Lactose intolerance can occur in Crohn's disease where ileal damage or resection results in malabsorptive problems (Mishkin, 1997; Von Tirpitz *et al.*, 2002), but there is evidence that IBD patients avoid dairy products more often than necessary (Mishkin, 1997; Banos-Madrid *et al.*, 2004). Lactose intolerance is much less likely to be associated with ulcerative colitis (Mishkin, 1997; Ginnard *et al.*, 2003), other than in patients with primary lactose

intolerance. In all such patients, lactose intake may need to be limited but rarely needs to be excluded altogether (see Chapter 7.4.6). Consideration of calcium intake should be addressed where dairy foods are limited (see Chapter 7.4.6).

7.4.9 Intestinal failure and intestinal resection

Alison Culkin

Key points

Intestinal failure

- Type 1 and 2 intestinal failure is common, usually reversible and requires short term parenteral nutrition.
- Type 3 intestinal failure is rare and irreversible and requires home parenteral nutrition.
- Dietary treatment is determined by the type, length and quality of the remaining intestine.
- Patients with a jejunostomy are recommended a diet high in energy, protein, fat and sodium, but restricted in fibre and fluid.
- Patients with a colon in continuity are recommended a diet high in energy, protein and carbohydrate, and moderate in fat to achieve energy balance whilst avoiding steatorrhoea. A reduced oxalate intake is advised to prevent kidney stones.
- Enteral support should be provided in the form of polymeric supplements and feeds usually have sodium added. Elemental formulae provide no benefit over polymeric formulae.

Resection of the large intestine

- Sodium and fluid balance should be closely monitored.
- A well-balanced diet based on the principles of healthy eating should be encouraged without unnecessary food restrictions.

Intestinal failure

The term intestinal failure was first used by Fleming & Remington (1981) to describe patients with 'a reduction of functioning gut mass below the minimal amount necessary for adequate digestion and absorption of nutrients'. More recently, a group of international experts agreed the following definition, 'Intestinal failure results from obstruction, dysmotility, surgical resection, congenital defect, or disease associated loss of absorption and is characterised by the inability to maintain protein energy, fluid, electrolyte, or micronutrient balance' (O'Keefe *et al.*, 2006).

Disease diagnosis and classification

The diagnosis and classification of intestinal failure is not yet agreed. The following classifications attempt to combine severity, type and length of nutritional support required (Lal *et al.*, 2006; Carlson *et al.*, 2010):

- *Type 1* – self limiting, usually <28 days duration; includes postoperative ileus or small bowel obstruction requiring short term parenteral nutrition (PN).

- *Type 2* – lasting >28 days' duration and includes complex Crohn's disease, trauma, intestinal fistula or abdominal sepsis. These patients are severely ill with major resections of the bowel plus septic, metabolic and nutritional complications requiring multidisciplinary intervention with metabolic and nutritional support to permit recovery.
- *Type 3* – generally irreversible and therefore known as chronic intestinal failure resulting from massive bowel resection, leading to short bowel syndrome, e.g. mesenteric infarct/thrombosis, massive intestinal volvulus, inflammatory bowel disease and chronic radiation enteritis. This group also includes failure of intestinal motility, e.g. chronic idiopathic intestinal pseudo obstruction, visceral myopathy/neuropathy, scleroderma and sclerosing peritonitis. These patients usually require long term home PN (HPN).

Type 1 and 2 are often referred to as acute intestinal failure. Occasionally, in type 2 intestinal failure it is not appropriate to close the abdomen after surgery and the patient is left with an open abdomen (laparostomy). The prevalence of type 1 and 2 is currently unknown, but

estimates range from 10 to 15% of patients undergoing intestinal resection and intestinal obstruction. The Association of Surgeons of Great Britain and Ireland has published principles on the surgical management of patients with acute intestinal failure, which include information on the prevention and treatment of type 1 and 2 (Carlson *et al.*, 2010). The introduction of enhanced recovery after surgery (ERAS) programs may reduce the incidence of postoperative ileus in the future (see Chapter 7.17.5).

The incidence of type 3 is also unknown but estimates can be made based on the number of patients requiring HPN in data collected by national surveys, including the British Artificial Nutrition Survey. The latest report estimated a prevalence of seven patients per million population, although it is recognised that this may be an underestimate (Jones *et al.*, 2009).

Nutritional consequences of intestinal failure and short bowel syndrome

Short bowel syndrome (SBS) is a subcategory of intestinal failure and has been defined by O'Keefe *et al.* (2006) as '*Short-bowel syndrome-intestinal failure results from surgical resection, congenital defect or disease-associated loss of absorption and is characterised by the inability to maintain protein-energy, fluid, electrolyte or micronutrient balances when on a conventionally accepted, normal diet*'. The effect of intestinal resection is best understood by considering where nutrients are normally absorbed. Most nutrients are absorbed within the first 100–150 cm of jejunum. Exceptions are vitamin B₁₂ and bile salts, which are absorbed at specific receptor sites in the terminal ileum (Figure 7.4.6). Resection of the small

bowel will therefore affect absorption, but the outcome for the patient will depend on the type, length and quality of the remaining small bowel and the presence or absence of a functioning colon. Extensive resection may result in the remaining end of the small intestine being anastomosed to the colon (jejunocolic or ileocolic anastomosis) or ending at a stoma on the abdomen (jejunostomy or ileostomy). The loss of the ileum and some of the jejunum considerably impairs digestive and absorptive function. A residual small bowel length of <200 cm can be deemed as SBS, and can lead to nutritional, fluid and electrolyte depletion if not adequately managed. When the absorptive function of the colon is no longer available, more fluid and electrolytes will be lost. Nightingale *et al.* (1992) have shown that the following lengths of small bowel are inadequate to be managed on diet alone, and parenteral support of some form is required:

- <100 cm of jejunum will need long term intravenous fluid and electrolyte replacement.
- <75 cm of jejunum will need long term PN, fluid and electrolytes.
- <50 cm of jejunum plus colon will need long term PN, fluid and electrolytes.

All patients with SBS have problems with fluid and electrolyte balance, particularly in the immediate postoperative period, with nutrient requirements increased as a result of malabsorption.

Nutritional assessment

It is important that all patients undergoing surgery have their intestinal function assessed on a daily basis. A

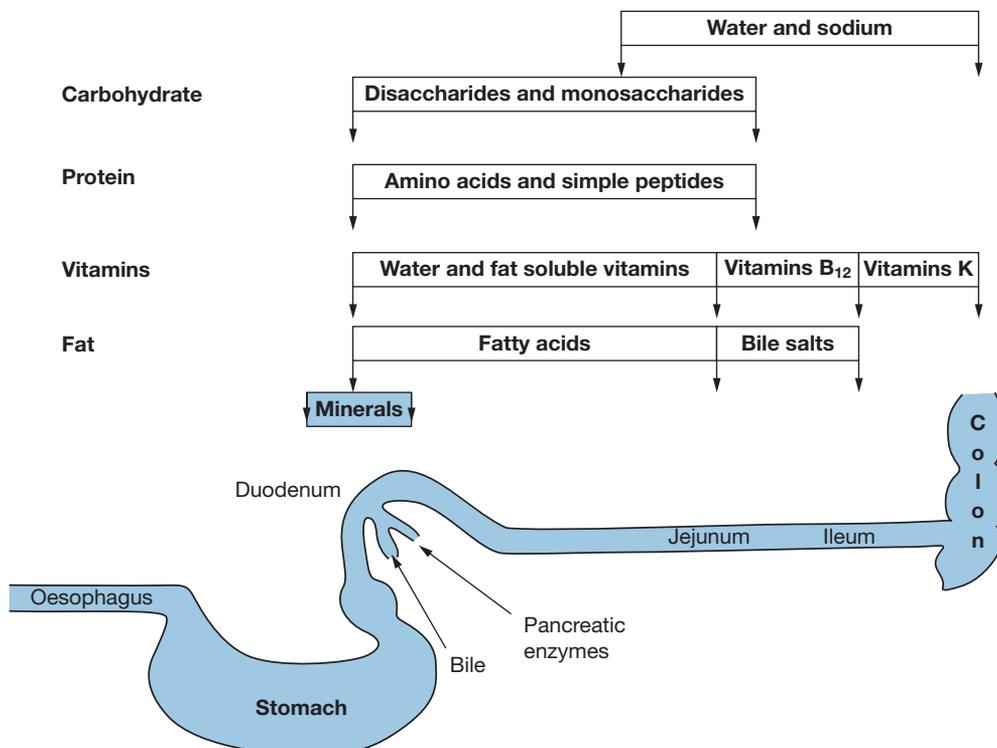

Figure 7.4.6 Sites of nutrient absorption (adapted from Thomas & Bishop 2007, figure 4.11.1, 9. 497. Reproduced with permission of Blackwell Publishing)

dietitian or nutritional support team should assess patients who fail to regain adequate function after day 5 as follows.

Anthropometry

Determine the perioperative nutritional status. Assessment of nutritional status should include weight, body mass index (BMI), percentage weight loss, mid arm circumference (MAC), triceps skinfold thickness (TST), mid arm muscle circumference (MAMC) and grip strength. Is there evidence of oedema/ascites? If so, an estimated dry weight should be used to calculate BMI.

Biochemistry

Determine the hydration status of the patient. Do they appear dehydrated or overloaded? The administration of excessive volumes of 0.9% sodium chloride is common and can exacerbate postoperative ileus (Lobo *et al.*, 2002). Routine haematology and biochemistry, including urinary electrolytes, should be monitored. A random urinary sodium is invaluable in assessing hydration status; a value of <20 mmol/L indicates dehydration. Are there any other electrolyte deficiencies, i.e. potassium, magnesium, sodium? Are there micronutrient deficiencies, i.e. folate, iron, selenium, zinc, vitamins D or B₁₂.

Clinical assessment

Determine the underlying cause. What are the chances of resolution? Is the patient septic? Ongoing sepsis will result in increased nutritional requirements and a higher risk of metabolic and infective complications. Assessment of fluid balance is crucial, aiming for an intestinal output of <1500 mL/day and a urine volume of >1000 mL/day.

Dietary assessment

Determine the perioperative nutritional intake and compare with estimated requirements. Is nutritional support required? If a patient has failed or is expected to fail to establish on enteral nutrition (EN), then PN should be considered. An assessment of the adequacy of oral diet once weaned from PN or EN is also of importance.

Economic and social assessment

Postoperative complications cause a prolonged length of hospital stay that results in increased healthcare cost. Factors contributing to reduced quality of life for patients include:

- Infection including intra-abdominal sepsis.
- Inadequate wound, fistula and stoma care, which can result in excoriated skin.
- High intestinal losses leading to dehydration and electrolyte disturbances.
- Poor provision of nutrition resulting in malnutrition.
- Immobility.
- Depression.

All of the above increase the length of rehabilitation during which time the patient is unable to return to work and family life.

Clinical investigations

Computerised tomography (CT) is invaluable to investigate intra-abdominal sepsis along with a contrast study to assess the presence of an anastomotic leak. The management of abdominal sepsis is the most important aspect of care and can predict mortality and morbidity. Before considering reconstructive surgery in a patient with type 2 intestinal failure, it is important that radiological assessment has been completed as this provides a detailed understanding of the postoperative anatomy and the likelihood of parenteral independence (Carlson, 2003).

Clinical management

Fluid and sodium management of short bowel syndrome

The focus of treatment aims to reduce intestinal losses, thereby preventing dehydration and electrolyte disturbances; restricting oral fluid intake and using an oral rehydration solution achieves this. In some patients (known as secretors) intestinal losses of fluid and electrolytes may exceed the amount taken in by mouth, and parenteral replacement will be required. This is particularly likely to occur if the stoma is situated <100 cm along the jejunum (Nightingale *et al.*, 1990). Secretors may be in constant negative fluid and sodium balance. Those who can maintain sodium balance will still lose considerable amounts of sodium from their stoma and these losses will need to be replaced. Patients with an intestinal output of <1500 mL/day can usually maintain their sodium balance by adding extra salt to food, during cooking and by eating salty foods. An oral sodium supplement will be required when losses are greater than this. This should be provided as a glucose electrolyte solution with sodium content of at least 90 mmol/L, known as electrolyte mix (containing 20 g of glucose, 3.5 g of sodium chloride and 2.5 g of sodium bicarbonate). The patient should be encouraged to consume a litre of electrolyte mix, sipping it slowly throughout the day. The mix can be unpalatable and adding a small amount of juice or cordial, chilling and sipping through a straw may enhance its acceptability. Oral fluids with a lower sodium concentration, such as water or tea, should be restricted to <1L/day as they will increase intestinal losses (Nightingale, 1994). Some patients will not be able to achieve adequate fluid and sodium balance by oral means and will require either subcutaneous or intravenous saline, possibly with additional magnesium, which can be administered at home (Martinez-Riquelme *et al.*, 2005).

Although it is common practice to encourage patients to consume foods and fluids separately, there is no evidence to support this advice. Woolf *et al.* (1987) found that restricting fluid intake around meals did not improve nutrient absorption in stable patients either with or without a colon. However, many patients with a high output stoma or fistula anecdotally report a benefit.

Pharmaceutical management

Other factors such as increased gastric acid production and reduced intestinal transit time exacerbate the prob-

lems of dehydration and sodium depletion in patients with SBS (Lennard-Jones, 1994). Gastric antisecretory drugs such as proton pump inhibitors have been shown to reduce intestinal losses by 1.5 kg/24 hours (Nightingale *et al.*, 1991). Patients who fail to absorb oral preparations may benefit from parenteral administration (Jeppesen *et al.*, 1998). Octreotide is a somatostatin analogue that reduces gastric, pancreatic and biliary secretions (Rodrigues *et al.*, 1989). However, its use should be reserved for patients with very high intestinal losses as it is given by a subcutaneous injection, three times daily. If there is no improvement after 3 days, it should be discontinued. Octreotide is frequently used in an attempt to heal a fistula, but this use is not supported by randomised controlled trials (Lloyd *et al.*, 2006). Antidiarrhoeal agents such as loperamide and codeine phosphate benefit patients by decreasing the frequency and weight of intestinal output and prolonging the transit time (Mainguet & Fiasse, 1977). These drugs are usually needed in very high doses and should be taken 30–60 minutes before meals. Cholestyramine, an ion exchange resin used in patients with bile salt malabsorption, is likely to increase bile salt loss, decrease the bile salt pool and further reduce jejunal bile salt concentration, possibly to a level below the micellar concentration. It is therefore not recommended for patients with a colon in continuity except as a possible treatment for hyperoxaluria (Lennard-Jones, 1994). Magnesium deficiency is common and can usually be corrected with an oral magnesium oxide supplement, although this can also result in increased intestinal output. If oral supplements are ineffective, then magnesium sulphate can be added to normal saline and given subcutaneously or intravenously to maintain plasma concentrations (Martinez-Riquelme *et al.*, 2005). Vitamin D concentrations should be measured and replaced if found to be deficient as vitamin D will increase the intestinal and renal absorption of magnesium (Nightingale, 2001).

Nutritional management

The nutritional management of intestinal failure is a dynamic process that involves overlap or transition between diet, EN and PN as the patient's condition changes. The judgement to start nutrition support in type 1 and 2 intestinal failure is often fraught with indecision. The wait and see approach or the presence or absence of bowel sounds is misleading and can result in significant time without adequate nutrition in those who may benefit from PN. Despite the obvious benefits of PN support in patients with type 1 and 2 intestinal failure, a recent report on the use of PN revealed good standards of care in only 19% of UK hospitals. The report highlighted a lack of adequate consideration of EN, delays in the initiation of PN, and inadequate assessment and monitoring, resulting in avoidable metabolic and infective complications [National Confidential Enquiry into Patient Outcome and Death (NCEPOD), 2010]. It is common for patients who develop an enterocutaneous fistula to be placed nil by mouth and to start PN and octreotide in an attempt to heal the fistula. However, in patients where closure is

unlikely to occur spontaneously, an oral diet can be introduced. Patients with intestinal fistulae who have over 75 cm of normal small intestine distal to the fistula may be candidates for fistuloclysis, a technique in which EN is infused into the distal small intestine (Teubner *et al.*, 2004). Further details on this technique can be found on the website of the Intestinal Rehabilitation Unit at Salford Royal Hospital (www.i-rehab.org.uk).

The general principles of nutritional management can be summarised as:

- Immediately post surgery, PN will be required. Close attention should be paid to fluid and electrolyte balance (especially sodium and magnesium as losses may be very high).
- In order to stimulate gut adaptation, enteral intake should be introduced as soon as possible while still continuing some parenteral support. Initially, the patient's oral fluid intake should not exceed 500 mL/day.
- When fluids are tolerated, small meals and snacks can gradually be introduced. Food introduction to patients also likely to need long term PN should aim to find a balance between eating for pleasure and avoiding high intestinal losses. For those likely to be able to manage on diet alone, the aim should be to maximise intake to achieve adequate absorption.
- Parenteral support can be reduced as oral intake increases. However, parenteral fluids and/or oral glucose electrolyte solutions are likely to be needed to meet fluid and sodium requirements until gut adaptation takes place. Additional nutritional support in the form of polymeric supplements or overnight feeding may be required. If the patient is receiving an enteral feed, sodium may need to be added to increase the sodium content to >90 mmol/L. This can be achieved by adding 10–20 mL of 30% sodium chloride (50–100 mmol) to ready to hang feeds; this measure may allow the patient to stop taking oral electrolyte mix during the day.
- As adaptation occurs, gradual transition to a more normal diet can be made, with inadequacies in nutrition or fluid intake being compensated by nutritional support measures if indicated.
- Since restoration of intestinal lactase levels is one of the last adaptive mechanisms to occur, large lactose loads may need to be avoided initially. However, there is no evidence that stable patients, either with or without a colon, benefit from a lactose free diet (Arrighoni *et al.*, 1994). Therefore, foods containing lactose should not be excluded from the diet of short bowel patients as they provide a valuable source of macro- and micro-nutrients.

It is imperative that patients with SBS adhere to an appropriate regimen in order to maximise the remaining intestine and reduce dependence on PN. For over 50 years it has been known that patients who have significant bowel resections need to consume excessive oral nutrients to overcome malabsorption and avoid malnutrition. However, it was not until the 1990s that the exact

composition of the diet depending on intestinal anatomy was identified (Nordgaard *et al.*, 1994). Balance studies have shown energy requirements exceeding 2.5 times basal energy expenditure [30–60 kcal (125–250 kJ)/kg/day] and nitrogen intakes of 0.2–0.25 g/kg/day are required to prevent protein energy malnutrition (Woolf *et al.*, 1987; Messing *et al.*, 1991). Recent studies have confirmed these findings and recommendations (Crenn *et al.*, 2004; Estívariz *et al.*; 2008), and the promotion of a hyperphagic diet is now established. This involves the provision of high energy meals and snacks as well as food fortification and nutritional supplements. For patients who have difficulties in achieving recommended oral macronutrient intakes, oral nutritional supplements or enteral feeding may provide additional nutrients. Nocturnal EN is often utilised to maximise absorption by increasing the length of time the bowel is exposed to nutrients. McIntyre *et al.* (1986) compared an elemental versus a polymeric formula and found no significant differences in the percentage of macronutrient absorption. Cosnes *et al.* (1992) compared a semi elemental versus a polymeric formula and demonstrated improved nitrogen absorption on the semi elemental ($p = 0.012$). No other differences in absorption were shown. The contrasting results in nitrogen absorption are likely to be related to the composition of the formulae investigated. Elemental formula is less palatable, has a higher osmolality and requires larger volumes to meet estimated nutritional requirements in comparison to polymeric formula, and therefore if additional nutritional support is required to maintain or improve nutritional status in patients, then a polymeric formula is recommended. Joly *et al.* (2009) randomised patients to usual diet or usual diet plus continuous enteral feeding using a polymeric formula and found increased absorption of energy, nitrogen and fat with no increase in intestinal output whilst receiving continuous enteral feeding compared to those on diet alone. The continuous method of feeding may improve intestinal absorption to an extent that patients no longer require PN and should, therefore, be a treatment option for all short bowel patients with over 75 cm of small bowel. If a vitamin, mineral or trace element deficiency is demonstrated, an appropriate supplement can be prescribed. If >100 cm of terminal ileum is resected, then the patient will become depleted in vitamin B₁₂ and will require replacement via an intramuscular injection every 3 months.

In practice there are two types of patients with SBS and it has become apparent that patients differ in their response to dietary manipulation depending on the presence or absence of a colon, and this determines whether the additional energy requirements should be provided from fat or carbohydrate (Table 7.4.10).

Patients with a jejunostomy

Patients with a jejunostomy have had varying lengths of jejunum, ileum and colon removed. The remaining small bowel is then brought to the surface of the abdomen to create a stoma (jejunostomy) (Figure 7.4.7). Patients have immediate problems postoperatively due to large intesti-

Table 7.4.10 Summary of evidence based recommendations for the dietary treatment for patients with short bowel syndrome

	Jejunocolic anastomosis	Stoma (jejunostomy)
Total energy	30–60 kcal/kg/day (125–250 kJ/kg/day)	30–60 kcal/kg/day (125–250 kJ/kg/day)
Nitrogen	0.2–0.25 g/kg/day	0.2–0.25 g/kg/day
Protein	1.25–1.5 g/kg/day	1.25–1.5 g/kg/day
Fat (% of total energy)	20–30	30–40
MCT (% if total fat)	50	No proven benefit
Carbohydrate (% of total energy)	50–60	40–50
Fibre	Low to moderate	Low
Sodium chloride	Normal	Additions usually required
Enteral nutrition	Polymeric	Polymeric

MCT, medium chain triglyceride.

nal losses from the jejunostomy leading to fluid and sodium depletion. Malnutrition will occur if appropriate nutritional support is not instigated. In addition, the patient will also experience a rapid transit time, reducing the potential for nutrient absorption and resulting in subsequent weight loss and malnutrition. Studies of short

bowel patients consuming their usual diet indicate that on average <50% of oral fat intake is absorbed. The role of fat restriction has been controversial, with conflicting results from different research groups (Andersson *et al.*, 1974; Hessov *et al.*, 1983; Ovesen *et al.*, 1983; Woolf *et al.*, 1983; McIntyre *et al.*, 1986; Crenn *et al.*, 2004). Overall, it appears that there is no significant benefit to patients following a low fat diet and since fat provides a concentrated form of energy and makes the diet palatable in addition to providing essential fatty acids, these patients should therefore be encouraged to have a high intake of fat.

It is often recommended that due to the rapid transit through the intestine, that dietary fibre is limited in patients with SBS. However, only one study has been conducted manipulating the fibre content of the diet of jejunostomy patients. McIntyre *et al.* (1986) conducted a randomised controlled trial in four jejunostomy patients who received diets that were isocaloric and isonitrogenous, but with variable amounts of fat, fibre and carbohydrate over a 2–3-day period; no significant benefit of manipulating the diet was found. Despite a lack of evidence, patients anecdotally report a reduction in intestinal output on a low fibre diet.

Patients with a jejunocolic anastomosis

Patients with a jejunocolic anastomosis have had the ileum and some jejunum resected, and the remaining jejunum anastomosed to the colon (Figure 7.4.8). They

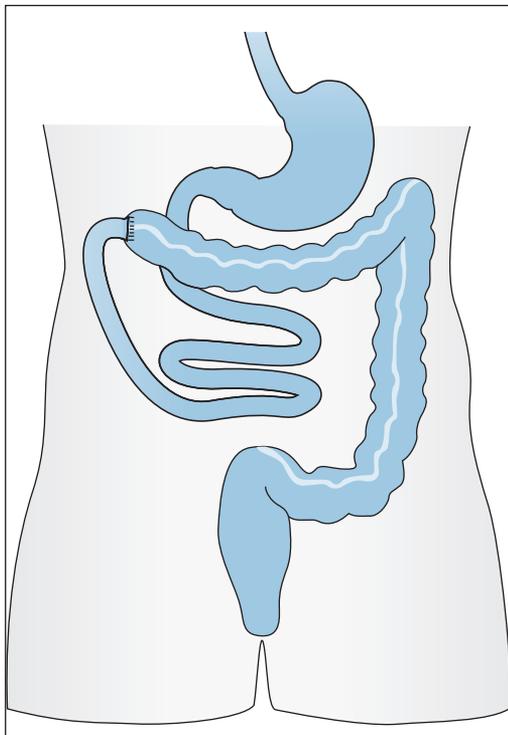

Figure 7.4.8 Jejunocolic anastomosis (courtesy of Northwest London Hospital Trust, Medical Illustrations Department)

experience diarrhoea and/or steatorrhoea with resultant malabsorption, weight loss and malnutrition. The presence of the colon in continuity is advantageous because it enables water and sodium to be absorbed, and results in a slower intestinal transit, aiding nutrient absorption. A comparison of the effects of a diet either high in carbohydrate (60%) and low in fat (20%) or vice versa (20% carbohydrate and 60% fat) found that patients with a colon absorbed a higher percentage of energy on the high carbohydrate, low fat diet, but that no such difference was seen in jejunostomy patients. This suggests that patients with a colon salvage energy as a result of the fermentation of unabsorbed carbohydrate to easily absorbed short chain fatty acids (Nordgaard *et al.*, 1994). Colonic digestion can supply up to 1000kcal (4.19kJ)/day in patients with <200 cm of jejunum in continuity (Nordgaard *et al.*, 1996). These patients should therefore be encouraged to take a diet as high in carbohydrate as can be tolerated without causing bloating due to increased gas production. A reduction in fat intake is often helpful as this decreases magnesium and calcium losses, and reduces steatorrhoea/diarrhoea and oxalate absorption (Lennard-Jones, 1994). However, a reduced fat intake will also reduce energy intake and so in practice, a compromise has to be found between including fat for energy and avoiding steatorrhoea. Replacement of long chain triglyceride (LCT) with a medium chain triglyceride (MCT) fat emulsion has been shown to increase energy and fat absorption in patients with a colon (Jeppesen & Mortensen, 1998).

A secondary consequence of steatorrhoea is a greater risk of calcium oxalate renal stones, due to increased colonic oxalate absorption and resultant hyperoxaluria. A low oxalate diet is advisable in these circumstances; will restrict intake of tea, spinach, beetroot, rhubarb, peanuts and chocolate. Avoiding chronic dehydration is another important measure to reduce the risk of renal stones (Nightingale *et al.*, 1992).

In conclusion, short bowel patients need to consume as much as twice the average estimated requirements of energy and protein to compensate for lack of absorptive capacity. Patients with a jejunostomy will benefit from a high fat diet whereas those with a colon should focus on increasing the carbohydrate content of the diet (see Table 7.4.10). Close dietetic supervision of these patients is vital during the early stages and until intestinal adaptation has taken place. Manipulation of the diet and changes in medication should be staged, with several days allowed for each stage and to assess the impact of each change on intestinal output. Each patient is individual and it will need a lot of time and patience to find the combination that best suits. Patients benefit from the support of a multidisciplinary team where there is close liaison between doctors, nurses, dietitians and pharmacists.

Future advances in treatment

Glucagon like peptide 2 (GLP 2), a hormone secreted by the intestine, has been shown to increase the growth of

normal cells in the intestine, allowing the intestine to absorb more fluid and nutrients, which may help to reduce dependency on PN. An analogue of GLP 2 is being evaluated and could be a promising therapy for patients with SBS (Jeppesen *et al.*, 2005).

Small bowel transplantation offers an alternative treatment to patients with chronic intestinal failure dependent on HPN. However, although survival is improving, it does not yet match that achieved by HPN and should be reserved for patients with complications of HPN, such as liver disease and poor venous access (Middleton, 2007).

Resection of the large intestine

Disease processes

Resection of the large intestine is usually performed due to inflammatory bowel disease (IBD), cancer of the colon, diverticulitis or the genetic condition familial adenomatous polyposis (FAP).

Disease consequences

Until the early 1980s, resection of the colon and rectum resulted in the creation of a permanent stoma, either an ileostomy (following complete removal of the colon and rectum) or colostomy (after removal of the terminal segment of the colon and rectum). Intestinal effluent is collected in a bag fixed around the stoma onto the skin. These procedures are still performed if disease requires such extensive rectal resection that no functioning muscle tissue in the anal area remains, e.g. as in IBD. A major improvement has occurred with the development of the restorative proctocolectomy, a procedure that involves the creation of a pouch reservoir from a segment of ileum, which is then joined to the anus. The pouch acts as an artificial rectum, thus conserving anal continence and avoiding the need for a stoma. This technique is commonly used to treat patients with ulcerative colitis or FAP and is much more acceptable to patients than a permanent ileostomy.

Ileal pouches derive their names from the number of limbs of ileum used in their fashioning (J pouch, S pouch and W pouch). These surgical procedures, which anastomose different pouch types to the anal canal (the ileal pouch anal anastomosis), share common methodology. Ileal reservoirs can also be constructed without an ileal pouch by anal anastomosis, e.g. the continent ileal reservoir or Kock pouch, but these procedures are now less frequently performed.

Pouch creation is complex and the operation is often done in two stages. First, colectomy (removal of the colon) and proctectomy (removal of diseased rectal mucosa) are performed, leaving the rectal muscular cuff and anal sphincter intact. A pseudo rectum (pouch) is constructed by joining a portion of the terminal ileum to the anal canal and a temporary ileostomy created to divert bowel contents away from the newly formed pouch, allowing it to heal. A further operation then anastomoses the pouch to the intestine and reverses the ileostomy. The

safety, feasibility and short term outcome of performing this operation laparoscopically has demonstrated similar results to open surgery with improvements shown in recovery outcomes (Larson *et al.*, 2006).

Following surgery, problems with stool frequency and/or consistency are likely to occur, but continence is usually achieved within 10 days and over a period of about 1 year, the pouch gradually adapts with bowel movements becoming less frequent and more solid in consistency (Nicholls & Williams, 2002).

Nutritional consequences

Removal of the colon results in considerable loss of absorptive capacity in respect of fluids and electrolytes, especially sodium. Initially, considerable quantities of both electrolytes and fluid will be lost (between 1200 and 2000 mL/day) and requirement for both will be increased for at least 6–8 weeks. After this time, the ileum appears to adapt and losses decrease, although they still remain in the order of 400–600 mL/day. However, in contrast to those with accompanying ileal resection, the digestive and absorptive capacity of the small intestine remains, so that no major nutritional deficiencies are to be expected, except for vitamin B₁₂ and bile acids, which occur in about one-third of patients (Christl & Scheppach, 1997). More recently, concerns have been raised that patients with an ileostomy are chronically dehydrated and have depleted calcium and magnesium stores, putting them at risk of renal impairment, renal stones and bone demineralisation (Ng *et al.*, 2004).

Nutritional assessment

Anthropometry

Determine the perioperative nutritional status. Patients may be malnourished prior to surgery and their nutritional risk will need to be identified and action taken in order to avoid a deterioration in nutritional status and poor surgical outcome (Fulham, 2004). Assessment of nutritional status should include weight, BMI, percentage weight loss, MAC, TST, MAMC and grip strength. Is there evidence of oedema/ascites? If so, an estimated dry weight should be used to calculate the BMI.

Biochemistry

Determine the hydration status of the patient. Do they appear dehydrated or overloaded? The administration of excessive volumes of 0.9% sodium chloride is common and can exacerbate postoperative ileus (Lobo *et al.*, 2002). Are there any electrolyte deficiencies, i.e. potassium, magnesium, sodium. Are there any micronutrient deficiencies, i.e. folate, iron, selenium, zinc, vitamin D or B₁₂.

Clinical assessment

Is the patient septic? Ongoing sepsis will result in increased nutritional requirements and a higher risk of metabolic and infective complications. Assessment of fluid balance is crucial aiming for an intestinal output of <1500 mL/day and a urine volume of >1000 mL/day.

Dietary assessment

Determine the perioperative nutritional intake and compare this to estimated requirements. Is nutritional support required? If a patient has failed or is expected to fail to establish on EN, then PN should be considered. Assessment should be made of the adequacy of an oral diet once weaned from PN or EN.

Economic and social assessment

Postoperative complications cause a prolonged length of hospital stay that results in increased healthcare cost. Factors contributing to reduced quality of life for patients include:

- Infection including intra-abdominal sepsis.
- Inadequate wound, fistula and stoma care, which can result in excoriated skin.
- High intestinal losses leading to dehydration and electrolyte disturbances.
- Poor provision of nutrition resulting in malnutrition.
- Immobility.
- Depression.

All of the above increase the length of rehabilitation during which the patient is unable to return to work and family life.

Clinical management

Perioperative fasting in gastrointestinal surgery is no longer recommended and early enteral feeding should be encouraged (Fearon *et al.* 2005; Lewis *et al.* 2009). The long term consequences in terms of faecal volume and biochemistry appear to be similar in patients after restorative proctocolectomy with a J pouch (Okamoto *et al.*, 1995) and those with conventional panproctocolectomy and permanent ileostomy. However, due to the kidneys' attempt to conserve water and sodium, both groups of patients are at greater risk of uric acid stones as a result of producing urine that is low in volume and pH, and with a high concentration of calcium and oxalate compared with control subjects (Christie *et al.*, 1996). In addition, J pouch patients may be at increased risk of calcium stones and abnormal bile acid metabolism. Patients with pouches should be advised regarding the possibility of developing pouchitis, inflammation within the pouch, which can occur in up to 50% patients. Symptoms include increased pouch frequency, reduced stool consistency and urgency, and usually respond well to antibiotics. The probiotic VSL#3 may be beneficial in maintaining remission of pouchitis and is recommended by the British Society of Gastroenterology (Mowat *et al.*, 2011) and a Cochrane systematic review (Holubar *et al.*, 2010).

Nutritional management

While the ileum is adapting and the stool or stomal effluent remains liquid, fluid losses should be replaced by the consumption of 1.5–2L/day of fluid. Additional salt, e.g. up to one teaspoon added to food during the course of

a day, may be necessary in hot weather or if losses are particularly high. As stool frequency and consistency improve, losses will decrease, but it remains important to ensure adequate fluid and sodium provision. An episode of vomiting or diarrhoea can rapidly create an electrolyte imbalance and the provision of extra potassium (via fruit juices) and sodium (via extra salt on food or salty beverages such as soup or meat extracts) is advisable (Pearson, 2008). In severe cases, parenteral saline may be necessary.

It should not be overlooked that many patients will be nutritionally depleted after colorectal surgery, particularly if they suffered chronic ill health beforehand and food intake was poor. If, as in the case of pouch patients, two, or even three, operations are required, this is a further strain on nutritional status. It will also take some time before normal appetite is restored. It is therefore important that patients are encouraged to consume small, frequent, nutrient dense meals and snacks, and that additional oral nutritional support measures are instituted when necessary. Return to normal body composition in ulcerative colitis patients undergoing J pouch has been described (Christie & Hill, 1990; Jensen *et al.*, 2002).

Dietary guidance for ileostomy and pouch patients is similar. People should be encouraged to:

- Adopt a regular meal pattern. Some may need smaller meals at more frequent intervals. Those with pouches may need to avoid eating late at night to avoid nocturnal stool production.
- Eat a varied well balanced diet based on healthy eating principles.
- Consume meals slowly and chew foods well.
- Drink plenty of fluids (1.5–2L/day) and more in hot weather.
- Consume extra fluid and salt if stool or stoma losses suddenly increase or during episodes of vomiting or fever. Medical advice may be needed if these losses are severe or persistent.

The range of foods consumed can be gradually increased and patients should be encouraged to eat a normal diet based on the principles of healthy eating. No foods are specifically contraindicated for ileostomy or pouch patients, but some foods can cause unpleasant symptoms such as stool odour or flatulence. Blockage with undigested food residues can occur, particularly if the stoma or anastomosis is tight. Occasionally, a low residue diet is required if obstruction regularly occurs. However, in most people this is unnecessary and avoidance of the few specific foods that typically cause the problem is sufficient to prevent it. There is a small amount of evidence (Steenhagen *et al.*, 2006; Chartrand-Lefebvre *et al.*, 1990; Pearson 2002; 2008) on food related problems in ileostomy/pouch patients, including:

- *Poorly digested foods* (most likely to cause blockage) – grapefruit, lettuce, mushrooms, sweet corn, fruit or vegetable skins, lentils, peas, nuts, seeds, tomatoes, coconut, fibrous fruit and vegetables such as celery or pineapple, and Chinese food.

- **Increased stool odour** – onions, garlic, brassica vegetables (Brussel sprouts, cabbage, cauliflower and broccoli), beans, fish and eggs.
- **Increased flatulence/bloating** – baked beans, lentils, peas, onions, garlic, brassica vegetables, fizzy drinks, beer and lager.
- **Increased stool frequency** – beer, spirits, Chinese food, wholewheat cereals, corn, apples, wine, fried and spicy foods, strawberries, potatoes, bread, bananas, fruit, fruit juice and vegetables.
- **Decrease in stool consistency** – beer, wine, fried fish, strawberries, corn, popcorn, spirits, coleslaw, grapefruit, turnips, raspberries and fruit juice.
- **Perianal irritation** – spicy foods, citrus fruit, raw carrot, nuts and seeds.

It appears that the majority of patients with an ileal pouch report that some form of dietary restriction is required to help prevent unpleasant symptoms and that this impacts on quality of life (Coffey *et al.*, 2002). However, it should be remembered that individual tolerance may vary considerably, so patients should be encouraged to discover for themselves on a trial and error basis which foods are best tolerated. Patients should also be warned that foods such as beetroot could change the colour of the stool to such an extent that it can be mistaken for bleeding. Continuing problems with stool frequency may be treated with loperamide. There is no evidence that supplementary fibre in the form of pectin or methylcellulose is helpful in this respect (Thirlby & Kelly, 1997). A recent study investigated the effect of a fermentable oligo-, di- and mono-saccharides and polyols (FODMAP) diet on bowel function in 15 patients without a colon and reported a significant reduction in daily stool frequency. However, this result was limited to those without pouchitis (Croagh *et al.*, 2007).

All patients should receive regular follow-up to ensure that diet related problems are remedied, unnecessary food restrictions avoided and adequate nutritional status maintained.

Drug–nutrient interactions

The following should be noted:

- Proton pump inhibitors – no interaction with food or nutrients demonstrated.
- Loperamide – no interaction with food or nutrients demonstrated. Aim to avoid syrup formulations as these contain sorbitol, which can act as a laxative.
- Octreotide – no information available.
- Colestyramine – no interaction with food or nutrients demonstrated. Other drugs should be taken at least 1 hour before or 4–6 hours after to reduce possible interference with absorption.

7.4.10 Irritable bowel syndrome

Yvonne Mckenzie

Key points

- Irritable bowel syndrome is a common gastrointestinal disorder of medically unexplained symptoms.
- Management aims to improve the severity and frequency of symptoms and quality of life, and may require a combined lifestyle, dietary and pharmacological approach.
- A new efficacious treatment is the restriction of short chain carbohydrates (low FODMAP diet). Successful management requires advanced dietetic knowledge, adequate clinical time and resources for patients.
- Patient empowerment should be supported to enable them to self manage their condition in the long term.

Irritable bowel syndrome (IBS) is a common functional gastrointestinal disorder. The UK prevalence is 10–20%, with a similar incidence worldwide despite differences in lifestyle (Spiller *et al.*, 2007). With functional dyspepsia, IBS accounts for 40–60% of all gastroenterology outpatient referrals (Jones *et al.*, 2000). Irritable bowel disease was first described in 1818 (Thompson, 2006) and since then diagnostic criteria and treatment options have evolved, but the heterogeneity of IBS continues to challenge clinicians. It is no longer a diagnosis of exclusion of organic pathologies, but one of medically unexplained symptoms. Irritable bowel syndrome is chronic, recurring abdominal pain or discomfort associated with disturbed bowel habit in the absence of an organic cause (Longstreth *et al.*, 2006). Until recently, dietetic practice utilised dietary fibre modification and exclusion diets to manage symptoms.

Diagnostic criteria

There are no pathology tests to diagnose IBS, but the National Institute for Health and Care Excellence (NICE, 2009) guidance gives positive, cost-effective diagnostic criteria (Box 7.4.1). Red flags or red flag indicators prompt secondary care referral for investigation of more serious pathologies (Table 7.4.11). In research, the more complex Rome III criteria (Drossman, 2006) are used.

Classification

Recognised subtypes of IBS are based on the predominant stool pattern (Longstreth *et al.*, 2006). The Bristol Stool Form Scale (Heaton *et al.*, 1992) is recommended to assess stool consistency (Longstreth *et al.*, 2006) (Table 7.4.12).

Disease processes

The cause of IBS symptoms is only partially understood. A leading hypothesis is enteric nervous system dysfunction, with an individual's emotional and physical wellbeing being relevant to risk (Spiller *et al.*, 2007). Central nervous system interaction may potentially lead to symptoms of dysmotility (pain) and transit (altered bowel habit). Approximately 60% of IBS patients report symptom worsening, especially pain, within 15 minutes or up to 3 hours after eating (Simrén *et al.*, 2001). Motility studies have demonstrated delayed gastric emptying, and exaggerated

Box 7.4.1 Positive diagnostic criteria for irritable bowel syndrome and tests to be carried out to exclude other diagnoses (NICE, 2008)

- Abdominal pain or discomfort that is:
 - Relieved by defaecation *or*
 - Associated with altered bowel frequency or stool form
 and at least two of the following:
 - Altered stool passage (straining, urgency, incomplete evacuation)
 - Abdominal bloating
 - Symptoms made worse by eating
 - Passage of mucus
 for at least 6 months.
- Supporting diagnosis: lethargy, nausea, backache and bladder symptoms
- Tests: full blood count (FBC), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), antibody testing for coeliac disease

Table 7.4.11 Red flag indicators, red flags for referral to secondary care (NICE, 2008) and differential diagnoses for irritable bowel syndrome (IBS)

Red flag indicators and red flags for non-IBS disease	Differential diagnoses for IBS
Unintentional or unexplained weight loss	Bowel infections, e.g. <i>Giardia lamblia</i>
Rectal bleeding	Coeliac disease/gluten sensitivity
Family history of bowel or ovarian cancer	Crohn's disease
Change in bowel habit to looser and/or more frequent stools persisting for more than 6 weeks in a person aged over 60 years [NB: US guidelines: from age 50 years regardless of symptoms is used (Brandt <i>et al.</i> , 2009)]	Ulcerative colitis
Anaemia	Lymphocytic and collagenous colitis
Abdominal and/or rectal masses	Colorectal cancer
Inflammatory markers for inflammatory bowel disease	Small intestinal bacterial overgrowth
Symptoms suggesting ovarian cancer	Bile acid related diarrhoea
	Lactose or other carbohydrate intolerance
	Food hypersensitivity

Table 7.4.12 Irritable bowel syndrome (IBS) subtypes by predominant stool pattern

IBS with	Subtype	Definition	Bristol Stool Form Scale: predominant form
Diarrhoea	IBS-D	Loose (mushy)/watery stools for $\geq 25\%$ of bowel movements Hard or lumpy stool for $\leq 25\%$ of bowel movements	Types 6, 7
Constipation	IBS-C	Hard or lumpy stools for $\geq 25\%$ of bowel movements Loose (mushy)/watery stools for $\leq 25\%$ of bowel movements	Types 1, 2
Diarrhoea/constipation – mixed	IBS-M	Hard or lumpy stools for $\leq 25\%$ of bowel movements Loose (mushy)/watery stools for $\leq 25\%$ of bowel movements	Types 3–5
Unspecified	IBS-U	Insufficient abnormality of stool consistency to meet criteria for IBS-C, IBS-D or IBS-M	Type 3–5

small bowel and colonic responses to eating (Spiller *et al.*, 2007). Gut hypersensitivity, associated with pain, bloating and urgency to evacuate, results from the sensitisation of afferent nerve pathways originating from the gastrointestinal tract. A gut hypersensitivity prevalence of 50–90% in IBS patients has been shown (Azpiroz *et al.*, 2007).

Increasing evidence implicates a low grade inflammatory status (Barbara *et al.*, 2004; Spiller *et al.*, 2000; Walker *et al.*, 2009) and it is noteworthy that IBS like symptoms are often observed in quiescent inflammatory bowel disease. Increased colonic permeability is a suggested mechanism, which exposes the mucosa to abnormal dietary and bacterial challenges that maintain innate immune activation, possibly leading to secondary food hypersensitivity (Park & Camilleri, 2006; Tobin *et al.*, 2008). Stressors, psychological distress, life events and negative coping style may translate into physiological responses that exacerbate symptoms (Mayer *et al.*, 2001; Walker *et al.*, 1993; Whitehead *et al.*, 1992). Improvement may be delayed until such issues resolve (Bennett *et al.*, 1998).

Acute gastroenteritis is the strongest known risk factor for developing IBS (Spiller & Garsed, 2009). The consequential disruption of the intestinal ecosystem may lead to chronic symptoms in 30% of cases after 2–3 years and in 15% of cases after 8 years. Female gender, younger age, prior anxiety and/or depression and fever or weight loss during the acute enteric illness are risk factors for symptom persistence (Marshall *et al.*, 2010). Dysbiosis

(alteration in the gastrointestinal microbiota) exists in all IBS subtypes (Kassinen *et al.*, 2007; Parkes *et al.*, 2012). There is abnormal colonic bacterial fermentation in IBS compared with healthy controls (King *et al.*, 1998). However, a role for small intestinal bacterial overgrowth in IBS remains controversial (Ford *et al.*, 2009).

From twin studies there is a stronger association for environmental rather than genetic contributions to IBS (Spiller *et al.*, 2007), although IBS can cluster within families.

Disease consequences

Irritable bowel syndrome depreciates quality of life and is associated with substantial healthcare costs (Agarwal & Spiegel, 2011). Symptoms vary both within and between individuals. Bloating is the second most bothersome symptom after pain (Ringel *et al.*, 2009); distension may cause the abdominal girth to increase by >10 cm during the day. There are no long term complications of IBS, although an insufficient dietary fibre intake is associated with diverticular disease (Painter, 1985).

Comorbidity with somatic and chronic pain disorders, such as in fibromyalgia, chronic fatigue syndrome, temporomandibular joint disorder, chronic pelvic pain, non-ulcer dyspepsia, biliary dyskinesia, anxiety, depression and migraine, can exacerbate symptoms (Quigley *et al.*, 2009; Spiller *et al.*, 2007). Individuals with IBS have a normal life expectancy (Chang *et al.*, 2010).

Patient perspective

Many people with IBS suffer in silence due to a lack of awareness of the condition or ineffective treatment, but they should not feel alone with the burden of their diagnosis (Brandt *et al.*, 2009). Misconceptions exist about IBS being caused by dietary habits and colitis, worsening with age, causing malnutrition or developing into cancer (Halpert *et al.*, 2007). Therefore, patient reassurance and management of patient expectations are important once diagnosis is established.

Gastroenterology patients view diet as having an important role to play in their condition and, whilst a large proportion of patients are interested in receiving dietary advice, few expect to receive it in clinic (Adesokan & Neild, 2012). Individuals may self manage symptoms by carrying out food intolerance testing. The European Academy of Allergy and Clinical Immunology task force report (Stapel *et al.*, 2008) concluded that serum IgG4 is irrelevant in the diagnosis of food allergy or intolerance and should not be measured to account for food related symptoms.

Public health aspects

Access to clean public toilets can be a major issue for individuals with IBS. The UK's charity IBS Network supports people with IBS, campaigns on their behalf and offers a *Can't Wait* card scheme for its members, for international use as well as within the UK. Since 1977 the International Foundation for Functional Gastrointestinal Disease (IFFGD) has designated April as the International IBS Awareness month.

Nutritional consequences

Prevalence of perceived food intolerance is higher in IBS than in the general population (Monsbakken *et al.*, 2006), as patients frequently alter what they eat in an attempt to alleviate symptoms (Halpert *et al.*, 2007). However, without sound evidence, individuals should restrain from avoiding certain foods as this can lead to undernutrition, e.g. inadequate calcium intake due to dairy exclusion.

Assessment

Most patients are diagnosed and managed in primary care (Thompson *et al.*, 2000). Guidelines for the diagnosis and management of IBS in primary care (NICE, 2008) highlight the importance of avoiding unnecessary investigations to confirm diagnosis and good communication with the patient, supported by evidence based information. Dietitians should use evidence based IBS guidelines (BDA, 2010). Assessment should follow the ABCDE format.

Anthropometry

Weight, body mass index (BMI) and weight history should be assessed.

Biochemistry

The tests shown in Box 7.4.1 may be carried out. Coeliac disease should be ruled out and screening conducted at a time when the individual has been consuming gluten in more than one meal every day and has been doing so for at least 6 weeks (NICE, 2009). If endomysial antibodies (EMAs) or tissue transglutaminase (tTG) have not been checked, they should be measured prior to changing gluten intake. Other biochemistry, e.g. haematinics, should be normal (see Chapter 7.4.7).

Clinical assessment

Allergies and a family history of gastrointestinal problems, e.g. coeliac disease, inflammatory bowel disease, IBS, as well as any IBS medication or nutritional supplements should be recorded. Recording the IBS symptom profile before and after intervention is essential. There is no widely adopted validated method for measuring IBS symptom outcomes in clinical practice. The IBS Severity Score (IBS-SS) (Francis *et al.*, 1997), the Functional Bowel Disorder Severity Index (FBDSI) (Drossman *et al.*, 1995) and the Gastrointestinal Symptom Rating Scale (GSRS) (Svedlund *et al.*, 1988) are the most widely recognised tools. The Bristol Stool Form Scale (Heaton *et al.*, 1992) aids IBS subtyping. It is important to discuss IBS with the patient to ensure they understand that it is a positive diagnosis.

Faecal calprotectin is a cost effective sensitive marker of intestinal inflammation that is used to differentiate functional symptoms from active IBD in secondary and primary care. Hydrogen breath testing may help to identify which dietary management strategy is most appropriate (see Chapter 7.4.8).

Dietary assessment

Individuals may already have excluded certain foods and their thoughts on how these foods affect their IBS symptoms should be explored. Certain food avoidances may require nutritional intake assessment, e.g. calcium. Food and symptom diaries of an individual's usual diet may be useful. First line assessment is to:

- Identify any food allergies or intolerances – atopy, e.g. asthma and allergic rhinitis, may implicate food allergy in the symptomology.
- Check for regular eating pattern and a good eating lifestyle.
- Check for healthy eating, considering milk and lactose, non-starch polysaccharides (NSPs), fatty foods, fluid, caffeine and alcohol intakes.

Economic and social assessment

An empathic understanding of lifestyle circumstances is important and relevant to treatment options and concordance with dietary intervention, e.g. any stressors affecting a patient's quality of life, including physical activity, work, education and family circumstances.

Management

Clinical management

Options, either singly or in combination, include dietary, pharmacological and behavioural interventions to improve IBS symptoms and quality of life. These should be discussed with each individual to provide the most appropriate care pathway (NICE, 2008), imparting the education they need to self manage their symptoms long term. Self help information covering lifestyle modification should be considered in primary care (NICE, 2008).

Commonly prescribed drugs to manage IBS are:

- **Antispasmodics** – antimuscarinics and smooth muscle relaxants are used to reduce motility, e.g. for meal induced symptoms. Peppermint oil capsules, hyoscine butylbromide and mebeverine provide modest global symptom improvement (Ford *et al.*, 2008; Enck *et al.*, 2010).
- **Bulk forming, osmotic and stimulant laxatives**, e.g. macrogols, ispaghula husk, senna. NICE (2008) discourages lactulose.
- **Antidiarrhoeal agents**, e.g. loperamide.
- **Tricyclic analgesics**, e.g. amitriptyline and nortriptyline (at low doses if first line medication) give insufficient relief. Selective serotonin reuptake inhibitors are also used, but evidence favours the use of tricyclics.

Behavioural interventions and psychological therapy, such as cognitive behaviour therapy, relaxation techniques, psychodynamic interpersonal therapy, may reduce

pain and other symptoms and improve quality of life (Spiller *et al.*, 2007). These may be considered for those who have had symptoms for at least 12 months and have not responded to first line treatments (NICE, 2008). Reflexology, acupuncture and aloe vera have shown no benefit and are therefore not recommended (NICE, 2008). Self help organisations, such as IBS Network, can assist individuals to self manage and come to terms with their functional disorder.

Nutritional management

Nutritional management aims to improve the severity and frequency of IBS symptoms and quality of life through dietary and lifestyle modification, whilst supporting dietary adequacy in line with general healthy eating guidelines. The UK evidence based practice guidelines for the dietetic management of IBS in adults (BDA, 2010) are for dietitians' use in the UK healthcare setting. These give graded evidence statements, clinical and research recommendations, and good practice points stemming from five systematic reviews relating to IBS symptom improvement and the role of milk and/or lactose, NSPs, fermentable carbohydrates, probiotics and empirical and elimination diets.

An IBS algorithm (Figure 7.4.9), a logical three line sequence of interventions for successful dietetic management, forms the basis of these guidelines and can be used in clinical practice. The lifestyle and dietary clinical practice recommendations are summarised in Box 7.4.2; for further details see McKenzie *et al.* (2012).

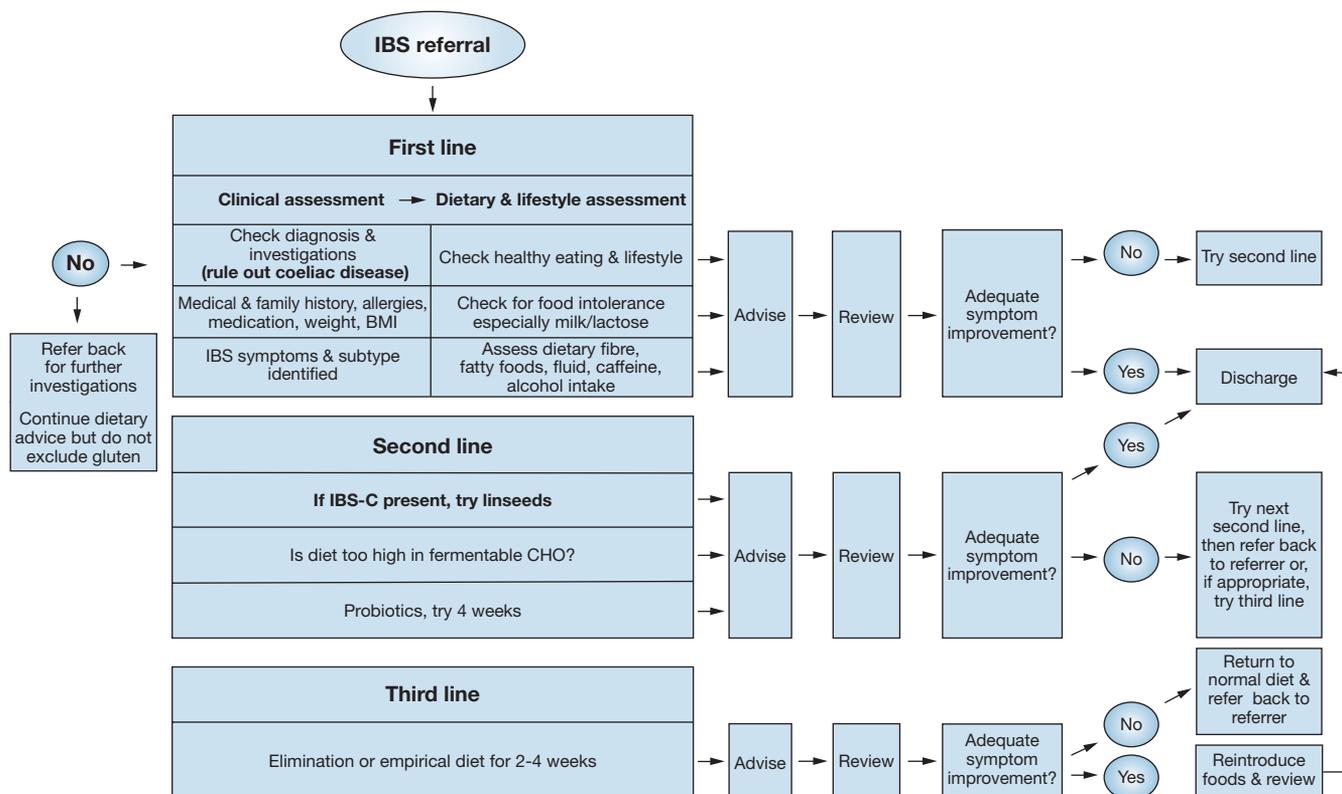

Figure 7.4.9 Algorithm for the management of irritable bowel syndrome (IBS) [source: The British Dietetic Association 2013. Reproduced with permission of the British Dietetic Association (www.bda.uk.com)]
CHO, carbohydrate; BMI, body mass index; IBS-C, irritable bowel syndrome – C

Box 7.4.2 Clinical practice considerations and evidence based recommendations for irritable bowel syndrome (IBS) [adapted from McKenzie *et al.* (2012)]

First line: Healthy eating and lifestyle management

- (a) Encourage a regular meal pattern, take time over meals, sit down to eat, chewing food thoroughly, avoid late night eating, encourage good food variety and ensure nutritional adequacy in line with general healthy eating guidelines
- (b) Drink plenty of caffeine free, alcohol free, non-fizzy fluids spread throughout the day, aiming for 1.5–3.0L/day (35 mL/kg)
- (c) Encourage exercise, relaxation and coping strategies for the demands of everyday life

SIGN 50
Grade of
recommendation

Removing milk and dairy products to improve IBS symptoms

- (d) In individuals in whom sensitivity to milk is suspected and a lactose hydrogen breath test is not available or appropriate, a trial period of a low lactose diet is recommended. This is particularly useful in individuals with an ethnic background with a high prevalence of primary lactase deficiency **D**
- (e) Use a low lactose diet to treat individuals with a positive lactose hydrogen breath test **D**
- (f) In individuals where milk is suspected as a problem food but symptoms do not improve on a low lactose diet, assess other components of milk, e.g. cow's milk protein, as a contributing factor. Recommend a milk free diet or, in some cases, an alternative mammalian milk **D**

Non-starch polysaccharides

- (g) First line: Avoid using dietary supplementation of wheat bran to treat IBS. Individuals should not be advised to increase their intake of wheat bran above their usual dietary intake **C**

Second line: Advanced dietary interventions: linseeds, fermentable carbohydrates; probiotics

- (h) For individuals with IBS-C, dietary supplementation of ground linseeds can be recommended for a 3-month trial. Improvements in constipation, abdominal pain and bloating from linseed supplementation may be gradual **D**

Fermentable carbohydrates, for all IBS subtypes

- (i) For individuals with IBS and suspected or diagnosed fructose malabsorption, assess dietary intake of all short chain fermentable carbohydrates (fructose, fructans, galactooligosaccharides and polyols). There is likely to be a benefit in reducing intake **B**
- (j) For individuals with IBS and abdominal bloating, abdominal pain and/or flatulence, assess dietary intake of fermentable carbohydrates as there may be a benefit in reducing intake **D**
- (k) There may be individual tolerance levels to fermentable carbohydrates. A planned and systematic challenge of foods high in fermentable carbohydrates will identify which foods can be re-introduced to the diet and what individual tolerance levels are **D**

Probiotics, no IBS subtype specified

- (l) Probiotics can be considered, ideally, after assessing the effectiveness of restricting intake of fermentable carbohydrates. Advise individuals choosing to try probiotics to select one product at a time and monitor the effects. They should try it for a minimum of 4 weeks at the dose recommended by the manufacturer **B**
- (m) There is considered to be no associated harm in taking probiotics for individuals with IBS **B**

Third line: Elimination and empirical diets

- (n) Where food is considered to be a trigger for IBS symptoms, particularly IBS-D, an elimination or empirical diet can be considered **D**
- (o) The initial phase of an elimination or empirical diet should be followed for 2–4 weeks **D**
- (p) If there is no symptom improvement within 2–4 weeks of the initial phase of an elimination or empirical diet, and foods consumed within the diet are not suspected to be symptom triggers, specific foods are an unlikely cause of IBS symptoms **D**

For mild symptoms first line management may be sufficient. Evidence suggests that in individuals with IBS, a fatty meal induces greater abdominal pain than it does in healthy controls (Simrén *et al.*, 2007) and bloating is exaggerated after lipid infusion (Serra *et al.*, 2002). There are no trials showing that individuals with IBS have greater sensitivity to caffeine or alcohol, and the placebo effect, known to be high in IBS (Kaptchuk *et al.*, 2008; Spiller, 1999), should be borne in mind.

In the UK, lactose intolerance is reported to be present in 10% of people with IBS, but lactose avoidance rarely cures IBS (Spiller *et al.*, 2007). Other currently unknown components of milk may contribute to symptoms (Parker *et al.*, 2001) and suitable alternatives to cow's milk include calcium enriched non-mammalian milks and yoghurt. A recent meta analysis (Ford *et al.*, 2008) was unable to show that dietary fibre was an efficacious treatment for IBS; however, many of the trials lacked good design criteria and used inappropriate placebos.

Successful advanced management relating to fermentable carbohydrates is achieved by providing detailed verbal and written resources on avoidance of the relevant foods, including suitable alternatives to ensure the diet is nutritionally adequate. A dietitian should provide education with advanced training in the necessary knowledge and skills. The required dietetic consultation times may be greater than that currently offered in many NHS outpatient clinics. An initial consultation may last 45–60 minutes, with the second taking 30–45 minutes. If healthcare settings are unable to facilitate dietary education on reducing fermentable carbohydrates, current practice is to follow the NICE guidelines (2008). Following adequate symptom relief after 4–8 weeks, planned and systematic reintroduction of foods high in these carbohydrates verifies individual tolerance to fermentable carbohydrates. This increases dietary variety and supports long term self care.

A diet restricted in short chain carbohydrates [fermentable oligo-, di- and mono-saccharides, and polyols (FODMAPs)] is a recent successful treatment for IBS, with evidence for its effectiveness coming from Australia and the UK (Gibson & Shepherd, 2010; Staudacher *et al.*, 2011). Examples of foods high in FODMAPs include wheat and rye based staples, e.g. bread, pasta, pizza, onion, garlic, pulses, apple, pear, stone fruit, sugar free chewing gum, mammalian milks and yoghurts. Examples of foods low in FODMAPs are oats, potatoes, rice, gluten free bread and pasta, spelt, green leafy vegetables, tomatoes, carrots, most berries, citrus fruit, lactose free milk and yoghurt, and (calcium enriched) plant based milks.

Therapeutic alteration of the gastrointestinal microbiota by probiotics could be beneficial and care should be taken to recommend the exact strain or species that research has shown to be of benefit in treating IBS (Parkes *et al.*, 2010).

Third line dietary intervention is usually unnecessary in IBS management. Dietitians should seek medical advice for any concerns over the management of existing or suspected allergy.

7.4.11 Disorders of the colon and rectum

Diane Brundrett

Key points

- Constipation may be a primary disorder associated with inadequate fluid, fibre or activity levels, or a secondary consequence of medication or underlying disease. Management may require a combination of dietary, behavioural and pharmacological strategies.
- Acute diarrhoea can cause severe dehydration, especially in young children and elderly people. The management of chronic diarrhoea depends on the underlying cause but aims to minimise or restore fluid and nutrient losses.

Diverticulitis (inflammation or inflammation of diverticula in the bowel wall) may necessitate bowel rest and a bland diet during acute phases of the disease. A high fibre intake may be more appropriate for secondary prevention. Disorders of the bowel include constipation, diarrhoea, diverticulitis, irritable bowel syndrome (IBS) and colorectal cancer. Irritable bowel syndrome or disease is a common functional bowel disorder. Management must be tailored to the symptom profile of the individual and may require a combined dietary, pharmacological and lifestyle approach. It is discussed in detail in Chapter 7.4.10. Colorectal cancer is the second most common cause of cancer in the UK. The aetiology is not fully understood but its development is associated with lifestyle, such as smoking, inactivity and dietary factors. The nutritional intervention may involve nutritional support or dietary modification (see Chapter 7.15.3). The nutritional effects and management of colon and rectum resection can be found in Chapter 7.4.9.

Constipation

The prevalence of constipation in North America is estimated to be 12–19% (Higgins & Johanson, 2004). Reported constipation prevalence rates in Europe are similar at 17% (Peppas *et al.*, 2008). However, prevalence rates vary due to varying diagnostic criteria. In England, nearly 16 million prescriptions were dispensed for laxatives in 2010 (NHS Business Services Authority, 2012). Constipation is twice as common in women as men (Higgins & Johanson, 2004) and appears to increase with increasing age, particularly after the age of 65 years. About 40% of pregnant women complain of constipation (Cullen & O'Donoghue, 2007).

The word constipation has a different meanings to different people. While some believe they are constipated if they do not have a daily bowel movement, normal stool elimination may be three times a day or twice a week depending on the person. Constipation is defaecation that is unsatisfactory because of infrequent stools, difficult stool passage or a feeling of incomplete evacuation. Stools can be hard and dry and may be large or small. Constipation is a symptom, not a disease. Factors associated with an increased risk of constipation include a low fluid intake, a low fibre diet and reduced mobility. A high

fibre intake is associated with a lower prevalence of constipation (Dukas *et al.*, 2003).

Diagnostic criteria

Diagnosis is confirmed using the Rome III Committee's diagnostic criteria (Longstreth *et al.*, 2006). Criteria must be fulfilled for the last 3 months, with symptom onset at least 6 months prior to diagnosis. The criteria are:

1. Must include two or more of the following:
 - Straining during at least 25% of defaecations.
 - Lumpy or hard stools in at least 25% of defaecations.
 - Sensation of incomplete evacuation for at least 25% of defaecations.
 - Sensation of anorectal obstruction or blockage for at least 25% defaecations.
 - Manual manoeuvres to facilitate at least 25% of defaecations, e.g. digital evacuation, support of the pelvic floor.
 - Fewer than three defaecations per week.
2. Loose stools are rarely present without the use of laxatives.
3. Insufficient criteria for IBS.

The Bristol Stool Chart (Lewis & Heaton, 1997) may aid diagnosis as it correlates well with colonic transit times (Figure 7.4.10).

Disease process

Constipation is a common gastrointestinal complaint that can cause physical and psychosocial problems. The cause of constipation can be multifactorial, but it can be divided into functional (primary) and secondary. Functional constipation is chronic constipation where there is no underlying disease but there is a neurological, psychological or psychosomatic cause. This type of constipation can be further classified into three categories:

- *Normal transit constipation* – stool passes through the colon at a normal rate, but the patient perceives difficulty in emptying their bowels. This condition is most common in young women.

Bristol Stool Chart

Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on its surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges (passed easily)
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type 7		Watery, no solid pieces, Entirely Liquid

Figure 7.4.10 Bristol stool chart [from Lewis & Heaton (1997) © Informa Health Care]

- *Slow transit constipation* – there are infrequent bowel movements, decreased urgency or straining to have bowels open and an increased colonic transit time.
- *Pelvic floor dysfunction* that is characterised by dysfunction of the pelvic floor or anal sphincter and can follow childbirth.

Those diagnosed with functional constipation may be particularly affected by behavioural or psychological factors. They may regularly ignore the urge to have a bowel movement, feel uncomfortable using toilets outside of their home or have limited access to toilet facilities. Constipation is common in those with a history of depression, anxiety, eating disorders, sexual abuse and physical abuse (Wald *et al.*, 1989; Levy *et al.*, 2006). Changes in routine, such as travel, reduced levels of exercise or mobility, can lead to an alteration in bowel habits.

Secondary constipation is constipation caused by a drug or a medical condition, as shown in Table 7.4.13.

Disease consequences

A population based study in individuals with constipation found a decrement in health related quality of life when compared to subjects without a functional gastrointestinal disorder (Irvine *et al.*, 2002). Chronic constipation can lead to faecal impaction with resulting faecal incontinence, increased risk of urinary tract infections, rectal bleeding and prolapse.

Table 7.4.13 Causes of secondary constipation

Cause	Examples
Endocrine and metabolic diseases	Diabetes (with autonomic myopathy) Hypercalcaemia Hypokalaemia Hyperparathyroidism Hypothyroidism Uraemia Pregnancy
Connective tissue disorders	Amyloidosis Scleroderma
Neurological diseases	Autonomic neuropathy Stroke Hirschsprung's disease Multiple sclerosis Parkinson's disease Spinal cord injuries or tumours
Structural abnormalities	Anal fissures or strictures Haemorrhoids Colonic strictures Inflammatory bowel disease Colorectal cancer Rectal prolapse Volvulus Megacolon or megarectum
Drugs	Opioid analgesics – codeine, morphine, fentanyl Diuretics Iron supplements Antacids Antispasmodics Antidepressants – commonly tricyclic antidepressants Antiepileptics Antipsychotics Calcium supplements Antihistamines Calcium channel blockers

Clinical assessment

When a patient presents complaining of constipation, an evaluation of their medical history and a physical examination may reveal the cause. The decision to do further investigations, such as a colonoscopy or colonic transit studies, will be based on the patient's symptoms, family history and age; laboratory tests are rarely useful. It is important that malignancy is excluded especially in the elderly or if there is a history of blood in the stools or weight loss. The aim of any intervention is to relieve the symptoms and to restore normal bowel habits with minimal side effects.

Nutritional assessment

Anthropometry

Assess the weight and height and calculate body mass index (BMI). Is there a history of weight loss? Constipation is more common in those with a history of an eating disorder.

Table 7.4.14 Oral laxatives used in the management of constipation

Category of laxative	Example	Mode of action
Bulking agents	Ispaghula husk, methylcellulose, sterculia, frangula	Increase the amount of fibre in the diet, increasing the weight and water absorbent properties of the stool Patients must be advised to have a good fluid intake
Stimulant laxatives	Senna, bisacodyl, sodium picosulfate	Increase intestinal motility by stimulation of colonic nerves
Faecal softeners	Liquid paraffin	Soften the stool, but their use is discouraged as has been associated with adverse effects, including anal seepage and irritation
Osmotic laxatives	Lactulose, magnesium salts (e.g. Epsom salts), magrocols (e.g. Movicol)	Act as a softening agent by increasing water absorption in the stool Lactulose may also have a stimulant effect

Biochemistry

Is the patient a poorly controlled diabetic? Is calcium raised or potassium level low? Check thyroid function. Is the patient uraemic? Is the patient dehydrated?

Clinical assessment

Check bowel frequency. Does the patient have a medical diagnosis that may increase their risk of constipation? Is the patient taking any drugs that may cause constipation? Are there any relevant psychosocial factors? Has the patient experienced a reduction in their mobility?

Dietary assessment

Take a diet history and review fibre and fluid intake.

Economic and social assessment

Does the patient express any concerns about lack of income or knowledge to achieve a well balanced diet? Are there any psychosocial factors that may be relevant?

Management

Lifestyle

Advice may be given to set time aside to go to the toilet, especially after meals to make the most of the gastrocolic response. Increased activity levels can help improve bowel habits.

Medication

If possible, adjust any constipating medication. Oral laxatives may be offered if non-pharmacological methods have not been successful. A patient will usually be prescribed a bulk forming laxative initially. If hard stools continue, patients are switched to or have an osmotic laxative added. If stools are soft but difficult to pass, or there is inadequate emptying, a stimulant laxative can be added. Patients with short term constipation should be advised to stop taking the laxatives once the stools have become soft and are easy to pass. For patients with chronic constipation, laxatives should slowly be withdrawn. Laxatives can be continued long term in patients who take a constipating drug that cannot be stopped or

there is a medical cause for the constipation. Further information on the use of oral laxatives is given in Table 7.4.14. Prucalopride is a new drug that may be prescribed for women with chronic constipation who have not had adequate relief of their symptoms using laxatives (NICE, 2010).

Biofeedback

Biofeedback is a bowel training programme run by specialist nurses or physiotherapists, which involves retraining muscles and nerves to coordinate and produce satisfactory effort to empty the bowel. Benefit from biofeedback therapy seems limited to patients with pelvic floor dysfunction (Frattoni & Norgueras, 2008).

Surgery

Surgery is considered in a minority of patients and the results of total or partial removal of the colon to improve bowel function are often poor. Even if there is an improvement in bowel habits, quality of life postoperatively can be adversely affected by abdominal pain, postoperative incontinence or diarrhoea (Fitzharris *et al.*, 2003). Kamm *et al.* (1988) recommend that those with normal transit constipation being considered for surgery have a preoperative psychosocial assessment as it is recognised that many of these patients have psychological issues that can predispose them to a poor surgical outcome.

Nutritional management

Advice should be given to ensure that the individual has regular meals with a well balanced diet containing wholegrains, fruit and vegetables. Adults should aim to eat 18–30 g of fibre/day. Patients should be advised to increase their fibre intake gradually to help minimise bloating and flatulence. Fibre increases the bulk of the stool, which distends the colon and stimulates propulsive activity and colonic transit. The beneficial effects of a higher fibre intake may be seen in a few days or it may take several weeks to be effective. More specific advice about types of dietary fibre may be of benefit to those with chronic constipation. There is evidence to support increasing the

soluble fibre intake of the diet for constipation (Suarez & Ford, 2011).

The beneficial effects of following a high fibre diet can be enhanced by increasing fluid intake to 1.5–2.0L/day (Anti *et al.*, 1998). An increased fluid intake is needed with bulking agents and osmotic laxatives. Currently, there is limited evidence available from controlled trials to support the routine use of probiotics in the treatment of constipation (Chmielewska & Szajewska, 2010).

Diarrhoea

Diarrhoea is an alteration of normal bowel movement characterised by an increase in water content, volume or frequency of stools. Diarrhoea is a symptom of which there can be many causes and it can be categorised as follows:

- *Acute diarrhoea* – that lasting <4 weeks.
- *Chronic diarrhoea* – that lasting >4 weeks.
- *Faecal incontinence* – inability to control bowel movements with the involuntary passing of liquid or solid stool.
- *Functional diarrhoea* – continuous or recurrent syndrome characterised by the passage of loose or watery stools without abdominal pain or discomfort.

Diagnostic criteria

There are many definitions of diarrhoea; Table 7.4.15 shows those that are generally accepted. The British

Society of Gastroenterology (Thomas *et al.*, 2003) defines diarrhoea as the abnormal passage of three or more loose or liquid stools per day for >4 weeks and or a daily stool weight >200 g/day. However, the Rome III Committee defines it as at least 75% of stools being loose (mushy) or watery and without pain for the last 3 months, and with symptom onset at least 6 months before diagnosis (Longstreth *et al.*, 2006). Use of the Bristol Stool Chart (Figure 7.4.10) can aid diagnosis; stool types 5–7 tending towards diarrhoea.

Disease process

Acute diarrhoea is usually a symptom of a bowel infection (gastroenteritis) that may be caused by a virus, food poisoning, a bacterial infection, consumption of contaminated food or water from a foreign country (traveller's diarrhoea) or antibiotics. *Clostridium difficile* is a common cause of hospital acquired diarrhoea (Baldi *et al.*, 2009). Disruption of the bowel microflora by antibiotics creates an environment in which *C. difficile* can proliferate. Other causes include anxiety, drinking excessive alcohol or caffeine containing fluids, chemotherapy, acute radiation enteritis, intestinal ischaemia and the early presentation of a chronic cause, e.g. the initial presentation of inflammatory bowel disease (IBD). Many drugs can cause diarrhoea, e.g. antacids, non-steroidal anti-inflammatory drugs, statins, selective serotonin reuptake inhibitors and some chemotherapy agents. Chronic diarrhoea has a broader range of possible causes than acute diarrhoea, as shown in Table 7.4.15.

Table 7.4.15 Causes of chronic diarrhoea

Cause	Example
Irritable bowel syndrome (IBS)	
Chronic infection	Functional disorders such as IBS may follow infection
Small bowel	Coeliac disease Crohn's disease Bile acid malabsorption – resection or disease of the terminal ileum leads to increased levels of bile salts in the colon that can stimulate diarrhoea Lactase deficiency, lactose intolerance Small bowel bacterial overgrowth Mesenteric ischaemia Radiation enteritis Lymphoma
Colonic	Diverticular disease Colon cancer Ulcerative colitis and Crohn's colitis Microscopic colitis
Pancreatic – associated with steatorrhoea	Chronic pancreatitis Pancreatic cancer Cystic fibrosis
Other	Hyperthyroidism Diabetes – may be related to metformin or autonomic neuropathy Laxative use Medication

Disease consequences

Diarrhoea is a common reason for people seeking medical advice. Acute infectious diarrhoea is one of the commonest illnesses worldwide, particularly in developing countries, where it is the primary cause of childhood mortality. Diarrhoea is the second leading cause of death worldwide (Lawler & Wallace, 2003). The prevalence of chronic diarrhoea in an elderly population has been reported to be 7–14% (Talley *et al.*, 1992). The prognosis of chronic diarrhoea will depend on the underlying cause.

Nutritional consequences

Consequences of prolonged diarrhoea include dehydration, malnutrition, weight loss, anaemia and electrolyte imbalances. In children from developing countries, diarrhoea may lead to zinc deficiency, stunted growth and impaired cognitive development (World Gastroenterology Organization, 2008a).

Nutritional assessment

A full nutritional assessment should be conducted.

Anthropometry

Measure weight and height and calculate BMI. Has the patient lost weight? Calculate their percentage weight loss. Consider assessing grip strength, mid arm muscle circumference and triceps skinfold thickness to assess fat mass and muscle mass.

Biochemistry

Acute diarrhoea can rapidly lead to a loss of potassium and sodium. Do the blood results indicate that the patient is dehydrated? Are they iron, folate, vitamin B₁₂ or zinc deficient? Does the patient have a raised C-reactive protein (CRP), white cell count (WCC) or erythrocyte sedimentation rate (ESR)?

Clinical assessment

Check bowel frequency and how long the patient has been experiencing symptoms for. Ask about stool consistency and colour. Use of the Bristol Stool Chart (Figure 7.4.10) may help your patient to describe their stools.

Does the patient look or feel dehydrated? Do they report a decreased urine output?

Does the patient have a medical diagnosis that could be the cause of the diarrhoea? Is the patient taking any medications that may cause diarrhoea?

Dietary assessment

Has the patient noticed a change in appetite? Take a diet history and evaluate fibre intake. Does the patient associate any particular foods with causing diarrhoea? Assess the types of fluid and the volume of fluid being drunk.

Economic and social assessment

Is there a history of anxiety? Are there food safety issues that may increase their risk of food poisoning?

Clinical assessment and management

Acute diarrhoea often resolves without complications in a few days, although dehydration can occur if symptoms are severe, especially in children and the elderly. If a bacterial infection is suspected, a stool sample should be sent to confirm whether antibiotic therapy is the appropriate treatment. Initial investigations for chronic diarrhoea will include blood and stool tests, although a detailed history in the assessment of the patient can help to establish whether the symptoms have an organic or functional cause. Symptoms of <3 months' duration, continuous or nocturnal diarrhoea and a significant weight loss are suggestive of an organic disease. Abdominal pain with intermittent diarrhoea and constipation is suggestive of IBS (Longstreth *et al.*, 2006). A diagnosis of overflow diarrhoea, which occurs due to faecal impaction following a period of constipation, should be excluded. Rectal examination, colonoscopy or flexible sigmoidoscopy and biopsy can exclude cancer, microscopic colitis and IBD. Antibody tests and duodenal biopsy may be performed to eliminate coeliac disease. A selenium homocholic acid taurine (SeHCAT) test or a trial of cholestyramine will help to determine if bile acid malabsorption is the cause and a hydrogen breath test can confirm small bowel bacterial overgrowth.

Antidiarrhoeal medication, e.g. loperamide, can relieve symptoms in adults by increasing gastrointestinal transit time, but it is not appropriate when the diarrhoea is caused by a bacterial infection.

Nutritional management

Acute diarrhoea

As episodes of acute diarrhoea are usually brief and self limiting, the focus of advice needs to be on the prevention of dehydration by encouraging a good fluid intake such as water, soft drinks (preferably not fruit juices) and savoury drinks. Oral rehydration solutions (glucose and electrolyte mixtures) increase water absorption by stimulation of sodium glucose transport in the small intestine and should be encouraged if dehydration is apparent. There is little evidence to support fasting as a treatment for acute diarrhoea (Wingate *et al.*, 2001), so if an individual wishes to eat, they should be encouraged to do so.

Babies should be encouraged to continue breast or bottle feeding (see Chapter 3.8). The World Gastroenterology Organization (2008a) recommends the administration of zinc sulphate supplements to children in developing countries suffering from persistent diarrhoea as this has been shown to help reduce the duration and severity of diarrhoeal episodes.

Much work has been done to investigate the role of probiotics in the treatment of diarrhoea. A systematic review (Allen *et al.*, 2010) concluded that probiotics appear to be safe and have beneficial effects in shortening the duration and reducing stool frequency in acute infectious diarrhoea. However, due to the wide variability in study design, more research is needed to develop specific treatment guidelines that can advise on which probiotics

to use in different patient groups. In children it has been demonstrated that *Lactobacillus reuteri*, *Lactobacillus rhamnosus GG* and *Lactobacillus casei* are useful in treating acute infectious diarrhoea (World Gastroenterology Organization, 2008b). Further research is needed to clarify the importance of probiotics in the prevention of acute diarrhoea in adults and children.

A Cochrane systematic review (Pillai & Nelson, 2007) examining the treatment of *C. difficile* infection in adults concluded that there was insufficient evidence to support the use of probiotics in combination with antibiotics. While Hickson *et al.* (2007) have reported that a proprietary yoghurt drink containing probiotics was more effective than placebo in preventing antibiotic associated diarrhoea and *C. difficile* infection, the reliability of these results has been questioned due to the study's exclusion criteria (Wilcox & Sandoe, 2007).

Chronic diarrhoea

Some conditions with diarrhoea as a symptom, such as coeliac disease (see Chapter 7.4.7), lactose intolerance (see Chapter 7.4.6) and intestinal failure (see Chapter 7.4.9) require dietary manipulation as part of their first line treatment. If chronic diarrhoea is thought to have a functional cause, then advising a low fermentable oligo-, di- and mono-saccharides and polyols (FODMAPs) diet can be an effective approach to management of this challenging condition (Gibson & Shepherd, 2010) (see Chapter 7.4.10). There is limited evidence on specific dietary modifications for other causes of chronic diarrhoea that may help to alleviate symptoms and the advice given is probably best described as anecdotal. General advice that may be given includes:

- Explain the importance of maintaining a good fluid intake to help replace intestinal losses. If drinking milk is perceived to worsen the diarrhoea, appropriate advice can be given to exclude it from the diet until symptoms have settled.
- Continue to eat small frequent meals, choosing soft, low fibre foods such as white bread, mashed potato, plainly cooked pasta or rice, white fish, plainly cooked chicken, plain biscuits or crackers and jelly.
- Avoid high fibre foods such as wholegrain breads, whole wheat cereals, nuts and seeds, fruit skins and pith, vegetable skins and stalks, which may increase intestinal transit time and exacerbate symptoms.
- Foods known to aggravate symptoms should be excluded; spicy and greasy foods may stimulate diarrhoea.
- Drinking large volumes of undiluted fruit juice, caffeine containing drinks and alcohol should be discouraged.

If there are concerns about nutritional adequacy, advice on food fortification and oral nutritional supplements may be needed.

Diverticular disease

Diverticular disease is a common condition that occurs when small pouches, called diverticula, form in the wall

of the colon. There are three terms used to describe diverticula in the large bowel:

- Diverticulosis – the presence of asymptomatic diverticula.
- Diverticular disease – when diverticula cause symptoms of abdominal pain and diarrhoea.
- Diverticulitis – when diverticula become inflamed or infected and cause severe pain, fever and changes in bowel habit.

Diagnostic criteria

Diverticular disease can be difficult to diagnose from the symptoms alone; these include pain on the left side of the abdomen and a change in bowel habit. A colonoscopy or barium enema may be carried out to confirm the presence of diverticula. When there is a history of diverticular disease, a diagnosis of diverticulitis may be made by physical examination, taking a medical history and carrying out a blood test to look for signs of infection.

Disease processes

Comparisons between different countries show that diverticular disease is more common in those countries with a typical western diet. A diet low in fibre is thought to be a significant risk factor for the development of diverticular disease, as first described by Painter & Burkitt (1971). A low dietary fibre intake leads to constipation and increases the intraluminal pressure in the sigmoid colon, segmentation and herniation of the mucosa through the muscle in areas of weakness.

Disease consequences

The prevalence of diverticular disease increases with age, from under 10% in those under 40 years to 50–66% in those aged over 80 years. Both sexes are equally affected by the condition. About 70% of those with diverticular disease will have one or more episodes of diverticulitis. As diverticular disease is predominantly a disease of the elderly, it will become an increasingly important health burden in the UK as a result of our ageing population. Complications of diverticulitis include the development of abscesses, fistulae, obstruction, diverticular haemorrhage and perforation of the bowel.

Nutritional assessment

Anthropometry

Is the patient underweight, normal weight or overweight?
Is there a history of weight loss?

Biochemistry

Has a change in bowel habit resulted in dehydration?
Does the patient have a raised CRP, WCC or ESR?

Clinical assessment

Is there a history of abdominal pain or a change in bowel habit?

Dietary assessment

If diverticulitis has been diagnosed, a fluid only diet for 2–3 days may be recommended until symptoms settle. Advise on supplementation with nutritious fluids until a normal diet can be resumed.

If diverticular disease has been diagnosed, a diet history should be taken to assess fibre and fluid intake. Advising on increased fibre intake, particularly from fruit and vegetables, may help to reduce the risk of disease progression.

Economic and social assessment

Does the patient express any concerns about having a lack of income or knowledge to achieve a well balanced diet?

Prevention

Epidemiological studies and the geographical distribution of the disease suggest that a high fibre intake may provide a protective role in the development of diverticular disease (Aldoori *et al.*, 1998). There is some evidence to suggest that vigorous exercise such as jogging or running can help to reduce the risk of developing this condition (Aldoori *et al.*, 1995).

No treatment is routinely offered to those with asymptomatic diverticular disease, but the results of a study by Aldoori *et al.* (1994) suggest that there is a prophylactic benefit from adopting a high fibre diet as a significant inverse relationship between dietary fibre intake and risk of developing clinically evident diverticular disease was found. Cereal fibres were found to be less protective than insoluble fibres from fruit and vegetables. A high fibre diet has also been suggested as beneficial for those with complications and recurrences of diverticulitis (Hyland & Taylor, 1980).

Clinical and nutritional management

Treatment of diverticulitis starts with antibiotics. A fluid only diet may be recommended until symptoms start to improve as digesting solid foods may make symptoms worse. An improvement will generally be seen after 2–3 days and then food can gradually be reintroduced. There is little research on diet and diverticulitis, but avoiding foods that can irritate the bowel, such as fruit and vegetable skins, seeds and nuts, and spicy foods, may be beneficial until symptoms have settled and a normal food intake can be resumed.

Surgery is recommended when it is acknowledged that other medical treatment is not working. Surgery is often undertaken to protect against the risk of peritonitis. Depending on the site and extent of bowel resection, dietary modification may be needed postoperatively (see Chapter 7.4.9).

Possible new treatments for diverticular disease include the use of 5-aminosalicylate compounds (Di Mario *et al.*, 2006) and probiotics. Interest in the role of probiotics in maintaining remission of symptomatic, uncomplicated diverticular disease is growing, but further work is needed

before specific recommendations can be made (Lamiki *et al.*, 2010).

7.4.12 Liver and biliary disease

Susie Hamlin and Julie Leaper

key points

- Malnutrition is common in cirrhosis in both obese and non-obese individuals.
- Assessment of nutritional status in all patients is essential and should include anthropometric measurements, clinical evaluation and review of dietary intake.
- Nutritional support should be provided to meet high requirements, whilst considering specific nutrient deficiencies.
- Restriction of essential nutrients should be assessed in individual cases and should be avoided unless indicated.

Liver disease refers to any disorder of the liver, including steatosis, fibrosis, hepatitis, cirrhosis or cancer. Liver disease is the fifth largest cause of death in the UK, with an upward trend in mortality compared with other major causes of death (BASL & BSG, 2009).

Anatomy and function of the liver

The liver is the largest solid organ in the body, weighing approximately 1.5 kg in adults and lies in the right upper quadrant of the abdomen, behind the rib cage. The liver has two anatomical lobes with the right lobe being the biggest (Figure 7.4.11). The portal vein provides blood from the splanchnic circulation and carries 75% of the blood entering the liver, which is rich in the end products of digestion. The hepatic artery supplies the liver with oxygen from the systemic circulation. The venous outflow from the liver is via the hepatic vein into the vena cava (Hill, 2009).

Sixty per cent of the liver consists of hepatocytes that are arranged in thin layers, resulting in a larger surface area for exchange of substances with blood. Bile canaliculi are very small channels between adjacent hepatocytes that allow bile, produced in the liver, to pass to the common bile duct. This travels via the cystic duct to the gall bladder for concentration and storage or into the duodenum via the common bile duct. The liver plays an essential role in the function of many processes, including the metabolism of nutrients (Table 7.4.16).

Classification of liver disease

Acute liver injury

Acute liver injury is rare and is found in previously healthy non-cirrhotic individuals who develop deterioration in coagulopathy and altered mental state over <26 weeks. It can be further subdivided into fulminant hepatic failure

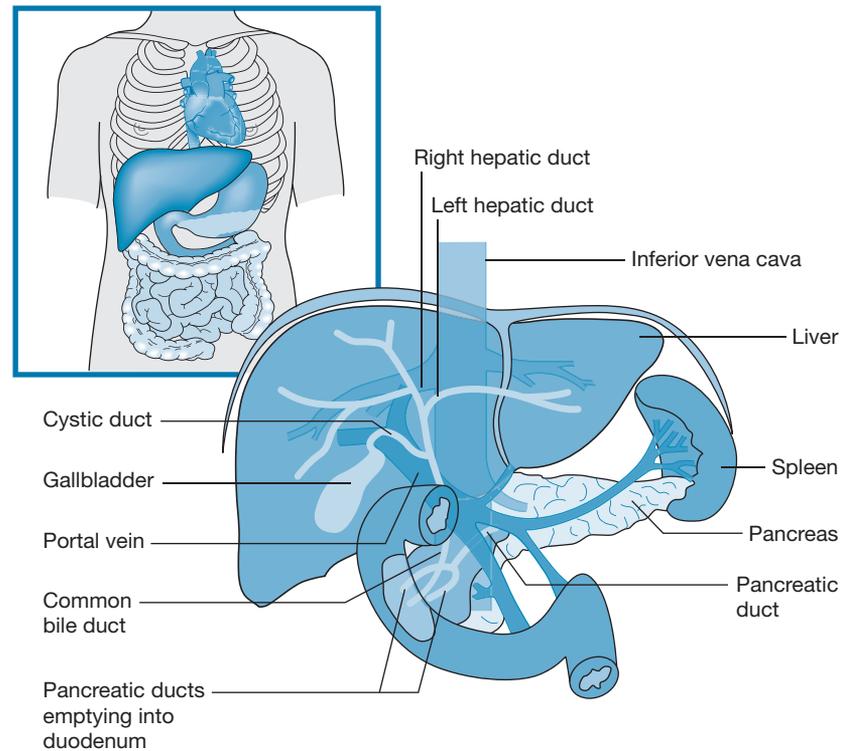

Figure 7.4.11 Anatomy of the liver [source: The British Liver Trust. Reproduced with permission of the British Liver Trust (www.britisHLivertrust.org.uk)]

Table 7.4.16 Major functions of the liver

Function	Examples
Digestion	Bile acid production
Carbohydrate metabolism	Maintenance of glucose homeostasis Storage of glycogen Gluconeogenesis Mobilisation of glucose in response to hypoglycaemia
Protein metabolism	Utilisation of amino acids for protein synthesis and gluconeogenesis Deamination of amino acids into urea for excretion Regulation of amino acid supply to peripheral tissues Synthesis of plasma albumin, prothrombin, fibrinogen and clotting factors
Lipids and lipoproteins	Production of triglycerides and lipoprotein formation Synthesis of phospholipids and cholesterol Synthesis and degradation of non-esterified fatty acids Ketogenesis
Vitamins	Storage of vitamins A, B ₂ , B ₃ , B ₆ , B ₁₂ , K, folate Synthesis of prothrombin and factor VII requiring vitamin K Conversion of tryptophan to nicotinic acid Hydroxylation of vitamin D
Detoxification/deactivation	Oxidation of alcohol → acetaldehyde → acetate → CO ₂ + fatty acids + H ₂ O Deactivation of drugs in the cytochrome P450 system Conjugation of oestrogens, corticosteroids and other steroid hormones for excretion
Excretion	Excretion of porphyrins, drugs, environmental toxins and heavy metals via bile secretion
Immune function	Adaptive immune system – T and B lymphocyte production Innate immune system Cytokine and inflammatory signalling cell production Kupffer cell formation (mononuclear phagocyte system) Tumour necrosis factor alpha (TNF-α) production
Haematological function	Synthesis of haem Regulation of iron metabolism

Table 7.4.17 Common causes of acute liver failure

Cause	Examples
Drugs	Paracetamol Tetracycline Halothane Troglitazone Antibiotics Non-steroidal anti-inflammatory drugs
Viral infections	Hepatitis viruses A, B and E Hepatitis viruses non-A, non-B Epstein–Barr virus Cytomegalovirus Yellow fever virus Reye’s syndrome Herpes simplex
Alcohol	Alcoholic hepatitis
Non-viral infections	Toxoplasmosis Leptospira
Bacterial infections	Tuberculosis Pyogenic – liver abscess
Protozoal infections	Malaria Amoebiasis
Toxins	Amanita phalloides Aflatoxin Carbon tetrachloride
Other	Acute fatty liver of pregnancy Wilson’s disease Herbal medicines Budd–Chiari Idiopathic HELLP syndrome of pregnancy

(FHF) and subfulminant hepatic failure. Fulminant hepatic failure is diagnosed in patients who develop encephalopathy within 8 weeks of the onset of symptoms of liver disease, with subfulminant hepatic failure described in those who do not develop encephalopathy for up to 26 weeks.

Acute liver injury often affects younger people and has a high morbidity and mortality (Polson & Lee, 2005). The most common cause of FHF in the UK is paracetamol toxicity (Table 7.4.17). Other causes include medication and hepatitis A, B and E, with 17% of cases of unknown cause (Bernal *et al.*, 2010). Prognosis depends, to some extent, on the grade of encephalopathy:

- 20% survival without transplant if grade IV encephalopathy.
- 60% survival without transplant if grade II encephalopathy.

Patients who survive FHF usually make a full recovery (Vaquero *et al.*, 2003).

Chronic liver disease

Hepatocellular damage may occur over several years initially via a build up of fat in the liver (fatty liver), which develops via inflammation and scarring to irreversible

Table 7.4.18 Causes of chronic liver disease

Cause	Examples
Alcohol	Alcoholic liver disease
Metabolic syndrome	Non-alcoholic fatty liver disease (NAFLD) Non-alcoholic steatohepatitis (NASH)
Infections	Viral hepatitis B and C (most common) Viral hepatitis D, E and G Schistosomiasis Syphilis
Autoimmune	Autoimmune hepatitis Primary biliary cirrhosis and coeliac disease often coexists
Biliary tract disease	Primary sclerosing cholangitis and-inflammatory bowel disease often coexists
Biliary obstruction	Biliary atresia/neonatal hepatitis Congenital biliary cysts Secondary biliary cirrhosis as a result of bile duct occlusion by gallstones or strictures Cystic fibrosis
Vascular disorders	Budd–Chiari syndrome Veno-occlusive disease/portal vein thrombosis
Drugs and toxins	Methotrexate Amiodarone Isoniazid
Metabolic disorders	Tyrosinaemia Wilson’s disease Haemochromatosis Alpha-1-antitrypsin deficiency Porphyria Glycogen storage diseases
Bacterial infections	Tuberculosis Pyogenic – liver abscess
Miscellaneous	Sarcoidosis Jejunioileal bypass Caroli’s syndrome
Cryptogenic	Liver disease of unknown aetiology

cirrhosis. An acute episode may also be superimposed on pre-existing chronic disease (Table 7.4.18).

Compensated cirrhosis occurs where the liver is cirrhotic, but there is no evidence of liver failure and no symptoms have developed. A patient can be asymptomatic with up to 80% of the liver damaged. Decompensated cirrhosis can appear where the liver is cirrhotic and symptoms of liver disease, e.g. ascites, jaundice, varices or encephalopathy, have developed. Decompensation can be part of progressive liver disease or can result from a sudden insult to an already cirrhotic liver.

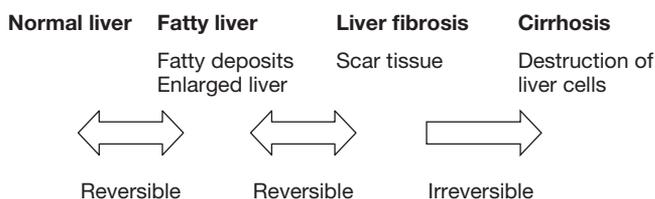

Diagnostic criteria and classification

Presentation

Patients commonly present with elevated liver enzymes or decompensated liver disease. Many patients are asymp-

Table 7.4.19 Common investigations for liver disease

Test	Abnormality	Interpretation
Hepatitis B surface antigen	Positive	Implies chronic infection
Hepatitis C antibody	Positive	Suggests chronic infection
Alpha-1-antitrypsin level	Low	Investigations in alpha-1-antitrypsin deficiency
Antendomysial antibodies	Positive	Suggestive of coeliac disease
Ferritin and iron binding studies	Elevated	Suggestive of haemochromatosis
Autoantibodies and immunoglobulins	ASM/ANA positive IgG	Suggestive of autoimmune hepatitis
Full blood count	Macrocytosis	Specific for alcohol excess only if gamma-glutamyltransferase elevated
	Thrombocytopenia	Suggestive of hypersplenism (portal hypertension)

**Figure 7.4.12** Stages of liver disease

tomatic until routine blood tests reveal abnormal liver function tests, which require further investigation or become unwell with an episode of decompensation. Many symptoms may be apparent such as malaise, itch and lethargy, which are common in patients with chronic liver disease.

Patient history

Weight, height and abdominal girth will be considered as risk factors for non-alcoholic fatty liver disease (NAFLD) in addition to alcohol history and risk factors for hepatitis C virus such as intravenous drug use. Prescribed and non-prescribed medication and herbal remedies will be investigated. Tattooing and prior medical interventions, surgery and transfusion history are all important information to obtain. To reach a diagnosis, investigations are performed that are relevant to the patient's history. Some common investigations are listed in Table 7.4.19, but this list is by no means exhaustive.

In response to liver injury, e.g. alcohol, NAFLD or chronic hepatitis C infection, fatty liver progresses to fibrosis. If the causative agent is removed, e.g. abstinence from alcohol, weight loss and antiviral treatment, normal hepatocyte structure can be restored at this stage. If the injury is chronic or recurrent, fibrosis can progress to cirrhosis, which is irreversible. The fibrous progression disrupts the architecture of the liver and impairs liver function (Figure 7.4.12).

Cirrhosis is often scored using the Child–Pugh score (sometimes the Child–Turcotte–Pugh score). It is used to determine prognosis as well as the required level of treatment, and is one of the scoring systems used when considering the need for referral for liver transplantation.

Table 7.4.20 Severity of cirrhosis using grading scores – modified Child–Pugh classification for cirrhosis (source: Friedman 2011. Reproduced with permission of Elsevier)

Measure	1 point	2 points	3 points
Total bilirubin [$\mu\text{mol/L}$ (mg/dL)]	<34 (<2)	34–50 (2–3)	>50 (>3)
Serum albumin (g/L)	>35	28–35	<28
Prothrombin time (seconds increased)	1–3	4–6	>6
Ascites	None	Mild	Moderate/severe
Hepatic encephalopathy	None	Grade I–II (or suppressed with medication)	Grade III–IV (or refractory)

Table 7.4.21 Classification of Child–Pugh score (source: Pugh *et al.* 1973. Transection of the oesophagus for bleeding oesophageal varices. *British Journal of Surgery* 60: 646–649)

Points	Class
5–6	A
7–9	B
10–15	C

The score employs five clinical measures of liver disease (Table 7.4.20). Each measure is scored 1–3, with 3 indicating most severe derangement. Chronic liver disease is classified into Child–Pugh class A, B or C, using the added score from Table 7.4.21. In primary sclerosing cholangitis (PSC) and primary biliary cirrhosis (PBC), the bilirubin references are altered to reflect the fact that these diseases feature high conjugated bilirubin levels.

Other measures have become more common over the past 10 years in assessing the severity of liver disease,

prognosis and need for referral for liver transplantation. The Model for End Stage Liver Disease (MELD) scoring system and the United Kingdom End Stage Liver Disease (UKELD) system are used to predict the mortality among patients on the waiting list for liver transplantation (Malinchoc *et al.*, 2000, Neuberger *et al.*, 2008).

Disease processes

Changes in metabolism

Carbohydrate and fat metabolism was demonstrated by Owen *et al.* (1983) to be altered in cirrhosis following an overnight fast. Cirrhotic patients develop starvation type metabolism similar to that of a 2–3-day fast in healthy people. This is due to decreased hepatic glycogen stores and reduced glycogenolysis. Fat and protein are metabolised as a short term energy source, which creates an accelerated response to starvation. Altered glucose metabolism is common in chronic liver disease with up to 96% exhibiting impaired glucose tolerance (Hickman & Macdonald, 2007) and up to 35% developing diabetes (Muller *et al.*, 1994). In these patients insulin resistance has been implicated by reduced hepatic degradation and increased secretion of insulin, with elevated plasma levels of insulin alongside normal glucose tolerance (Matos *et al.*, 2002).

Metabolism of protein and amino acids is abnormal, with increased protein catabolism present even in early stages of cirrhosis. Protein deficiency worsens as liver disease develops (Sanchez & Aranda-Michel, 2006). The alterations in amino acid metabolism associated with liver disease are shown by the reduced levels of circulating branched chain amino acids (leucine, isoleucine and valine), increased levels of circulating aromatic amino acids (phenylalanine, tryptophan and tyrosine) and methionine.

Alcoholic liver disease

Alcoholic liver disease is a major cause of liver disease throughout the world and patients often have risk factors for other liver diseases, e.g. NAFLD or chronic viral hepatitis (O'Shea *et al.*, 2010). The risk of developing the disease increases with overall alcohol intake. However, where intakes of alcohol are high and over a long time, 90–100% have fatty liver but only 20–35% develop alcoholic hepatitis and 8–20% develop alcoholic cirrhosis (Barve *et al.*, 2008). Oxidative stress, proinflammatory cytokines and reduced levels of adiponectin, which has anti-inflammatory properties, have been implicated as pathways of injury as a result of alcohol (Tilg *et al.*, 2011). The disease ranges from steatosis (fatty liver) through steatohepatitis to cirrhosis.

Alcoholic hepatitis

Alcoholic hepatitis presents as an acute decompensation of the liver function in a person with a history of alcohol abuse (Sougioultzis *et al.*, 2005). By itself, alcoholic hepatitis does not lead to cirrhosis and is distinct from cir-

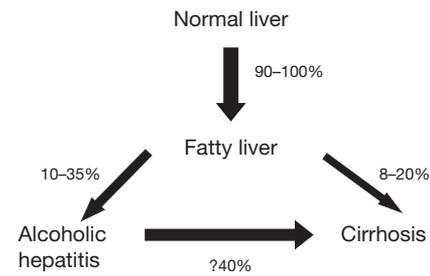

Figure 7.4.13 Progression of alcoholic liver disease in heavy drinkers (source: McCullough & O'Connor 1998. Reproduced with permission of Wiley-Blackwell Publishing)

rhosis caused by long term alcohol consumption. The progression of alcoholic liver disease in heavy drinkers is shown in Figure 7.4.13 (McCullough & O'Connor, 1998). Patients with alcoholic hepatitis usually present with the rapid onset of jaundice, fever, hepatomegaly and anorexia. Symptoms of portal hypertension may also be involved, such as ascites, encephalopathy and variceal bleeding.

There is a significant mortality associated with severe alcoholic hepatitis; Stickel *et al.* (2003) reported a 28-day mortality of higher than 40% in patients with severe alcoholic hepatitis. Typical age of presentation is between 40 and 60 years, and the female gender is an independent risk factor for alcoholic hepatitis (Lucey *et al.*, 2009). Maddrey's discriminant function is a formula with good correlation and predictive value for 30-day mortality. A value of >32 is indicative of severe alcoholic hepatitis with a 3-month mortality rate of 55% (Sargent, 2005). Other factors that correlate with a poor prognosis are renal impairment, encephalopathy and increased white cell count (Philippe, 2007).

Primary biliary cirrhosis

This is a chronic and progressive autoimmune disease where the bile ducts become inflamed and destroyed, resulting in biliary cirrhosis. The aetiology is largely unknown, although genetic, immune system and environmental factors have been considered (Levy & Lindor, 2003). Up to 95% of those diagnosed are female with average age of onset between 30 and 70 years (Lee & Kaplan, 1998). Symptoms include osteoporosis, pruritus (itching), fatigue and jaundice. Patients with advanced primary biliary cirrhosis and cirrhosis may develop ascites and hepatic encephalopathy. The association between primary biliary cirrhosis and coeliac disease has been investigated extensively and the incidence ranges from 0–11% (Rubio-Tapia & Murray, 2007).

Primary sclerosing cholangitis

This is a chronic progressive disorder characterised by inflammation and fibrosis of the biliary tree, leading to liver cirrhosis, portal hypertension and liver failure (Maggs & Chapman, 2008). It is associated with inflammatory bowel disease in a large number of cases (Weis-

muller *et al.*, 2008). The aetiology is still unclear, although primary sclerosing cholangitis could be caused by autoimmune, genetic or inflammatory disease. The incidence of hepatic osteodystrophy is between 4% and 10% and should be investigated at new diagnosis (Chapman *et al.*, 2010).

Non-alcoholic fatty liver disease

This is described in detail in the Clinical investigation and management section.

Viral hepatitis

Viral hepatitis is mainly caused by chronic disease, namely hepatitis B virus (HBV) and hepatitis C virus (HCV). Other causes include hepatitis A, D and E virus, but these are not discussed within the scope of this chapter.

Hepatitis B virus

Worldwide, an estimated 2 billion people have been infected with hepatitis B virus (HBV), and >350 million have chronic liver infections (WHO, 2008). Hepatitis B virus may cause an acute illness or develop into a chronic disease, which causes cirrhosis and possibly, liver cancer. It is transmitted by the blood and body fluids of an infected person and can be transmitted from mother to child at the time of birth, within households (non-sexual), between sexual partners and via needle sharing, as well as through occupational and healthcare related incidents (Shepard *et al.*, 2006).

Hepatitis C virus

About 130–170 million people are chronically infected with hepatitis C virus (HCV) and >350 000 people die from HCV related liver diseases each year (WHO, 2011). It causes chronic hepatitis, leading to cirrhosis with increased risk of hepatocellular carcinoma and intrahepatic cholangiocarcinoma (El-Serag *et al.*, 2009). Transmission is usually via infected blood, which can include drug use, blood products prior to HCV screening, tattooing or piercing. Treatment includes the use of pegylated interferon, in combination with ribavirin as preferred treatment (NICE, 2010b). Direct acting antiviral agents are now being developed that may change the drug regimens currently used (Ghany *et al.*, 2011).

Autoimmune hepatitis

Autoimmune hepatitis is a progressive disease of unknown aetiology, which may occur as a result of an environmental trigger in a genetically susceptible person, e.g. virus or drug induced. At least 70% of patients are female, with half younger than 40 years of age; however, onset may range from childhood to the elderly (Makol *et al.*, 2011).

Metabolic liver disease

Wilson's disease

This is an autosomal recessive genetic disorder in which copper accumulates in tissues, resulting in acute or

chronic liver disease with neuropsychiatric symptoms. Acute Wilson's disease appears in approximately 5% of patients, with an increased ratio of 3:1 in females; however, the cause for this is uncertain (Taylor & Corbani, 2009). Fulminant Wilson's disease is usually fatal without transplantation (Polson & Lee, 2005).

Chronic Wilson's disease usually presents with hepatitis or cirrhosis and symptoms of hepatomegaly, ascites or jaundice. The progression of disease depends on the effectiveness of chelation treatment.

Haemochromatosis

Haemochromatosis is an autosomal genetic recessive disease characterised by the abnormal accumulation of iron in major organs, leading to accumulation in tissues and primarily the liver, causing cirrhosis (van Bokhoven *et al.*, 2011). Iron deposits can also accumulate in endocrine organs and the heart. Diagnosis can be suspected in middle aged men with cirrhosis, bronzed skin, joint inflammation and diabetes (Pietrangelo, 2006).

Alpha-1-antitrypsin deficiency

This is an autosomal recessive genetic disorder caused by defective production of alpha-1-antitrypsin (AAT), which affects the liver and lungs. There is no treatment other than symptom management and liver transplantation (Fairbanks & Tavill, 2008) (see Chapter 5.1).

Disease consequences

Mortality

Liver disease mortality in the UK is rising at a time when liver death rates are dropping in most of Europe. Ninety-five per cent of all liver disease is largely preventable. The average age of death from liver disease is 59 years (compared with 82–84 years for heart and lung disease or stroke). Government mortality statistics for the UK highlight that deaths from liver disease are showing an upward trend, increasing by 12% in the last 3 years, which is equates to 46 244 deaths. Over the last 10 years people have been presenting with and dying from liver disease at a younger age, with a five-fold increase in the development of cirrhosis in 35–55-year olds. There has been a 32% increase in people under 35 years dying from alcoholic liver disease in England and Wales (British Association for the Study of the Liver & British Society of Gastroenterology, 2009). Deaths from liver disease over the next 20 years are predicted to double (British Liver Trust, 2009). Effective prevention strategies or treatments need to be available for the three main causes of liver disease; alcohol, viral hepatitis and obesity. These decrease the risk of developing cirrhosis, liver cancer and their associated mortality.

Patient perspective

Patients with liver disease may need the support of outside agencies and charities. Some are listed in the additional contacts section at the end of the chapter. The British Liver Trust (2011) stated, '*Patient support groups*

prove to be an invaluable resource helping to inform, educate and reassure patients. The mutual sharing of factual information and coping strategies can help reduce the fear associated with illness and help people to manage their condition and symptoms more effectively'.

Public health aspects and prevention

The key risk factors for liver disease in developed countries are NAFLD, alcoholic liver disease and hepatitis C. These risk factors are relevant to a large proportion of the population and are modifiable. Examples of early prevention measures include early identification of HCV infection through screening and its treatment, reduction in heavy drinking, and use of interventions for obesity and the metabolic syndrome. Early prevention and management of these factors also form the basis for treatment.

Alcohol

Alcoholic liver disease is a major health and economic problem in the western world. Alcohol misuse and alcohol related problems, especially binge drinking and alcohol related liver disease, are major public health concerns. There is also an increasing number of people with alcohol related problems who services need to be provided for. In 2006/2007, alcohol misuse cost the UK economy £25.1 billion; £2.7 billion of this was NHS expenditure. In 2008, over 78% of the incurred costs were for hospital based care. The projected cost to the NHS is continuing to rise as >1 in 25 adults are dependent on alcohol, and the UK has one of the highest rates of binge drinking in Europe. This continued rise in alcohol misuse will significantly burden liver services (NICE, 2010a). The National Institute for Health and Care Excellence guidelines describe the problems associated with hazardous drinking behaviour and the difference between alcohol dependence and alcohol use disorders.

However, not everyone who is alcohol dependent goes on to develop liver disease. Risk factors of alcohol induced liver disease include:

- *Alcohol dependence* – liver damage only occurs in approximately 20% of people with alcohol dependence (Stokkeland *et al.*, 2008).
- *Gender* – women are more susceptible to alcohol related liver damage than men, with one study suggesting the risk is almost 50% higher (Corrao *et al.*, 1997).
- *Body mass index* – being overweight or obese increases the risk of alcohol related liver disease (Bellantani *et al.*, 1997).
- *Race* – some studies suggest people of African origin are more susceptible than Caucasians (Stranges *et al.*, 2004).
- *Genetic predisposition* – there is no clear evidence, but the fact that only a minority of heavy drinkers develop liver disease suggests a genetic predisposing factor (Zintzaras *et al.*, 2006).
- *Pattern of drinking* – drinking alcohol only at meal times appears to carry a lower risk of alcohol related

liver disease than other patterns of alcohol consumption (Bellantani *et al.*, 1997).

- *Hepatitis C infection* – there is a strong association between hepatitis C, unlike hepatitis B, and the development of advanced alcoholic liver disease (Mendenhall *et al.*, 1991).

UK government advice

Official UK guidance recommends that men should not regularly drink >3–4 units of alcohol/day and women no >2–3 units/day. Regular drinking is defined as drinking every day or most days of the week. It is also recommended that people do not drink alcohol for 48 hours after a heavy drinking session to enable recovery (see Chapter 4.2).

Pregnant women and women trying to conceive should avoid drinking alcohol. If they do choose to drink alcohol, they are advised to not drink >1–2 units of alcohol once or twice a week and not to get drunk, to minimise the risk to the baby. The National Institute for Health and Care Excellence (2010a) advises women to avoid alcohol in the first 3 months of their pregnancy in particular, because of the increased risk of miscarriage. However, in 2011 the Royal College of Physicians (RCP, 2011) submitted a report to the House of Commons' Science and Technology Committee that aimed to change this advice. The RCP argued that the last systematic review of the evidence by the government was in 1995 and that the current wording of the UK guidelines appears to sanction daily or near daily drinking. The frequency of alcohol consumption is an important risk factor for the development of alcohol dependency and alcoholic liver disease, and the RCP wants increased clarity in the guidance. Someone drinking 4 units/day (the current upper limit for men) would be classed as a hazardous or high risk drinker using the World Health Organization's standard tool for identifying people at risk of alcohol related harm (WHO, 2009).

In addition, the RCP recommended limits for safe drinking by older people in a separate guidance, as they may be particularly vulnerable to harm from alcohol due to biological changes associated with ageing. The current guidelines are based primarily on evidence for younger age groups and there is concern they are not appropriate for older people. The RCP has proposed a change to no more than 21 units/week for men and 14 units/week for women, with some alcohol free days.

Obesity

The Health Survey for England showed that nearly one in four adults and over one in 10 children (aged 2–10 years) are obese. In 2007, the Foresight report predicted that if no action were taken, 60% of men, 50% of women and 25% of children would be obese by 2050. The prevalence of NAFLD is estimated at between 20% and 30% in western adults (Browning *et al.*, 2004; Bedogni *et al.*, 2005) and rises to 90% in extreme obesity (Machado *et al.*, 2006). The rising burden of obesity will clearly have huge implications for the future burden of liver disease. Strategies to reduce obesity will reduce the burden of NAFLD.

Obesity is a major public health priority and the UK government is developing strategies to deal with this issue (see Chapter 4.2). Non-alcoholic fatty liver disease is discussed further in this chapter and obesity management is discussed in Chapter 7.13.2 and Chapter 7.13.3.

Hepatitis C

Alcohol and obesity advice is important in the treatment of hepatitis C (Lieber, 2001; Monto *et al.*, 2010). Obesity can reduce the effectiveness of antiviral treatments; obese patients [body mass index (BMI) >30 kg/m²] should be advised to try to lose weight prior to starting antiviral treatment (Bressler *et al.*, 2003). Key advice to people with hepatitis C is weight maintenance within a healthy BMI to avoid obesity, in particular central obesity, and to follow the appropriate guidance for alcohol intake specific to their stage of disease and past medical history.

Nutritional consequences

Malnutrition is an increasingly recognised complication of liver disease that has been shown to adversely affect outcome (Alberino *et al.*, 2001). Protein energy malnutrition (PEM) is common in chronic liver disease, with a prevalence of up to 20% in compensated cirrhosis (Coltorti *et al.*, 1991) and 75–90% in decompensated cirrhosis (Carvalho & Parise, 2006; DiCecco *et al.*, 1989). For those awaiting transplant, the figure is almost 100% (Figueiredo *et al.*, 2000). Protein energy malnutrition has been shown to have a correlation with the following (Mullen & Weber, 1991; McCullough & Bugianesi, 1997; Plauth *et al.*, 1997; Runyon, 1998):

- Worsening ascites.
- Increased infection rate.
- Worsening encephalopathy.
- Higher rate of variceal bleeding.
- Increased hospital readmissions.
- Increased mortality.

There is a direct correlation between the progression of liver disease and the severity of malnutrition. Patients with cirrhosis develop PEM irrespective of the aetiology of disease (Thuluvath & Triger, 1994), with the incidence similar in alcoholic and non-alcoholic patients (McCullough & Bugianesi, 1997). The reasons patients experience these severe changes to their nutritional status are multifactorial, and are most often seen in patients with chronic liver disease, although they can develop with acute disease that is not resolving.

Reduced nutrient intake

Protein energy malnutrition is exacerbated by reduced nutrient intake and is a result of one or a combination of factors (Saunders *et al.*, 2010; O'Brien & Williams, 2008; Tsiaousi *et al.*, 2008) including:

- Loss of appetite due to the presence of cytokines, e.g. tumour necrosis factor.
- Early satiety, commonly found when ascites results in reduced gastric capacity.

- Unnecessary dietary restrictions further exacerbating the choice and volume of food.
- Nausea and vomiting due to gastroparesis, small bowel dysfunction and bacterial overgrowth.
- High alcohol intakes replacing food energy, or reduced intake due to oesophagitis, gastritis or pancreatitis.
- Altered taste sensation due to deficiency of zinc or magnesium.
- Weakness or fatigue affecting inclination to eat or prepare food.
- Malabsorption, e.g. steatorrhoea.
- Repeated investigations that require prior fasting.

Altered energy expenditure

Debate continues as to whether hypermetabolism contributes to body wasting in cirrhotic patients. The causes of this increase in energy expenditure are unclear and metabolic rates may change frequently over time with complications of liver disease, e.g. infection, gastrointestinal bleeding or development of ascites. Muller *et al.* (1999) studied 473 clinically stable patients with liver disease and identified 34% of these as hypermetabolic, defined as resting energy expenditure 120% of the expected values. Clinical or biochemical markers of liver disease did not predict increased metabolism, suggesting that it may be caused by extrahepatic events, e.g. systemic inflammatory response. Some patients may compensate for the increased energy expenditure by reducing activity levels, but remain at high risk of malnutrition.

Malabsorption

A number of mechanisms can contribute to malabsorption. Patients with cholestatic liver disease, e.g. primary sclerosing cholangitis and primary biliary cirrhosis, may experience a reduction in the bile salt pool, resulting in fat malabsorption. Those with alcoholic liver disease frequently experience pancreatitis, which leads to malabsorption of fat (Renner *et al.*, 1984) and changes in the structure of the small intestine and brush border enzymes due to alcohol (Bhonal *et al.*, 2008). Many patients with alcoholic liver disease experience rapid intestinal transit times, increased permeability of the mucosa, and altered salt and water absorption. The administration of medicines, e.g. neomycin, lactulose or cholestyramine, as part of the specific medical management of symptoms may also result in increased bowel movements and reduced absorption of nutrients.

Hepatic osteodystrophy

An important complication of chronic liver disease is osteodystrophy, which includes osteoporosis and osteomalacia. Clinically these patients present with bone pains, backache, reduced height, fractures and scoliosis (Goel & Kar, 2010). The reasons for this are multifactorial, including poor intake and absorption of calcium, altered vitamin D synthesis, malnutrition and steroid use in certain liver conditions.

Osteoporosis

Risk factors for osteoporosis and subsequent fracture irrespective of cirrhosis include a low BMI of $<19\text{ kg/m}^2$, alcohol excess, steroid use, physical inactivity, previous fragility fracture, early maternal hip fracture (<60 years), hypogonadism and premature menopause (<45 years). Cirrhotic patients frequently present with increasing age, especially when in the middle decades; these patients often have a low BMI, may have had excessive alcohol intakes and could be receiving steroids (Collier *et al.*, 2002). Foods often advised for nutritional support measures correlate with foods rich in calcium, such as milk, cheese and yoghurts. Dietary intake usually decreases with disease progression. Cirrhotic patients should routinely be supplemented with 800 IU of vitamin D and 1000 mg of calcium (Collier *et al.*, 2002). However, in patients with increased cardiovascular risk, such as those with NAFLD, DEXA scanning may be performed to confirm osteodystrophy prior to commencing supplements (Bolland *et al.*, 2011) (see Chapter 7.9.1s).

Vitamins

Thiamine deficiency is discussed further in the section on Alcoholic liver disease.

There is a high incidence of fat soluble vitamin deficiencies in liver disease, with levels related to the severity of disease (Abbott-Johnson *et al.*, 2011). In primary biliary cirrhosis, vitamin A deficiency is seen in 20% of cases, but is often clinically asymptomatic (Talwalkar & Lindor, 2003). In advanced primary sclerosing cirrhosis, up to 82% of patients will be deficient in vitamin A (Lee & Kaplan, 2002). Malham *et al.* (2011) demonstrated that compromised vitamin D status can be found in 85% of patients with alcoholic liver disease and up to 47% with primary biliary cirrhosis, and that more than standard clinical dose repletion may be required.

Deficiency of vitamin E is rare, but can be seen in chronic cholestatic liver disease. Symptoms include muscle weakness, ataxia and haemolysis, and in advanced primary sclerosing cirrhosis these can be seen in 40–50% of patients (Lee & Kaplan, 2002). Vitamin K requires bile salts for absorption and therefore cholestasis can affect levels in liver disease. Supplementation may be given by intramuscular injections, but should be avoided in patients with low muscle mass or abnormal clotting; therefore, intravenous injection of vitamin K may be preferable.

Minerals

Serum magnesium levels are decreased in liver cirrhosis, which may be attributed to decreased intake or increased excretion (Das *et al.*, 2011). Zinc is discussed in the Nutritional management section.

Nutritional assessment

Detailed nutritional assessment is critical in patients with liver disease in order to provide optimal nutritional

support. Some markers of nutritional status used in other clinical areas are not useful in liver disease as symptoms, dietary intake and nutritional status are prone to rapid change. The dietary advice provided must be monitored regularly and alterations made to treatment plans to reflect these changes.

Anthropometry

Weight

Correct interpretation of the weight of fluid in patients with ascites and oedema is vital. Body mass index, percentage weight loss and nutritional requirements must be calculated using dry weights or estimated dry weights. Body mass index can be grossly misleading in interpreting the level of malnutrition if adjustments for dry weight are not made. Dry weight can be estimated from:

$$\text{Dry weight} = \text{wet weight} - \text{estimated weight of ascites or oedema}$$

The amount of ascites and/or oedema can be calculated using Mendenhall's (1992) figures (Table 7.4.22). These figures have limitations and often patients have more fluid than this evidence based estimate advises. Weight histories and dry weight following paracentesis can provide the best estimate of actual flesh weight, with adjustment if necessary for peripheral oedema. Patients may have up to 20–30 L of ascites and therefore 20–30 kg must be taken off the wet weights, as well as further subtraction for peripheral oedema, in order to calculate estimated dry weights.

Upper arm anthropometry

Measurement of mid arm circumference (MAC), triceps skinfold thickness (TSF) and mid arm muscle circumference (MAMC) should be taken to identify fat and muscle stores (see Chapter 2.2). Morgan *et al.* (2006) showed that MAMC and TSF could be used to develop a subjective global assessment tool for patients with cirrhosis where anthropometry showed substantial interobserver agreement.

The ESPEN guidelines (Plauth *et al.*, 2006) recommend simple methods for identifying undernutrition, including anthropometry or handgrip. Mid arm muscle circumference has been shown to detect body cell mass depletion and its effect on adverse outcome in end stage liver disease (Figueiredo *et al.*, 2000).

Table 7.4.22 Estimation of fluid weight in ascites or oedema (source: Mendenhall 1992, pp 363–84. Reproduced with permission of Taylor & Francis)

Severity	Ascites (kg)	Peripheral oedema (kg)
Minimal	2.2	1.0
Moderate	6.0	5.0
Severe	14.0	10.0

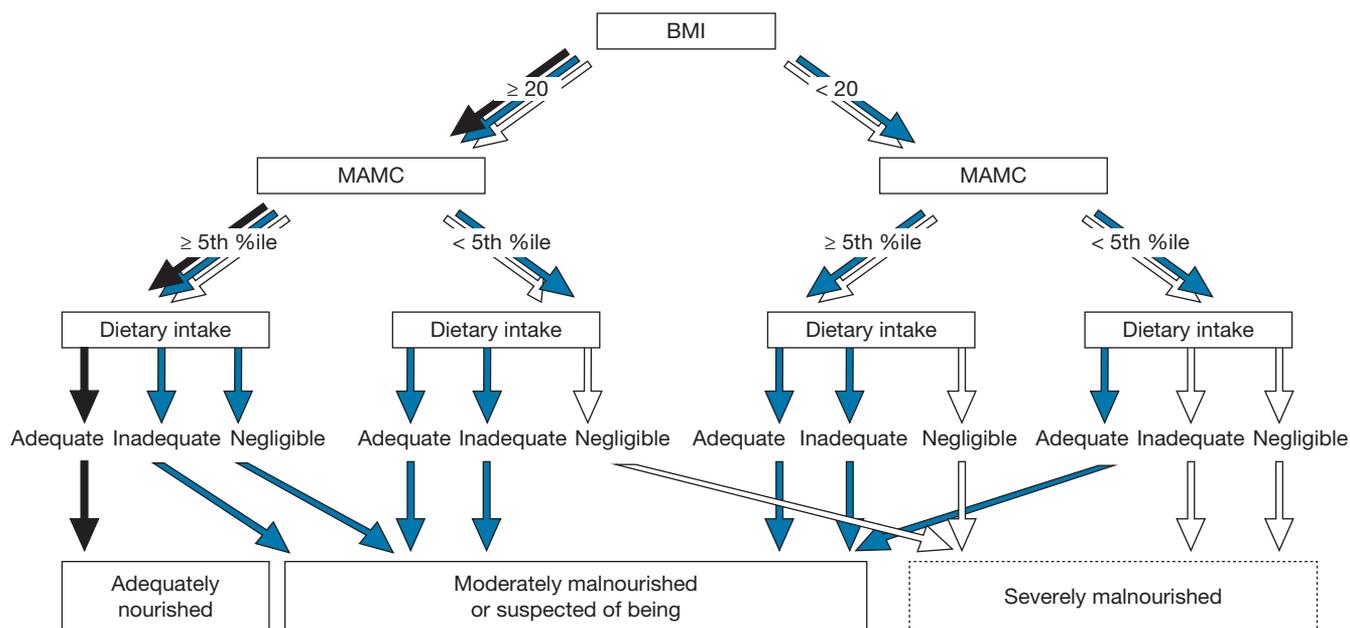

Figure 7.4.14 Royal Free Hospital Global Assessment (RFH-GA) scheme for determining nutritional status in patients with cirrhosis (source: Morgan *et al.* 2006. Reproduced with permission of Nature Publishing Group) BMI, body mass index; MAMC, mid arm muscle circumference; %ile, percentile

Bioelectrical impedance analysis

Kyle *et al.*, (2004) suggested that bioelectrical impedance analysis (BIA) use in the routine assessment of patients with ascites and oedema was not adequately validated. However, Plauth *et al.* (2006) suggested that estimation of body cell mass with BIA could be used despite limitations in patients with ascites. However, BIA is not used routinely in clinical practice.

Grip strength dynamometry

Alvares-da-Silva & Reverber da Silveira (2005) showed that lower handgrip strength predicted a poorer clinical outcome in patients with cirrhosis, who had higher rates of development of:

- Uncontrolled ascites.
- Hepatic encephalopathy.
- Spontaneous bacterial peritonitis.
- Hepatorenal syndrome.

Changes in measurements can be found over 1–2 weeks and therefore help in monitoring of nutritional advice. Care needs to be taken when interpreting results with encephalopathic patients due to their difficulty following the instructions properly.

Screening tools

Malnutrition Universal Screening Tool

The Malnutrition Universal Screening Tool ('MUST') (Elia, 2003) was developed in order to categorise patients for risk of malnutrition, and has been found to be an easy, quick, reproducible and internally consistent method. Patients with liver disease frequently have fluid overload and therefore dry weights have to be calculated, including percentage dry weight loss, in order to use the tool.

Adequate training is essential to ensure dry weight is calculated accurately in order to use BMI and percentage weight loss in this tool.

Royal Free Hospital Global Assessment

This tool uses dry weight BMI, MAMC and an assessment of nutritional intake to categorise patients into adequately, moderately (or suspected of being so) or severely malnourished.

In 2006, Morgan *et al.* validated the Royal Free Hospital Global Assessment (RFH-GA) tool, which is simple, reproducible and capable of predicting outcome in patients with cirrhosis (Figure 7.4.14). Dietary intakes were assessed as inadequate if the patient's intake failed to meet estimated requirements but were >500 kcal/day, with intakes under 500 kcal/day being categorised as negligible. The category of malnutrition established was found to predict poorer survival in those who were moderately or severely malnourished, and those with decompensated liver disease were more likely to be malnourished than those with compensated liver disease. A BMI of <20 kg/m² was associated with poorer survival. The subjective override can be used to change the categorisation by a single category if there has been recent change, e.g. weight loss or steatorrhoea.

Interestingly, the study showed a preferential decrease in fat mass for women compared with muscle mass in men, with this area warranting further research. Further confirmation of the RFH-GA predictive power was found when it was compared with the Child–Pugh and MELD scores (Gunsar *et al.*, 2006). Dietitians use this tool as part of the patient assessment at UK liver transplant centres.

Recently, a nutritional prioritising tool for patients with cirrhosis has been developed and validated against the RFH-GA. Initial results suggested that it can identify

patients with cirrhosis who are at high risk for malnutrition, although further multicentre validation is required (Arora *et al.*, 2011).

Biochemistry

Careful interpretation of biochemistry is required in liver disease. Hepatic albumin synthesis is decreased in liver disease and therefore using albumin as a marker of nutritional status is unreliable (Campos *et al.*, 2002). Declining albumin and deterioration in liver function tests (LFTs), e.g. bilirubin and alkaline phosphatase, are a better indicator of liver disease or acute phase response rather than nutrition.

Alkaline phosphatase

Alkaline phosphatase (ALP) is present in two major sites in the body, the liver and bones. It is associated with the biliary tract and elevated levels can indicate biliary tract diseases. If glutamyl transpeptidase (GGT) is not elevated in conjunction with ALP, the ALP is most likely of bone origin.

Glutamyl transpeptidase

Glutamyl transpeptidase (GGT) is present in hepatocytes and biliary cells. It is interpreted in conjunction with ALP and elevated levels are associated with the biliary tract diseases. It is sometimes incorrectly interpreted as a sensitive and specific marker of alcohol misuse, but studies have shown that the sensitivities of elevated GGT for alcohol varies between 52% and 94% (Aithal & Ryder, 2005).

Alanine aminotransferase and aspartate transaminase

Alanine aminotransferase (ALT) and aspartate transaminase (AST) are found within hepatocytes and are sensitive markers of hepatocyte injury.

Bilirubin

The bile pigments bilirubin and biliverdin are produced from substances containing haem, e.g. haemoglobin. They are transported in the blood attached to serum albumin (unconjugated bilirubin). In the liver, two glucuronate groups are attached to form conjugated bilirubin, which is excreted into the bile canaliculi. Bacteria in the gut convert bilirubin to stercobilinogen, which then forms stercobilin; stercobilin is responsible for the colour of faeces. When bilirubin is elevated, jaundice develops with the characteristic yellowing of the skin and viscera. Bilirubin is usually elevated with ALP as it is present in the biliary tract. Pale stools and jaundice are indicative of biliary tract disorders.

Albumin

Albumin is one of the many proteins synthesised by the liver and accounts for 65% of serum protein (Martin & Friedman, 2004). Albumin has a half-life of approximately 21 days and therefore serum albumin concentrations are slow to respond to alterations in protein synthesis. The liver normally produces 12–15 g of albumin/day and hypoalbuminaemia may be indicative of poor synthetic

function in cirrhosis (Johnson, 1999). As a result, albumin is one of the criteria for the Child–Pugh classification of cirrhosis (Table 7.4.21). Caution is needed in interpreting hypoalbuminaemia as it may not be specific to liver disease. It is also seen in postsurgical patients, acute pancreatitis and chronic inflammatory conditions, or reflects gastrointestinal or glomerular losses in conditions such as nephrotic syndrome.

Clinical assessment

Physical signs of liver disease and potential nutritional issues include (Figure 7.4.15):

- *Muscle wasting* – identified by visceral muscle loss, especially in the upper arms and temples, decreased activities of daily living or fatigue. Subcutaneous fat stores may mask this.
- *Presence of jaundice* – shown by yellow skin, eyes and scratch marks, which increase suspicion of potential fat malabsorption.
- *Encephalopathy* – reversed sleep patterns or confusion affecting meal patterns.
- *Development of ascites and/or oedema* – increased abdominal or peripheral swelling leading to fatigue and early satiety.
- *Spider nevi, red palms or altered nail appearance* (white half moon extends down the nail bed), indicate deteriorating liver disease and cirrhosis).
- *Micronutrient deficiencies* – hair loss, poor skin condition and dentition, night blindness and altered taste may all indicate various vitamin or mineral deficiencies.

Dietary assessment

Food intake can be assessed using a diet history or recall method. Patterns of eating will identify issues with altered sleep patterns and bloating, especially towards the evening. It is important to establish when symptoms such as fatigue, nausea, early satiety or abdominal pain may affect appetite and nutritional intake. Encephalopathic patients may not be able to reliably recall their intake and relatives may help to provide a more accurate history of their intake. Food charts may also be useful where staff can monitor intakes for inpatients and using local hospital systems to identify where accurate reporting is required.

Calculation of requirements

In clinical practice, either the ESPEN guidelines (Plauth *et al.*, 2006) of 35–40 kcal/kg of body weight/day or calculation of basal metabolic rate (BMR) using the Henry (2005) equations (see Chapter 6.1) with added stress and activity factors according to the Parenteral and Enteral Nutrition Group (BDA) guidelines (Todorovic & Micklewright, 2011) are used (Table 7.4.23). It is important for both calculations to use estimated dry weight as previously described. The stress factor chosen should relate to the symptoms present, i.e. if only ascites is present, then a 30% stress factor is appropriate. Patients with multiple

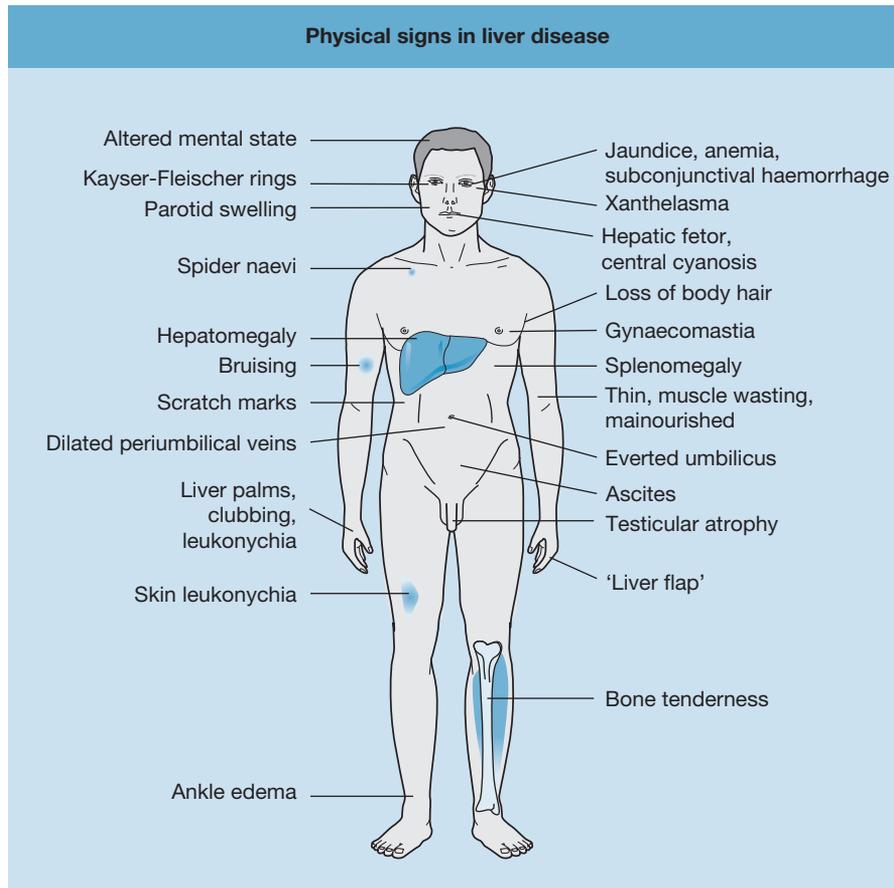

Figure 7.4.15 Signs of liver disease (source: Bacon *et al.* 2006, p 62. Reproduced with permission of Elsevier)

Table 7.4.23 Stress factors for liver disease (Kondrup & Muller, 1997; Hasse, 2001; Plauth *et al.*, 2009)

Compensated liver disease	0–20%
Decompensated liver disease	30–40%
Acute (fulminant) liver failure/ventilated	20–30%
Post transplant (postoperative period)	30%

symptoms require a 40% stress factor. Nitrogen or protein requirements are shown in Table 7.4.24 (Plauth *et al.*, 2006).

Obesity

There is a lack of evidence regarding energy requirements in patients with liver disease who have a high BMI; however, the following may be used:

- For compensated liver disease, weight loss can be appropriate. Requirements for BMR are estimated using dry weight, omitting stress and activity factors.
- For decompensated liver disease, weight loss, even in those with a high BMI, should not be actively encouraged unless the patient can be closely monitored. Requirements for energy are calculated as described previously, adding stress and activity factors. Energy

Table 7.4.24 Nitrogen and protein requirements for liver disease (Plauth *et al.*, 2006)

	Nitrogen (g)	Protein (g)
Compensated liver disease	0.19–0.20	1.2–1.3
Decompensated liver disease (nitrogen balance)	0.20–0.25	1.2–1.5
Acute (fulminant) liver failure	0.20–0.25	1.2–1.5
Post transplant	0.20–0.25	1.2–1.5

intake may be reduced only under close monitoring of protein stores with anthropometry. It should be ensured that 0.5–1 kg/week weight loss is not exceeded and there is clarity between wet and dry weights.

Nitrogen and protein requirements should be adjusted according to BMI (Todorovic & Micklewright, 2011):

- BMI >30 kg/m² × 0.75.
- BMI >50 kg/m² × 0.65.

These recommendations are a guide for calculation of energy and nitrogen requirements for maintenance of nutritional status. The key element is the monitoring of nutritional status, i.e. weight (if not fluid overloaded),

upper arm anthropometry and hand grip strength. On monitoring it may become necessary to increase protein requirements upwards in obese decompensated patients.

Requirements for repletion and weight gain

For weight gain it may be necessary to add 400–1000 kcal/day to previous totals with adequate anthropometric monitoring. Patients with liver disease require significantly higher protein intakes to maintain nitrogen balance. Most guidelines suggest an intake of 1.2–1.5 g of protein/day to achieve nitrogen balance and accrual of lean body mass (Plauth *et al.*, 2006). However, Nielsen *et al.* (1995) suggested that dietary protein retention remains efficient at intakes of up to 2 g/kg/day without adverse effects, including in encephalopathy. Kondrup & Muller (1997) suggested protein intakes of 1.5–2 g/kg may be required in patients with decompensated liver disease for nitrogen repletion. Where anthropometric monitoring and careful assessment indicate no improvement in nutritional status, these higher levels may be tried.

Economic and social assessment

Essential information regarding economic or social issues is critical to identify whether these are impacting on nutritional status or will prevent compliance with dietary advice. Finances can be significantly affected, as patients may be chronically unwell, resulting in reduced income and reliance on benefits. There may be cultural differences in the treatment of illness as this may need to take account of dietary beliefs.

Assessment in fulminant hepatic failure

This group of patients may not exhibit PEM to the same extent as those with chronic liver disease. However, it is still essential to assess the presence of fluid overload, jaundice and encephalopathy, which may contribute to a decline in nutritional status in the context of a hypermetabolic state. In patients who are awake and not encephalopathic, a full assessment can be performed as for chronic liver disease. In intensive care settings where patients are sedated, intubated and ventilated due to grade IV encephalopathy, assessment will be more difficult. Weight may need to be estimated or information may be required from relatives.

Clinical investigation and management

Non-alcoholic fatty liver disease

This is closely related to obesity and represents the hepatic manifestation of the metabolic syndrome. The prevalence of NAFLD has risen rapidly in parallel with rising levels of obesity and diabetes, and is now the commonest cause of liver disease in the West (de Alwis & Day, 2008). Though the natural histories of alcoholic liver disease and NAFLD differ, both may finally progress to end stage liver disease. Non-alcoholic fatty liver disease is a spectrum of fatty liver diseases in which there is a build up of fat in liver cells. These range from simple steatosis

Table 7.4.25 International Diabetes Federation waist circumference cut offs for central obesity (source: Alberti *et al.* 2007. Reproduced with permission of Blackwell Publishing)

Country/ethnic group		Waist circumference (as a measure of central obesity)
South Asian/Chinese/South and Central American/Japanese	Male	>90 cm
	Female	>80 cm
Europeids	Male	>94 cm
	Female	>80 cm

In the USA, adult treatment panel (ATP) III values are used for clinical purposes: male >102 cm; female >88 cm. For ethnic South and Central Americans, use South Asian recommendations until further data are available. For sub-Saharan Africans, use European data until more specific data are available. For Eastern Mediterranean and Middle East (Arab) populations, use European data until more specific data are available.

(fatty liver) to non-alcoholic steatohepatitis (NASH). Non-alcoholic steatohepatitis is an inflammatory fibrosing disease, which can eventually lead to cirrhosis and end stage liver disease. The principal causes of NAFLD are genetic predisposition, lack of exercise and increase in calorie intake leading to overweight and obesity (Day, 2002).

Abdominal obesity increases the flux of free fatty acids to the liver. Excessive circulating fatty acids increase insulin resistance and in NAFLD there is no insulin mediated suppression of lipolysis. This increases the risk of NAFLD and is an important parameter to measure when carrying out an assessment (Table 7.4.25). It is estimated that 48–100% of people with NAFLD are asymptomatic. Many have no specific symptoms, such as fatigue and right upper quadrant pain, and NAFLD is often an incidental finding on abnormal LFTs, predominately ALT. Often the ratio of AST to ALT is >1, which differentiates NAFLD from alcohol related fatty liver disease (Day, 2002).

Factors that increase the likelihood of developing NAFLD include:

- Overweight, particularly central obesity.
- High cholesterol or triglyceride levels.
- Type 2 diabetes.
- Insulin resistance.
- Hypertension.

These are all features of the metabolic syndrome, defined as the presence of central obesity with at least two of the following (International Diabetes Federation, 2006):

- Hypertension of 130/85 mmHg or higher, or on treatment.
- Hypertriglyceridaemia – fasting triglyceride of >1.7 mmol/L or current use of fibrates.
- Low high density lipoprotein (HDL) cholesterol of <1.03 mmol/L (male) and <1.29 mmol/L (female).
- Glucose intolerance or known type 2 diabetes mellitus.

Consequently, the presence of NAFLD is also strongly associated with increased cardiovascular risk and its incidence is rising with the increasingly obese UK population. Therefore, it should always be considered important even if the liver is not at the more fibrotic end of the spectrum.

Management

Patients with NAFLD will require treatment of each aspect of the metabolic syndrome and prescription of appropriate medications. If blood cholesterol is high and patients are insulin resistant or hypertensive, dietary advice as well as medical treatment may be necessary.

Secondary non-alcohol fatty liver disease

It is possible for some conditions to lead to the same liver clinical picture as NAFLD; this is known as secondary NAFLD. Secondary NAFLD/NASH is rare in adults and is unrelated to insulin resistance or metabolic syndrome. Causes of secondary NAFLD/NASH include pregnancy related fatty liver disease and intestinal jejunioileal bypass surgery (Adams & Angulo, 2006).

Ascites

Ascites is the most common complication of cirrhosis, and approximately 60% of patients with compensated cirrhosis develop ascites within 10 years (Ginès & Schrier, 2009). The development of ascites in cirrhosis indicates a poor prognosis with mortality of approximately 40% at 1 year and 50% at 2 years (Guevara & Ginés, 2005). Patients with cirrhosis and ascites are at high risk for other liver disease complications, including refractory ascites, spontaneous bacterial peritonitis (SBP), hyponatraemia or hepatorenal syndrome (HRS) (Moore & Aithal, 2006). The absence of these ascites related complications qualify ascites as uncomplicated.

Ascites only occurs when portal hypertension has developed and is related to an inability to excrete an adequate amount of sodium into urine, leading to a positive sodium balance. Hypoalbuminaemia contributes by reducing vascular oncotic pressure, retaining fluid within the vessels and fluid leaks into the peritoneal space. Ascites can be very distressing and patients often suffer from early satiety, reflux and lack of mobility. In addition, paracentesis drains are highly protein losing and peripheral muscle wasting has the potential to be severe without adequate nutritional support. The European Association for the Study of the Liver (EASL, 2010) has graded ascites and given suggestions for treatment. Treating ascites can reduce abdominal pain and discomfort, and may improve appetite, reduce early satiety and allow an increase in food intake. The risk of spontaneous bacterial peritonitis is reduced with a reduction in the ascites and this also reduces stress on the respiratory system and the risk of pleural effusion.

Diuretic resistant ascites and diuretic intractable ascites are collectively known as refractory ascites. Once refractory ascites has developed, the median survival of patients is approximately 6 months and liver transplantation may

be considered (Guevara & Ginés, 2005; Moreau *et al.*, 2004).

Management

Sodium restriction

See section on Nutritional management for detailed information.

Diuretics

Diuretics are prescribed when patients present with the first episode of grade 2 (moderate) ascites. Aldosterone antagonists are prescribed initially, and depending on response the dose is increased to a maximum of 400 mg. If there is poor response (<2 kg/week) or if patients develop hyperkalaemia, loop diuretics are added, e.g. furosemide (Angeli *et al.*, 2010).

Aldosterone antagonists such as spironolactone are potassium sparing and weak natrietics. If patients develop hyperkalaemia of >6 mmol/L in the absence of renal failure, this should resolve with the discontinuation of the drug and long term potassium restriction is unlikely to be necessary. Loop diuretics such as furosemide may be used in combination to aldosterone antagonists. These are powerful natrietics and are potassium losing. The dose is 40 mg, increasing in 40-mg increments to 160 mg/day. If patients develop severe hypokalaemia (<3 mmol/L), loop diuretics need to be discontinued (Angeli *et al.*, 2010). The maximum recommended weight loss during diuretic therapy is 0.5 kg/day in patients without oedema and 1 kg/day in patients with oedema (EASL, 2010).

Fluid restriction

Fluid intake should be restricted only in patients with dilutional hyponatraemia where a serum sodium level of 120–125 mmol/L can occur (Moore & Aithal, 2006). Close liaison with the medical team is necessary regarding the level and length of restriction, which can be relaxed as serum sodium levels normalise. Nutritional support products and nutritious fluids should be prioritised within fluid restrictions if, as is common, the patients are malnourished and suffering from early satiety due to volume of ascites.

Paracentesis

Paracentesis is the therapeutic drainage of ascites from the abdomen using a transabdominal catheter. The volume of ascitic fluid removed may vary from 20 mL for diagnostic purposes to over 20 L to relieve abdominal distension. Large volume paracentesis (LVP) is the first line therapy in patients with large ascites (grade 3 ascites). It is performed together with the administration of albumin (8 g/L of ascitic fluid removed) (Ginès *et al.*, 1996). This is required to maintain circulating blood volume, prevent rapid shifts of body fluid and subsequent hypovolaemic shock, and to prevent circulatory dysfunction after LVP. Serial paracentesis may be the only means of treating refractory ascites. These patients are at risk of high protein losses from repeated drainage of protein rich ascitic fluid. Therefore, dietary intake must include

sufficient protein to compensate; up to 2.0g/kg of dry weight can be tolerated with close monitoring and anthropometry (Nielsen *et al.*, 1995).

Transjugular intrahepatic portosystemic shunts

Transjugular intrahepatic portosystemic shunts (TIPS) decompress the portal system with a shunt inserted between the high pressure portal venous area and the low pressure hepatic venous area. This reduces portal pressure and is effective in the control of recurrent ascites. It also beneficially affects renal function and may have beneficial effects on nitrogen balance and body weight (Plauth *et al.*, 2004). A major complication after TIPS insertion is the development of hepatic encephalopathy, which occurs in 30–50% of patients undergoing the procedure (Riggio *et al.*, 2008).

Encephalopathy

Hepatic encephalopathy has been explained as a reversible impairment of cognitive function or altered level of consciousness (Voight & Conn, 1995). The severity of encephalopathy is commonly quantified using the West Haven criteria (Ferenci *et al.*, 2002) (Table 7.4.26). Encephalopathy is usually an acute presentation in a cirrhotic, decompensated patient or a patient with acute liver injury. The common causes of acute encephalopathy are illustrated in Box 7.4.3. The management of encephalopathy

Table 7.4.26 West Haven criteria for grading encephalopathy (source: Lockwood *et al.* 2002. Reproduced with permission of Wiley-Blackwell Publishing)

Grade	
1	Trivial lack of awareness; euphoria or anxiety; shortened attention span; impaired performance of addition or subtraction
2	Lethargy or apathy; minimal disorientation for time or place; subtle personality change; inappropriate behavior
3	Somnolence to semi stupor, but responsive to verbal stimuli; confusion; gross disorientation
4	Coma (unresponsive to verbal or noxious stimuli)

Box 7.4.3 Common causes of acute encephalopathy

- Portosystemic shunting – 30–50% incidence post shunting
- Sepsis/infections (including bacterial peritonitis)
- Constipation
- Dehydration caused by vomiting and/or diarrhoea/poor nutritional intake
- Uraemia/azotaemia, e.g. diuretic induced
- Gastrointestinal bleeding/variceal bleeding
- Electrolyte disturbances
- Acid–base disturbances
- Drugs (sedatives, alcohol)

lopathy secondary to both acute and chronic liver failure involves the treatment and prevention of its precipitants.

Sepsis

Patients with chronic liver disease are more susceptible to infections including spontaneous bacterial peritonitis. Good infection control management, full septic screen when an infection is suspected and the use of antibiotics, if appropriate, is necessary. Preserving the integrity of the gut wall to reduce the risk of bacterial translocation could also help reduce sepsis and can be achieved with small frequent meals or enteral nutrition in cognitively impaired patients (MacFie, 2004).

Constipation

Current treatment of encephalopathy assumes that colonic bacteria produce ammonia and constipation must be avoided in patients with encephalopathy. Patients are prescribed laxatives so they pass two to four soft stools daily. Lactulose is commonly prescribed and has a prebiotic effect in addition to the osmotic laxative effect it exerts.

Poor nutritional intake

Endogenous waste from protein catabolism can precipitate encephalopathy; therefore, periods of fasting should be avoided and aggressive nutritional support is necessary to meet calculated nutritional requirements in this group of patients. Providing adequate protein in malnourished patients with end stage liver disease can improve mental status and preserve lean body mass (Bemeur *et al.*, 2010). Aggressive nutritional support is necessary and is discussed in more detail in the section on Nutritional management.

Wernicke's encephalopathy

The Wernicke–Korsakoff syndrome develops in thiamine deficient people. Thiamine is an essential cofactor in the metabolism of carbohydrate and alcohol. People with excessive or hazardous drinking habits are at high risk of developing Wernicke's encephalopathy. It comprises of a combination of global confusion, eye signs and ataxia. Uncommonly, the patient is drowsy or in a state of stupor, but may also be disorientated, apathetic or have impaired memory. These clinical abnormalities may develop acutely or evolve over several days. It is reversible with thiamine administration.

Korsakoff's psychosis is an amnesic state in which there is profound impairment of memory but relative preservation of other intellectual abilities; confabulation may be a feature. Korsakoff's psychosis generally develops after an acute episode of Wernicke's encephalopathy and is irreversible (NICE, 2010a).

As thiamine requirements are linked to carbohydrate intake, it is very important that intravenous dextrose and excessive carbohydrate from food or enteral nutrition is not given to a thiamine deficient patient without thiamine being administered. In patients who present intoxicated, unconscious or confused, especially those with known

Table 7.4.27 Percentage risk of hepatocellular carcinoma (HCC) development related to cause of cirrhosis (Ryder, 2003)

Cause of cirrhosis	Gender	Percentage risk per year of development of HCC
Hepatitis B	Males and females	3–12
Hepatitis C	Males and Females	3–5
Genetic haemochromatosis	Males and Females	7–9
Alcoholic liver disease	Males	1–4

cirrhosis or alcohol histories, Wernicke's encephalopathy should always be considered a potential diagnosis and treated accordingly. Initially, parenteral thiamine may be required on admission, followed by oral preparations of at least 100 mg/day as per refeeding guidelines and up to 300 mg/day (NICE, 2006).

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) was previously thought to be a relatively rare cancer but it is becoming increasingly more prominent in the UK with the hepatitis C epidemic. It occurs more frequently in Asia due to the high incidence of hepatitis B, but it is usually detected earlier due to HCC screening programmes in the hepatitis B population. The percentage risk of HCC development related to cirrhosis is shown in Table 7.4.27. The average age in the UK at which HCC develops is 66 years. Treatments offered depend on the size and stage of the tumour (Ryder, 2003).

Management

Surgery

The only proven curative therapies are surgical, either hepatic resection or liver transplantation, and criteria for referral exist (Ryder, 2003). Many patients have established cirrhosis and therefore surgery is often carried out in specialist centres as patients can be at risk of liver decompensation after surgery. Non-surgical treatments are used when surgery is considered inappropriate.

Percutaneous alcohol injections

Alcohol is injected into the tumour to cause tumour necrosis.

Chemoembolisation

Concentrated chemotherapy drugs are delivered via a catheter direct to the tumour site. This avoids any dilutional effect that may occur during standard administration of chemotherapy.

Chemotherapy

Standard chemotherapy regimens show poor response, so they usually only offered in the context of trials.

Radiofrequency ablation

Radiofrequency ablation is a procedure where the hepatocellular tumour is ablated using the heat generated from the high frequency alternating electrical current. A general anaesthetic is not always necessary and therefore it may be performed in day care.

Liver transplantation

There are seven liver transplant centres in the UK and Ireland. The UK has approximately 6000 surviving liver transplant recipients and annually about 600 people with liver disease receive a liver transplant. The post transplant population is growing. Nearly 550 of those 600 patients survive for 1 year after transplant and at least 50% live 20 years. Patients meeting transplant criteria should be offered a transplant only if it is felt they have a >50% probability of survival at 5 years after transplantation with a quality of life that is acceptable to the patient (Neuberger *et al.*, 2008).

Nutritional management

When taking into account the incidence and consequence of PEM and specific micronutrient deficiencies, meeting the patients calculated requirements is pivotal to their management. Close liaison with the multidisciplinary team (MDT) is vital in order to prevent unnecessary dietary restrictions.

Oral nutrition

The pattern of food intake can influence energy balance in liver cirrhosis. Verboeket-van de Venne *et al.*, (1995) showed that after a short term fast of 9 hours, fat is used as an alternative fuel to glucose, which cannot be produced in sufficient quantities due to the depleted glycogen stores in the liver. By giving four to six meals/day, oxidation of carbohydrate was significantly lower than carbohydrate intake, which resulted in a positive balance of carbohydrate. This pattern may also help patients with early satiety caused by reduced volume as ascites increases. Interestingly, Le Cornu *et al.* (2000) found that nutritional counselling may produce similar outcomes when compared with oral nutritional supplements (ONS) and therefore these simple changes can be very effective.

Owen *et al.* (1983) established that after an overnight fast, patients with cirrhosis show increased rates of fat oxidation and gluconeogenesis. Whilst glucose oxidation and glycogenolysis are reduced compared with healthy controls, Swart *et al.* (1989) found that a late evening snack improved nitrogen balance, with Plank *et al.* (2008) showing that there is an improvement in nutritional status as a result. The late evening snack, which reduces fasting periods overnight, should include 50g of carbohydrate, and examples of suitable snacks are shown in Box 7.4.4. Thought should be given to inpatient snacks and meal times in order to allow the provision of at least a 50-g carbohydrate snack or supplement in the evening. Tsien *et al.* (2012) critically reviewed the evidence for provision of a late evening snack, concluding that there

Box 7.4.4 Examples of 50g carbohydrate snacks

- Two crumpets with 200 mL of milk
- One to one and a half milk based 1.5 kcal/mL supplement (dependent on composition)
- One juice based 1.5 kcal/mL supplement (dependent on composition)
- Two and a half thick slices of bread
- Breakfast cereal (30g) with milk
- One slice of fruit cake
- Scone with jam and 300 mL of milk
- Five dried dates and 200 mL of milk
- Small square of flapjack and 300 mL of milk

is insufficient evidence to recommend a branch chain amino acid (BCAA) enriched supplement in preference to a high carbohydrate supplement. Further randomised adequately powered trials are required that also investigate effect on clinical outcome.

Patients who are unable to meet their nutritional requirements from a normal diet will require ONS (see Chapter 6.3). Standard polymeric supplements can be used according to patient preference and should be prescribed to make up the energy and protein deficit. The use of sip feeds that contain 20g of protein per bottle can be especially useful when trying to meet nutritional requirements. This group of patients may need to use sip feeds long term and therefore it is vital that time is spent establishing flavour and product preferences in order to aid compliance. Fluid restrictions create increased difficulty when trying to meet requirements and close liaison with the MDT is vital (see Ascites section on fluid restrictions). Plauth *et al.* (2006) supported the use of ONS, which can improve nutritional status and survival in severely malnourished patients with alcoholic hepatitis. Close monitoring is essential, both of oral intakes and tolerance as patients can vary quickly from one day to another.

Enteral nutrition

If patients are unable to tolerate an oral diet or fail to achieve adequate requirements orally, a nasogastric (NG) tube should be inserted (see Chapter 6.4). There should be a low threshold for initiation of enteral feeding as patients deteriorate quickly, with the priority being to meet nutritional requirements consistently. Historically, there has been a reluctance to pass NG tubes when varices are present; however, this is not supported by evidence (Plauth *et al.*, 2006). Cabré *et al.* (1990) demonstrated that albumin levels and Child–Pugh scores were improved with enteral nutrition in severely malnourished patients with cirrhosis. In patients with alcoholic liver disease, aggressive enteral nutrition decreased bilirubin levels and improved hepatic encephalopathy (Kearns *et al.*, 1992). Overnight NG feeding decreases the fasting period and helps achieve nutritional requirements in those who are

taking an oral diet and supplements but still not achieving estimated requirements or have deteriorating anthropometric measurements.

For those who are encephalopathic, 24-hour NG feeding should be encouraged in order to avoid protein boluses and minimise fasting periods so as to utilise the nutrition most effectively. Placement of NG tubes can be difficult as increasing confusion leads to tubes becoming dislodged, resulting in suboptimal nutritional intake. The MDT is essential in order to discuss local management of these patients, which may require increased nursing care, secure taping of the tube, fixation devices or even restraints.

A high energy density feed (at least 1.5 kcal/mL) should be used to achieve estimated requirements within smaller volumes for those who have delayed gastric emptying, complain of bloating or require fluid restrictions. Most feeds contain <100 mmol of sodium when meeting requirements and therefore specific low sodium feeds are usually not required. These can also have a low protein to energy ratio that prevents protein requirements from being met. The rate of feed should be built up according to local policy on enteral feeding and within refeeding syndrome guidelines if necessary.

Nasojejunal feeding

There are few specific guidelines regarding the use of nasojejunal (NJ) feeding tubes in liver disease. Wicks *et al.* (1994) identified that in post liver transplant patients NJ feeding was as successful in maintaining nutritional status as parenteral nutrition. In practice, NJ tubes may be used for patients who have poor absorption, indicated by high aspirates, nausea and vomiting, or early satiety caused by ascites and chronic malnutrition. Continuous infusion of enteral feed into the small bowel has the added benefit of avoiding fasting times and therefore optimising carbohydrate oxidation and improvements in nitrogen balance.

Gastrostomy and jejunostomy feeding

The placement of percutaneous endoscopic gastrostomy (PEG) tubes is associated with a higher risk of complications due to ascites or varices, and is contraindicated according to Plauth *et al.* (2006). However, Ponsky *et al.* (1989), cited in Loser *et al.* (2005), suggested that the presence of mild to moderate ascites is not a contraindication for PEG placement due to the absence of increased complications, although altered coagulopathy [international normalised ratio (INR) >1.5] would be an absolute contraindication.

Jejunostomy tubes have been used historically for post liver transplant patients and were placed during surgery. Their use has declined significantly as patients can be adequately fed with NG or NJ tubes. Elective placement of jejunostomy tubes in post transplant patients may be for prolonged feeding with gastric aspirate or vomiting issues.

Parenteral nutrition

Parenteral nutrition (PN) should be reserved for patients for whom there is no enteral feeding route available (Plauth *et al.*, 1997) (see Chapter 6.5). This form of nutritional support is more expensive, and associated with a higher incidence of infections and electrolyte imbalance when compared with enteral nutrition (Sanchez & Aranda-Michel, 2006). Hepatic abnormalities, e.g. hepatic steatosis, intrahepatic cholestasis or elevated liver function tests, can occur in up to 75% of adults receiving PN (Guglielmi *et al.*, 2006). Other causes must be identified first, e.g. sepsis when patients develop a deterioration in their LFTs. Usually only monitoring, or a small reduction in the energy content of the feed (to 25 kcal/kg when including nitrogen energy or to 20 kcal/kg from non-nitrogen sources) is required (Kumpf, 2006).

Guidelines from the ESPEN (Plauth *et al.*, 2009) have further clarified the use of PN in liver disease when clinically indicated. In alcoholic hepatitis and liver cirrhosis intravenous glucose (2–3 g/kg/day) should be given when fasting for >12 hours, with thiamine prescribed prior to starting. Parenteral nutrition should be started immediately in moderate to severely malnourished patients, and where fasting will occur for 72 hours or more, water soluble vitamins and trace elements should be included. Energy and protein requirements should be calculated as described in the Enteral assessment section. Monitoring is essential for blood glucose and electrolytes for refeeding syndrome. Plauth *et al.* (2009) also suggested that PN should be started in acute liver failure where patients are unlikely to eat or receive enteral nutrition for 5–7 days. Intravenous glucose should be given (2–3 g/kg/day) to maintain glucose levels or in the case of hyperglycaemia, adequate insulin regimens to maintain normoglycaemia should be prescribed. Blood glucose monitoring continues to be essential, as well as blood ammonia levels in order to adjust PN amino acid content.

For those with ascites or oedema, fluid restriction may be required. These patients would normally also be sodium restricted to 80–100 mmol/L/day.

Studies suggest that the provision of a small amount of enteral nutrition may minimise complications such as sepsis. This may be due to decreasing the risk of bacterial translocation by preventing alterations to the structure and function of the gut (Guglielmi *et al.*, 2006). In long term PN, liver function may be aided by the use of structure lipids, n-3 fatty acids or cyclical feeding (Rubin *et al.*, 2000).

Alcoholic hepatitis

Conventional therapy is based largely on abstinence from alcohol as well as general supportive and symptomatic care. Patients with alcohol related liver disease are often malnourished and this has a detrimental effect on survival. The Veterans Affairs Cooperative study (Mendenhall *et al.*, 1991) found the prevalence of PEM to be 100% in patients with alcoholic hepatitis, the severity of which

correlated with the degree of liver dysfunction. Protein energy malnutrition correlated with short and long term mortality, clinical severity of liver disease and biochemical hepatic dysfunction.

A randomised trial by Cabré *et al.* (2000) investigated both the short and long term effects of steroids (prednisolone 40 g/day) or total enteral nutrition (2000 kcal/day) in patients with alcoholic hepatitis. During the 28-day treatment phase, mortality was similar between the groups, but occurred earlier in the total enteral nutrition (TEN) group (median day 7 versus median day 23). Mortality during the 1-year follow-up period was significantly higher in the steroid group and occurred in the immediate weeks after the treatment phase, mainly due to infections. The trial concluded that TEN is no worse than steroid treatment in the short term management of alcoholic hepatitis.

Patients fed after a period of reduced nutritional intake and heavy alcohol use are at risk of developing refeeding syndrome. It is important to ensure vitamin B Co strong and a treatment dose of thiamine are prescribed or intravenous Pabrinex preparation given prior to commencing enteral feeding. The management of refeeding syndrome is discussed further in Chapter 6.4.

Nutritional assessment and goals

All patients with alcoholic hepatitis should be assessed for PEM, as well as vitamin and mineral deficiencies. Those with severe disease should be treated aggressively with enteral nutritional therapy (O'Shea *et al.*, 2010). An energy intake of 35–40 kcal/kg of dry body weight/day and protein intake of 1.2–1.5 g/kg of body weight are recommended (Plauth *et al.*, 2006). Some researchers suggest a higher energy intake of 45 kcal/kg may be necessary (McCullough & O'Connor, 1998), but the key to adequate nutritional support is close monitoring.

Steroid use

Corticosteroids have been studied intensively in alcoholic hepatitis. They are used as anti-inflammatory agents but are associated with side effects, including poor wound healing and susceptibility to infection (Rambaldi *et al.*, 2008). The National Institute for Health and Care Excellence (2010a) recommends the use of steroids in severe alcoholic hepatitis with a Maddrey's discriminant function of 32 or more. Patients should be concurrently prescribed calcium and vitamin D supplements as bone protection with blood glucose monitoring and treatment if elevated.

Fulminant hepatic failure

Stabilisation of metabolic disturbances is essential as alkalosis and acidosis can both occur (Polson & Lee, 2005). Hepatic encephalopathy symptoms may hide those of hypoglycaemia; therefore, continuous glucose infusions and monitoring is critical. Nutritional support is vital with NG or NJ feeding following local guidelines. Current practice in UK specialist liver centres favours high energy,

high protein feeds to meet requirements in this highly catabolic group.

Wilson's disease

Initial medical therapy is with chelating agents, e.g. D penicillamine and trientine. Zinc may also be used alone or in combination with a chelating agent. Foods high in copper, including chocolate, liver, nuts, mushrooms and shellfish, are best avoided, especially in the first year of treatment (Roberts & Schilsky, 2008).

Liver transplant nutrition

Initially following a liver transplant, patients are often enterally fed. Long term management involves food safety advice, weight maintenance and lifestyle advice. Some immunosuppression medication can cause hyperkalaemia, but this is often transient and short term low potassium diets may be indicated. If required, further advice can be obtained from specialist transplant centres.

Haemochromatosis

Haemochromatosis cannot be treated with a low iron diet. It is managed by reducing the systemic iron overload through therapeutic phlebotomy to achieve a serum ferritin of $<50 \mu\text{g/L}$. Patients however are often reluctant to eat foods rich in iron as they feel anxious regarding absorbing iron. Simple advice can be:

- Avoid vitamin and mineral supplements containing iron and vitamin C (ascorbic acid) as vitamin C aids iron absorption.
- Avoid drinking fresh fruit juice with meals due to their high vitamin C content.
- Limit intake of red meat to 70g cooked weight/day (Scientific Advisory Committee on Nutrition, 2010).
- Do not avoid fruit and vegetables, including green leafy iron rich ones, as phytates and oxalates reduce iron bioavailability.
- Alcohol can accelerate disease progression; therefore, reduced alcohol intake is recommended.
- Calcium and tannins inhibit iron absorption so drinking dairy products and tea with meals may inhibit dietary iron absorption.

Non-alcoholic fatty liver disease

Obesity

Weight reduction improves all risk factors associated with the metabolic syndrome and further reduces the risk for type 2 diabetes (Targher *et al.*, 2007). A reduction of 10% from baseline weight over 6–12 months has been shown to correct aminotransferase levels and decrease hepatomegaly. However, too rapid weight loss can cause worsening steatohepatitis and increase the risk of gall stone disease. Crash diets where weight loss exceeds 1.5 kg/week should be discouraged. Monitoring LFTs may be necessary if patients lose weight rapidly as this may precipitate deterioration in liver function (Day, 2006).

Dietary changes alone are associated with high failure rate at achieving and maintaining weight loss for multifactorial reasons. Dietary intervention should include behaviour modification therapy, cognitive behavioural therapy and the use of support groups. Consensus is lacking as to what diet or lifestyle approach is best for NAFLD and NASH patients, primarily due to insufficient evidence (Zivkovic *et al.*, 2007). Obesity and further strategies for its management are discussed in Chapter 7.13.2.

Non-cirrhotic patients

It is important to assess the stage of liver disease as the advice for a cirrhotic NAFLD (NASH) patient differs from a patient with a fatty liver or fibrosis. At initial assessment, the stage of liver disease, weight, BMI and waist circumference should be obtained and clear goals for weight loss discussed with the patient, with advice to avoid crash dieting or excessive weight loss. Exercise should be encouraged as this improves insulin sensitivity independently of change in weight. (Duncan *et al.*, 2003) Basic principles of weight loss in NAFLD pre cirrhosis are to:

- Aim for a BMI below 25 kg/m^2 .
- Aim for a reduction of 10% from baseline weight over 6–12 months.
- Calorie restriction to achieve a 0.5–1 kg (1–2 lb)/week weight loss.
- Avoid weight loss that exceeds 1.5 kg/week.
- Encourage exercise for 30 minutes/day minimum.
- Encourage weight maintenance through long term lifestyle changes.
- Give food group advice as illustrated in the eatwell plate (see Figure 4.2.2):
 - Aim for five portions of fruit and vegetables/day.
 - Eat low glycaemic index foods.
 - Avoid refined sugars and saturated fats.

Diets high in soluble and insoluble fibre have been shown to improve insulin resistance, and low glycaemic index diets have proved beneficial (Harrison *et al.*, 2002). Excessive carbohydrate intakes should be avoided. In addition, each aspect of the metabolic syndrome should be addressed individually and treated with appropriate medical and dietary therapy as appropriate. Alcohol should be discussed with the patient's doctor.

Hyperlipidaemia

Dyslipidaemia is present in 20–80% of patients with NAFLD. Improvement in lipidaemia also helps in the prevention of coronary heart disease. Diets should be low in saturated and *trans* fat, with proportionally more unsaturated fat. Total fat intake should be advised to be below 35% of daily intake with 15–20% made up of monounsaturates and minimal *trans* fats. n-3 Fatty acids have antiarrhythmic and anti-inflammatory effect and reduce triglycerides. An intake of 450 mg/day (equivalent to the recommended two portions of oily fish/week) is recommended. Fibrates should be used if indicated (Day, 2002).

Hypertension

Hypertension should be treated with antihypertensives as necessary for tight blood pressure control of

<140/80 mmHg, especially in those with impaired fasting glucose or type 2 diabetes mellitus. Management of hypertension is similar to that in other patients: restriction of sodium to a no added salt diet, which is 80–100 mmol of sodium (4.6–5.75 g salt)/day (American Gastroenterological Association, 2002).

Diabetes mellitus or impaired fasting glucose

Type 2 diabetes mellitus is common in patients with NAFLD as it is an element of the metabolic syndrome. Tight glycaemic control is necessary and is achieved by maximising use of oral hypoglycaemic agents or insulin.

Cirrhotic patients

In cirrhosis, despite the appearance of obesity, some patients with advanced liver disease will have PEM, and therefore require a full dietary assessment for evidence of protein malnutrition. Dietary restriction in patients with elevated nutritional requirements risks worsening PEM, and should only be contemplated under careful supervision with regular anthropometric measurement. Calculating nutritional requirements in the obese patient is discussed in the Nutritional assessment section. Protein energy malnutrition is associated with reduced transplant graft and patient survival (Stickel *et al.*, 2008). Weight loss should not be recommended in cirrhotic patients with end stage liver disease due to the risk of PEM. For patients with stable compensated cirrhosis and HCC, it may be appropriate to try and achieve weight loss before proceeding to or whilst waiting for a liver transplant (British Transplant Society, 2011).

Hepatitis C

Hepatitis C affects people differently and can affect appetite, especially if patients have cirrhosis. However, many people have no symptoms at all. If patients are well there is no evidence for any sort of therapeutic diet, vitamin supplements or herbal preparations. Patients should be encouraged to eat a healthy well balanced diet, such as those promoted by the eatwell plate (see Chapter 4.2) and maintain a BMI within a health range.

A rising incidence of NAFLD with increasing obesity and in combination with hepatitis C are intrinsically linked to poorer outcomes in liver disease (EASL, 2011). Weight maintenance is important for many reasons. There is growing evidence that obesity and insulin resistance can accelerate hepatitis C progression and increase the risk of HCC in chronic hepatitis C (Okuda *et al.*, 2002, Lonardo *et al.*, 2004, EASL, 2011). Obesity can also reduce the effectiveness of antiviral treatments, so patients with a BMI of >30 kg/m² should be advised to try to lose weight prior to starting antiviral treatment as this may help the antiviral response (Bressler *et al.*, 2003).

Patients on antiviral treatments

Antiviral treatments are usually prescribed for 6- or 12-month periods with the aim of eradicating the virus. Side effects include poor appetite and weight loss, nausea and vomiting, sore mouth and throat, metallic taste, lethargy and depression.

If patients unintentionally lose >10% of their body weight, it becomes clinically significant and malnutrition risk is heightened (Heymfield & Matthews, 1994). As first line advice, food fortification advice is appropriate. If weight loss persists, oral nutritional supplements can be prescribed under the ACBS indication for disease related malnutrition and reviewed on a monthly basis. Occasionally, chaotic lifestyles make the use of such products difficult and staggered prescribing may be necessary.

Alcohol

Regular alcohol consumption in hepatitis C leads to accelerated fibrosis progression and possibly reduced response to antiviral therapy. Therefore, intake should be limited, especially if antiviral treatment is to commence (Anand *et al.*, 2006). Alcohol advice depends on the patient and their clinical state and previous alcohol history; medical staff should direct the decision regarding alcohol intakes. If patients are drinking alcohol to excess (hazardous or dependent drinking), thiamine and vitamin B₁₂ should be prescribed to reduce the risk of clinically significant complications of B vitamin deficiency, such as neuropathy and Wernicke's encephalopathy (NICE, 2010a).

Telaprevir

Telaprevir (VX-950), marketed under the brand name Incivek, is a pharmaceutical drug for the treatment of hepatitis C. Patients are usually prescribed this for a 12-week period, three times per day. Telaprevir is ineffective if taken on an empty stomach and patients must consume at least 20 g of fat with each dose (Revill *et al.*, 2007). This can be in any form, in standard meals or fatty foods as per patient preference. In theory, the increase in energy from this advice could cause weight gain. However, in reality, patients may have a poor appetite as a side effect of antiviral treatment and, if appropriate, fat supplements such as Calogen (Nutricia) or Fresubin 5cal shot (Fresenius) can be prescribed to be taken at the same as Telaprevir.

Ascites and oedema

The diagnosis and classification has been covered in the section on Clinical investigation and management. By the time patients have developed ascites they have advanced cirrhosis and appetites are so poor nutritional support is often necessary. The volume of abdominal fluid that can build up in ascites can severely limit dietary intake due to feelings of satiety, reflux and constipation, and reduced mobility and ability to shop, cook and prepare meals. As with any dietary modification in liver disease, the priority is to meet nutritional requirements as PEM is common by this stage of liver disease. It is important that nutritional requirements are met whilst keeping sodium intake within the recommended level for the patient's current condition.

Salt reducing advice should be given to patients with Grade 2 (moderate) ascites or above. Salt should be restricted to 4.6–6.9 g (80–120 mmol)/day (EASL, 2010).

Traditionally, a no added salt diet is advised, which is 80–100 mmol of sodium (4.6–5.75 g salt)/day. The recommendation for the general population is 6 g/day (Cappuccio *et al.*, 2011).

Refractory ascites

Salt should be restricted to 5.2 g/day, which corresponds to 90 mmol/day of sodium. There is no evidence to support the prophylactic use of salt restriction in cirrhotic patients who have never had ascites, nor is bed rest advocated as a treatment of ascites (EASL, 2010). Sodium intakes vary enormously between patients and each patient should be assessed individually. Very often, reducing a few key foods can have a profound impact on daily net sodium intake while maintaining a regular intake. Simple no added salt advice includes the following points:

- No added salt to meals.
- Avoid salty snacks such as crisps (20 mmol of sodium) and soups.
- Encourage high energy high protein snacks with a 50-g carbohydrate rich snack in the evening.

However, if this advice needs to be expanded, assess current dietary intake and reduce the following as required:

- No salt added at the table.
- Only a pinch in cooking.
- Avoid salt substitutes.
- Up to 100 g of cheese/week.
- Up to four slices bread/day.
- Reduce processed foods:
 - Bacon, ham, sausages, paté.
 - Smoked fish and meat tinned in brine.
 - Fish and meat pastes.
 - Tinned and packet soup.
 - Auce mixes, stock cubes, soya sauce, mono sodium glutamate.
 - Tinned vegetables.
 - Bottled sauces and chutneys.
 - Meat and vegetable extracts.
 - Salted nuts and crisps.

Patients can find it helpful to be able to calculate how much salt is in their diet and the following guidance can be helpful. Advise patients to look at food labels and check to see how much salt there is per 100 g. If there is only a figure for sodium on the label, patients should be advised to multiply this by 2.5 to obtain the salt content. Patients can calculate whether food is high, medium or low in salt using the figures:

- High salt – >1.5 g/100 g (0.6 g of sodium).
- Medium salt – 0.3–1.5 g/100 g portion (0.6–1 g of sodium).
- Low salt – 0.3 g/100 g (0.1 g of sodium).

Nutritional support

Most milk type nutritional supplements contain 8–10 mmol of sodium, while juice based supplements have very small amounts. However, milk type sip feeds have considerably

higher protein than juice based sip feeds and are often the supplements of choice, especially if patients are undergoing therapeutic paracentesis when protein losses per drain can exceed 90 g of protein.

If artificial enteral feeding is necessary, most standard enteral feeds (1 kcal/mL) are suitable as they contain <40 mmol of sodium/L. High energy and protein feeds are often prescribed (1.5–2 kcal/mL) as they provide more energy and protein in smaller volumes. Tolerance to larger volumes due to early satiety and bloating may be difficult and fluid restrictions need to be considered. Overnight NG feeding allows the patients to be disconnected from the feeding pump during the day and encourages the maintenance of oral intake during the day. Sip feeds, if prescribed in addition to the NG feed, can be flushed down the tube rather than drunk if the patient is struggling to consume them orally.

Hepatic encephalopathy

Protein energy malnutrition is a risk factor for hepatic encephalopathy and low protein diets are not recommended. There is a paucity of evidence that they contribute to any improvement in encephalopathy and may cause harm due to worsening nutritional status (Cordoba *et al.*, 2004; Plauth *et al.*, 2006). Adequate nutrition *per se* counteracts hepatic encephalopathy and should be provided by the enteral route if at all possible.

Nutritional energy and protein requirements should be calculated as discussed in the Nutritional assessment section. Periods of fasting should be minimised as endogenous waste from protein catabolism can precipitate encephalopathy. If patients are eating and drinking, a frequent meal pattern of four to six small meals and snacks should be recommended. Late evening 50-g carbohydrate snacks are crucial as these reduce protein catabolism during overnight fasting and promote a positive nitrogen balance (Tsuchiya *et al.*, 2005; Yamanaka-Okumura *et al.*, 2006).

If enteral feeding is indicated, overnight feeding helps break the overnight fast and maintain a positive nitrogen balance (Owen *et al.*, 1983; Zillikens *et al.*, 1993). If enteral nutrition is the sole source of nutrition, 24-hour enteral feeding may be required to avoid the fasting period until the encephalopathic episode resolves, and then reviewed.

Lactulose is a non-absorbable disaccharide used as a laxative as it inhibits ammonia producing bacteria in the gut wall and acts as an osmotic laxative. The antibiotics rifaximin, neomycin and metronidazole may also be prescribed, and fluid electrolyte imbalances corrected.

Branched chain amino acids

Supplementation with branched chain amino acids (BCAAs) remains under investigation both as a nutritional supplement and as a means to treat hepatic encephalopathy. The BCAAs, especially leucine, appear to have an important anabolic role in protein synthesis and there is an increased requirement for BCAAs with metabolic stress or injury. Studies have shown that BCAAs increase muscle

mass and performance (Laviano *et al.*, 2005) and it has been reported that supplementation with oral BCAAs improved energy metabolism in cirrhotic patients (Tsuchiya *et al.*, 2005; Als-Nielsen *et al.*, 2003). They also compete with the serotonin precursor tryptophan for the same amino acid transporter at the blood–brain barrier. Hence, it has been suggested that BCAA supplementation may reduce the brain uptake of tryptophan. Studies have shown levels of BCAAs to be depleted in advanced liver disease and malnutrition (Blonde-Cynober *et al.*, 1999).

The aromatic amino acids (AAAs) are tyrosine, tryptophan and phenylalanine. There is usually homeostasis in the concentration of BCAAs and AAAs. However, amino acid metabolism is altered in liver disease and there is a reduced ratio of BCAAs to AAAs. The increase in AAAs is related to the reduced capacity of the liver to remove them. The proposed cause for hepatic encephalopathy is enhanced passage of AAAs through the blood–brain barrier, resulting in the creation of false neurotransmitters, e.g. octopamine, which cause hepatic encephalopathy symptoms (Dejong *et al.*, 2007). It has been suggested that BCAA supplementation will improve hepatic encephalopathy by improving the ratio of BCAAs to AAAs.

The effect of BCAAs in liver disease has been studied for many years with inconsistent results. A Cochrane review described 11 randomised controlled trials and found that there was no convincing evidence that BCAAs had a significant benefit to patients with hepatic encephalopathy (Als-Nielsen *et al.*, 2003). However, more recently, two large randomised controlled trials (Marchesini *et al.*, 2003; Muto *et al.*, 2005) have shown positive results. Muto *et al.* (2005) concluded that with adequate energy and protein intake long term supplementation with BCAAs in decompensated liver cirrhosis improved event free survival, serum albumin and quality of life.

In 2006, the ESPEN (Plauth *et al.*, 2006) reviewed the additional evidence from the above trials and gave the following recommendations:

- Use BCAA enriched formulae in patients with hepatic encephalopathy arising during enteral nutrition.
- Oral BCAAs can improve clinical outcome in advanced cirrhosis.
- Ensuring an adequate nutrient intake should be the primary goal.
- Long term (12 and 24 months) nutritional supplementation with oral BCAA granules. Oral nutrient supplements are useful in slowing the progression of hepatic failure and prolonging event free survival.

The advised length of treatment varies from 12 to 24 months in most studies and to adopt this into clinical practice, compliance due to palatability is likely to be problematic. Benefits are unlikely to be seen in the inpatient population due to the length of time needed to see effects. Patient selection for the use of BCAAs needs to be carefully evaluated regarding their condition and likely prognosis with advanced cirrhosis.

There is no consensus on the recommended dose of BCAAs to date, although there is a recommendation to take them at night as BCAAs are used as energy during

the day but are used for protein synthesis at night (Fukushima *et al.*, 2003). In the UK, BCAAs have not been adopted in the UK liver transplant specialist centres, nor is a palatable product as yet available. However, this is a developing area and specialist centres should be contacted for advice regarding any UK developments.

Probiotics

Probiotics have been studied as a treatment for hepatic encephalopathy given the theory of altered ammonia production causing confusion. However, following a Cochrane review (McGee *et al.*, 2011), the use of probiotics cannot be recommended for patients with hepatic encephalopathy, with further randomised trials needed.

Wernicke's encephalopathy

See the section on Clinical investigation and management.

Diabetes

Conditions in which diabetes mellitus and glucose intolerance are most commonly seen are NAFLD, cirrhosis, acute viral hepatitis, steatohepatitis, chronic autoimmune hepatitis and acute liver injury. Steroid induced diabetes is often seen as steroids are commonly used in some liver diseases and for post transplant rejection.

Maintaining tight blood glucose control and optimising insulin and/or oral hypoglycaemic therapies is of vital importance in liver disease. In non-cirrhotic patients with conditions such as NAFLD, poor glycaemic control is associated with increased cardiovascular risk and increased infection, rates and can predispose to malnutrition in cirrhosis (Musso *et al.*, 2003). Diabetes is associated with mobilisation of adipose tissue, fatty acids and increased protein catabolism, which plays a role in the aetiology of muscle wastage. As a result hyperglycaemia will exacerbate muscle wastage and predispose to PEM. In addition, patients with liver cirrhosis are at increased risk of bacterial and fungal infection and increased blood glucose levels predispose to nosocomial infections. Blood glucose of >11 mmol/L has been shown to cause a 10-fold increase in infection rates (McMillan & Rizza, 1996).

Dietary intervention

Dietary advice should be modified to meet the patient's estimated protein and energy requirements and standard healthy eating diabetic dietary advice should only be used in patients who show no signs or are not at risk of PEM. In cirrhotic malnourished patients, healthy eating advice is inappropriate and simple low refined carbohydrate advice such as given below is adequate. Priority should be given to meeting elevated nutritional requirements, a small, frequent meal pattern inclusion of ONS as necessary, and a 50-g late evening snack. Close liaison with diabetes care teams is often necessary to optimise insulin and oral hypoglycaemic regimens. Simple dietary advice includes:

- Reduce refined carbohydrate, e.g. sugar, sweets, sugary drinks.

- Small frequent meals with snacks between, especially 50-g carbohydrate evening snacks.
- Fruit and vegetables used in moderation as they have low energy density and can result in early satiety.
- ONS as necessary to meet elevated energy and protein requirements.

If parenteral or enteral feeding is indicated, appropriate adjustment to oral hypoglycaemic agents and insulin regimens to optimise glycaemic control needs liaison with medical and diabetes teams as appropriate.

Reactive hypoglycaemia

Symptomatic reactive hypoglycaemia is common. Patients should be advised to avoid fasting and encouraged to eat in a small, frequent meal pattern with adequate quantities of carbohydrate and regular snacks. It is also advisable to have a meal or snack prior to exercising.

Zinc deficiency and liver disease

The liver plays an important role in zinc homeostasis and zinc deficiency in cirrhosis is associated with impaired liver function and regeneration (Grüngreiff, 2002), and alteration in taste perception (Madden *et al.*, 1997). Malnutrition in cirrhotic patients is also likely to contribute to zinc deficiency, especially in alcoholic patients (Poschl *et al.*, 2004). Cirrhosis has been implicated as a cause of zinc deficiency as a result of multiple factors including decreased intestinal absorption which in itself may cause damage to intestinal mucosa (Karayalcin *et al.*, 1988). Additionally, there are increased urinary losses of zinc through diuretics in patients with cirrhosis (Yoshida *et al.*, 2001) and reduced circulating albumin levels, which results in reduced binding of zinc to albumin.

The pathogenesis of hepatic encephalopathy derived from liver failure is likely to be related to zinc deficiency (Romero-Gomez *et al.*, 2001; Yang *et al.*, 2004). Despite mixed results from research, zinc supplementation should be considered for patients with hepatic encephalopathy who do not respond to standard therapy and in whom serum levels have been measured and deficiency established (Blei & Cordoba, 2001; Takuma *et al.*, 2010).

Malabsorption

Malabsorption and maldigestion of gastrointestinal nutrients frequently exists in patients with liver disease; however, the extent to which they occur can vary considerably depending on the underlying disease and the individual. Ulcerative colitis is commonly seen in people with primary sclerosing cirrhosis, and coeliac disease in patients with primary biliary cirrhosis. Additionally, in alcoholic liver disease pancreatic insufficiency is common. Other reasons for malabsorption can include bacterial overgrowth resulting from impaired small bowel motility or the administration of medications such as cholestyramine, lactulose and antibiotics. Malabsorption of fat soluble vitamins is common, especially in cholestatic disease where reduced absorption of carbohydrates,

protein, water soluble vitamins and minerals has also been demonstrated (Matos *et al.*, 2002).

Steatorrhoea

This develops if secretion of bile is significantly impaired (cholestasis) and as a result reduced amounts of bile salts reach the duodenum. Bile acids also act as cofactors for digestive lipases, protecting them from the proteolytic effects of other digestive enzymes. Steatorrhoea is a frequent symptom in cholestatic diseases, such as primary biliary cirrhosis where the small intrahepatic bile ducts are progressively destroyed, leading to cholestasis and primary sclerosing cirrhosis in which inflammation and fibrosis of the bile ducts lead to narrowing of the biliary system. Steatorrhoea may be so severe that it compromises the nutritional status of the patient and may be a direct cause of malnutrition (Zaina *et al.*, 2004). Cholestatic disease is frequently associated with a fat soluble vitamin deficiency (Feranchak *et al.*, 2005).

A subjective diagnosis can be made on classic steatorrhoea symptoms such as loose, bulky, greasy, pale, floating stools, with an offensive smell following ingestion of a fat containing food. Oily droplets may appear in the toilet water or on toilet tissue.

The initial dietary assessment of all patients with jaundice, primary biliary cirrhosis and primary sclerosing cirrhosis should include consideration of the potential of steatorrhoea. Even when symptoms are absent, the patient should be advised to observe bowel habits in case steatorrhoea develops in view of the risk of malnutrition.

Fat restriction

If indicated, the aim of dietary treatment is to alleviate symptoms, prevent decline in nutritional status and fat soluble vitamin deficiencies. Fat is an important and palatable source of energy for any patient requiring nutritional support, and for patients with liver disease a reduction in fat intake should only be used if:

- There is objective or subjective evidence of symptoms of steatorrhoea and these distress the patient.
- Symptoms of steatorrhoea are accompanied by weight loss and muscle wasting ascertained by upper arm anthropometry.
- The patient feels very nauseous or has marked indigestion or borborygmus (stomach rumbling) that does not respond to antiemetics or antacids following fat ingestion.

The degree of fat tolerance will vary between patients and needs to be assessed on an individual basis. A detailed diet history from the patient to assess which foods cause symptoms is necessary and advice should be to reduce the intake of these initially. If the patient cannot determine which foods are causing symptoms and the steatorrhoea is severe, then they should initially reduce foods that are high in fat. Steatorrhoea caused by pancreatic exocrine insufficiency can be treated with pancreatic enzyme replacement therapy (see Chapter 7.4.5). Pancre-

atic enzyme replacement therapy is not indicated in biliary steatorrhoea.

Nutritional support

Meeting the nutritional requirements for energy and protein of patients with steatorrhoea remains a priority to maintain or improve nutritional status. Fat intake should only be reduced to individual tolerance. As fat is such a valuable source of energy, a potential energy deficit from fat restriction has to be replaced with an appropriate replacement energy source:

- **Carbohydrates** – complex carbohydrate intake can be increased in patients with a good appetite. Refined carbohydrates such as sugar, sweets and glucose polymers can be useful in patients without diabetes.
- **Medium chain triglycerides (MCTs)** – water soluble and do not require bile salts for emulsification, e.g. Liquigen and MCT Procal.
- **Oral nutritional supplements** are useful, especially juice based sip feeds that contain only minimal fat and are fortified with fat soluble vitamins. Some high protein supplements are also low in fat and well tolerated.

If enteral feeding is required, consideration should be given to the enteral feed's fat source:

- **MCT based feeds** – provide a greater percentage of fat as MCTs. There are a number of feeds available ranging from 1 to 1.5 kcal/mL.
- **Low fat semi elemental feeds** – indicated where steatorrhoea is severe, but have the disadvantage that a high volume is needed to meet nutritional requirements.

Fat soluble vitamins

Patients with overt symptoms of steatorrhoea or chronic steatorrhoea are at risk of developing deficiencies of the fat soluble vitamins (Floreani *et al.*, 2000). Deficiency should be suspected, levels checked and supplemented if necessary. Patients with steatorrhoea without clinical signs of deficiency may benefit from a multivitamin supplement, including fat soluble vitamins. Absorption will be improved with resolution of steatorrhoea (Kennedy & O'Grady, 2002). Current practice regarding fat soluble vitamin screening and supplementation varies throughout the UK liver centres. It is important that dietitians check with their hospital pharmacy which supplements are available and what dosage is recommended.

Hepatorenal syndrome

Hepatorenal syndrome (HRS) is defined as the occurrence of renal failure in a patient with advanced liver disease in the absence of an identifiable cause of renal failure (Arroyo *et al.*, 1996). Often the precipitating factor is a bacterial infection on the background of vasodilatation in the splanchnic arterial bed and cardiac output that is insufficient for the patient's needs. There are two types of HRS.

Type 1 hepatorenal syndrome

This is a rapidly progressive acute renal failure that frequently develops as a result of a precipitating factor for deterioration of liver function together with deterioration of other organ function. Precipitating factors include sepsis, such as spontaneous bacterial peritonitis (SBP), and acute alcoholic hepatitis, although sometimes the identifiable cause for an episode of decompensation is unclear.

Type 2 hepatorenal syndrome

Type 2 occurs in patients with refractory ascites and there is a steady, but moderate, degree of functional renal failure, often with rapid sodium retention. Patients with type 2 HRS may eventually develop type 1 HRS either spontaneously or following a precipitating event such as SBP (Arroyo *et al.*, 1996).

Management

The renal function can often be improved by using vasoconstrictor drugs such as terlipressin to increase arterial pressure (Salerno *et al.*, 2007). Renal replacement therapy may be necessary when the patient becomes severely fluid overloaded or hyperkalaemic, or develops metabolic acidosis. The prognosis of HRS is poor, with an average median survival time of approximately 3 months (Ginès *et al.*, 1993; Ginès & Schrier, 2009).

Fluid management in patients with HRS is of particular importance and close liaison with the MDT is necessary to determine any fluid limitations. Serum potassium levels should be monitored on a daily basis and diet therapy and nutritional support adjusted as is necessary. Patients may be symptomatic of uraemia and antiemetics may be required. Careful consideration of protein intake is necessary and protein may need to be reduced to 1.0–1.2 g/kg of dry body weight if uraemia is problematic. Energy requirements should be calculated as described in the Nutritional assessment section, with the appropriate stress factors added to basal metabolic rate (see Chapter 7.5.1).

Drug–nutrient interactions

The following should be noted:

- Telaprevir – requires 20 g of fat with dose.
- Neomycin – malabsorption of calcium, iron and potassium.
- Metronidazole – avoid alcohol, consider sodium content.
- Furosemide – malabsorption of calcium, magnesium, potassium and zinc.
- Spironolactone – limit alcohol, risk of hyperkalaemia.

7.4.13 Cystic fibrosis

Alison Morton

Key points

- Cystic fibrosis is a multisystem disorder mainly affecting the respiratory and gastrointestinal systems.
- There is a positive association between nutritional status, lung function and survival.
- Patients have increased energy requirements, increased energy losses and often poor oral intake.
- Regular dietetic counselling aims to achieve a good nutritional status by minimising the effects of malabsorption with pancreatic enzyme replacement therapy and optimising nutritional intake.
- With increased longevity, new nutritional challenges occur, including diabetes, disordered eating, osteoporosis, liver disease, renal disease and transplantation.

The first clear description of cystic fibrosis (CF) was in the late 1930s (Andersen, 1938). Dietary management of CF has changed dramatically over the years and optimising nutrition has been integral to the improved life expectancy of patients. The replacement of the traditional low fat diet with a high fat diet in the 1980s and the introduction of acid resistant pancreatic enzyme replacement therapy (PERT) were milestones in management.

Cystic fibrosis is a complex multisystem disorder. Intestinal malabsorption occurs in approximately 90% of patients. In the past, malnutrition, weight loss and poor growth were considered inevitable consequences of disease progression, leading to impaired respiratory muscle function, immunological impairment and respiratory failure. Achieving and maintaining a normal nutritional status and growth is an integral part of modern CF management.

Prevalence

Cystic fibrosis is the most common autosomal recessively inherited disease in the UK, mainly affecting Caucasian. One in 25 people in the UK are carriers of a CF gene mutation (i.e. 2.3 million people) (Lewis, 2000), leading to an incidence of approximately 1 in 2500 births (Dodge *et al.*, 2007). The incidence in non-Caucasians is much lower, and estimated to be 1 in 20000 in ethnic Africans and 1 in 100000 in Oriental populations (Corey *et al.*, 1988). In the UK, approximately 9000 people have CF (Cystic Fibrosis Trust, 2011).

Aetiology

The genetic defect is located on the long arm of chromosome 7 and results in abnormalities in the production

and function of a protein called the cystic fibrosis transmembrane conductance regulator (CFTR). This protein acts as a chloride channel regulating sodium, chloride, bicarbonate and water transport across epithelial cell membranes. The lack of production or reduction of CFTR results in thick mucus secretions that can obstruct small airways, causing fibrosis and bronchiectasis. CFTR is widespread throughout the body and explains why CF is a multisystem condition affecting many organs. The two major systems affected are the respiratory system and the gastrointestinal tract.

Although over 85% of the CF population in the UK share the same genetic defect (p.Phe508del mutation) (Cystic Fibrosis Trust, 2011), >1800 different mutations have been identified (CF Mutation Database, 2011). Different gene mutations result in different levels of disease severity (see Chapter 5.1).

Diagnostic criteria and classification

National newborn screening for CF was introduced in the UK in 2005–2006. Newborn blood spot screening involves a heel prick blood sample being taken from all babies to test for a number of diseases. The screen for CF looks at the concentration of immunoreactive trypsin (IRT), which is raised in neonates with CF. If the IRT is positive, the infant is referred for a sweat test and genetic screening to confirm the diagnosis. An elevated chloride concentration in the sweat test is diagnostic of CF. Cystic fibrosis is usually confirmed by two positive sweat tests or by the identification of two genetic mutations. The gene mutations are determined from a sample of blood or cells from the oral mucosa. Initially, only the four most common mutations are looked for (followed by a 32 mutation panel). Infants presenting with meconium ileus should also have a sweat test and genetic testing.

Most patients are now diagnosed early by newborn screening or following investigation after presenting with meconium ileus. It is important to remember that in people with milder mutations and those born prior to national newborn screening, the diagnosis may be made later in life. Symptoms that are suggestive of CF include:

- Recurrent respiratory symptoms.
- Prolonged diarrhoea and pale, greasy, offensive stools.
- Failure to thrive in children, delayed puberty or undernutrition in adults.
- Male infertility.
- Pancreatitis.
- Rectal prolapse.

Disease process

As already mentioned, the two major systems affected are the respiratory system and the gastrointestinal tract.

Respiratory function

People with CF have chronic and often severe respiratory infections. The presence of viscid mucus in the lungs increases the risk of colonisation by pathogens. Chronic

chest infections cause inflammation and irreversible lung damage, leading to progressive lung disease. Infection and reduction in lung function contribute to the increased energy requirements of these patients. Regular antibiotic therapy, anti-inflammatory drugs and physiotherapy are aimed at preventing lung damage and preserving lung function.

Gastrointestinal function

Abnormal CFTR in the pancreas may cause the exocrine ducts to become obstructed, preventing secretion of pancreatic enzymes and resulting in malabsorption. Approximately 90% of patients in Northern Europe are pancreatic insufficient (Littlewood *et al.*, 2006). Patients with milder mutations are usually pancreatic sufficient. Pancreatic insufficiency results in significant fat malabsorption and steatorrhoea. Clinically relevant symptoms include frequent pale, oily and offensive stools, abdominal pain, poor growth, malnutrition and deficiencies of fat soluble vitamins and essential fatty acids.

Malabsorption in CF is multifactorial with contributory factors including abnormal ion transfer in the gut due to CFTR and altered bile salt composition, motility and transit time (Littlewood *et al.*, 2006). Pancreatic enzyme replacement therapy can be inactivated by increased duodenal acidity due to pancreatic bicarbonate deficiency, which may also result in bile salt precipitation.

Disease consequences

Prognosis

Cystic fibrosis was once a life limiting disease of childhood. Life expectancy, though still reduced, has increased dramatically due to many factors, including specialist centre care, better nutritional support and improved treatment of respiratory infections. Median survival in the UK is currently 34.4 years (Cystic Fibrosis Trust, 2011) and has been predicted to be at least 50 years for children born in 2000 (Dodge *et al.*, 2007). Over half of patients with CF in the UK are 16 years or older (Cystic Fibrosis Trust, 2011).

Impaired energy intake

Poor energy intakes are frequently reported in patients with CF. This may be a consequence of generalised poor appetite worsened by infection related anorexia during pulmonary exacerbations, abdominal pain and gastrooesophageal reflux. As the disease progresses, patients may find it difficult to maximise oral intake due to dyspnoea, early satiety and dry mouth or taste changes due to oxygen or drug therapy. Behavioural factors, including food refusal, eating behaviour problems, depression and disordered eating, may further limit food intake.

Increased energy expenditure

Energy requirements in CF vary greatly, but are largely related to the extent of lung disease and the frequency

and severity of respiratory infections. In addition, some of the medications used to treat respiratory symptoms increase resting energy expenditure.

With increased longevity, new nutritional comorbidities are emerging, including CF related diabetes, renal disease, osteoporosis, arthropathy, pancreatitis, liver disease, renal disease and need for transplantation. Many women with CF also face the nutritional challenge of pregnancy.

Nutritional consequences

Impaired nutrient absorption

Lack of pancreatic enzymes in pancreatic insufficient patients has a devastating effect on nutritional status. Pancreatic enzyme replacement therapy should be started if a patient has two CFTR mutations associated with pancreatic insufficiency. In addition, patients who present with obvious symptoms of malabsorption should commence PERT as soon as diagnosis of CF is made. Pancreatic insufficiency should always be confirmed by measuring faecal pancreatic elastase (FPE) (Borowitz *et al.*, 2009). If clinical symptoms of malabsorption are absent, measurement of FPE to establish pancreatic status should be undertaken and PERT should only be commenced if pancreatic insufficiency is diagnosed (Littlewood *et al.*, 2006; Borowitz *et al.*, 2009). Some patients may have persistent difficulties controlling malabsorption despite optimal PERT, and they experience increased losses of protein, fat and fat soluble nutrients in the stool. The undigested fat may bind other minerals and lead to increased excretion.

Fat soluble vitamins

Biochemical evidence of deficiencies of fat soluble vitamins (vitamins A, D, E and K) is found early in infants diagnosed with CF by newborn screening (Sokol *et al.*, 1989; Neville & Ranganathan, 2009). All pancreatic insufficient patients require daily supplementation with these vitamins. Pancreatic sufficient patients should be individually assessed and advised.

Vitamin A

The major consequence of vitamin A deficiency is ocular, with abnormal dark adaptation (night blindness) and xerophthalmia being reported (Petersen *et al.*, 1968). Asymptomatic conjunctival xerosis with abnormal dark adaptation despite vitamin A supplementation has been reported (Huet *et al.*, 1997). Although such problems are rare, subclinical deficiency may be common and the consequence of this is difficult to assess but may be significant.

Mild or subclinical vitamin A deficiency may also impair the integrity of the respiratory epithelium (McCullough *et al.*, 1999). Loss of ciliated cells and increased mucus secretion make bacteria more likely to adhere to the surface and colonise the lungs (Chandra, 1988; Biesalski & Nohr, 2003). Linking subclinical vitamin A deficiency and lung function is difficult. However, there is a correla-

tion between increased number of respiratory exacerbations (Hakim *et al.*, 2007) and reduced/poorer lung function (Aird *et al.*, 2006).

Beta-carotene has antioxidant properties, acting as a free radical scavenger that may prevent or slow oxidative damage in the lung. There is currently insufficient evidence to recommend routine supplementation with beta-carotene.

Vitamin E

Severe vitamin E deficiency is rare in modern CF care, but historically has been associated with neurological degeneration (Sitrin *et al.*, 1987), haemolytic anaemia (Wilfond *et al.*, 1994) and decreased cognitive function (Koscik *et al.*, 2005). Vitamin E is also an important antioxidant, helping to protect the lungs from damage during the inflammatory response to infection.

Vitamin D

Vitamin D is classically considered for its role in calcium absorption, metabolism and bone mineralisation. There is increasing recognition of the non-skeletal roles of vitamin D in muscle function, diabetes, cardiovascular disease, innate immunity and some forms of cancer (Holick & Chen, 2008). Overt vitamin D deficiency in CF is rare, but both rickets and osteomalacia have been reported (Scott *et al.*, 1977; Elkin *et al.*, 2002). Subclinical vitamin D status may be significant in the context of health outcomes rather than overt deficiency (Maqbool & Stallings, 2008). There is a lack of consensus on the optimal vitamin D level in CF to maintain bone health. A level of 20 ng/mL (50 nmol/L) has been recommended in the European Cystic Fibrosis Mineralisation Guidelines (Sermet-Gaudelus *et al.*, 2011), whilst the recommendation from the UK Cystic Fibrosis Trust (2007) and North American CF Bone Health Consensus Statements (Aris *et al.*, 2005) is a minimum level of 30 ng/mL (75 nmol/L).

Low or suboptimal vitamin D levels are common in most paediatric and adult patients with CF despite routine and high dose supplementation (Grey *et al.*, 2008; Green *et al.*, 2010). Although studies do not report a direct link between low vitamin D levels and low bone density, it is likely that low vitamin D levels do play a role in low bone mineral density in CF (Hall *et al.*, 2010).

Vitamin D status may also be linked to lung function, with evidence of a positive association between lung function and serum vitamin D levels in children (Green *et al.*, 2008) and adults (Stephenson *et al.*, 2007) being reported.

Vitamin K

Severe vitamin K deficiency prolongs bleeding time. In CF, vitamin K deficiency has been associated with coagulopathies, including haematomas, intracerebral haemorrhage and severe life threatening bleeds (Hamid & Khan, 2007; McPhail, 2010). Subclinical vitamin K deficiency is common in pancreatic insufficient patients and universal in patients with CF related liver disease (Rashid *et al.*, 1999) from an early age (Conway *et al.*, 2005). This level

of deficiency has been linked to reduced bone mineral density (Conway *et al.*, 2005).

Nutritional assessment

Individual assessment is essential to determine the interventions that are both appropriate and acceptable for each patient. Factors that need to be considered include age, clinical condition, nutritional status and history, pancreatic status, nutritional requirements, family circumstances, financial constraints, religious and cultural dietary beliefs, and food preferences and tolerances.

Anthropometry

This should include:

- Accurate measurement of weight, height, body mass index (BMI) (and head circumference in young children) should be undertaken at every clinic visit and plotted on the appropriate percentile chart in children (Sermet-Gaudelus *et al.*, 2011) (see Chapter 3.8).
- Assessment of pubertal stage in peripubertal children until puberty is complete (Sermet-Gaudelus *et al.*, 2011).
- Assessment of bone mineral density and body composition by dual energy X ray absorptiometry should be performed from around 8–10 years of age (Sermet-Gaudelus *et al.*, 2011).

Biochemistry

The following should be assessed:

- Annual assessment of fat soluble vitamin status (A, D, and E) (Borowitz *et al.*, 2009).
 - Assessment of vitamin A status in CF is difficult as both retinol and retinol binding protein (RBP) decrease during the acute phase response to infection; RBP is depressed in plasma zinc deficiency. Vitamin A status should be measured at a time of clinical stability together with RBP, plasma zinc and a positive acute phase protein such as C-reactive protein (CRP) (Stephenson & Gildengorin, 2000).
 - Serum or plasma vitamin E levels are used to assess vitamin E status. Vitamin E circulates in the blood bound to lipoproteins and therefore status is more accurately assessed using vitamin E to total lipid ratio in patients with high or low lipid levels.
 - Plasma 25 hydroxyvitamin D is the conventional marker of status. There should be awareness of seasonal variation in levels.
 - Assessment of vitamin K deficiency is difficult in CF as prothrombin time is not a very sensitive marker of vitamin K status. Protein or prothrombin induced by vitamin K absence or antagonism (PIVKA II) and undercarboxylated osteocalcin are more sensitive markers that are mostly used in research.
- Urea and electrolytes, liver function, full blood count at least annually.
- Annual oral glucose tolerance test.

Annual dietary assessment

The dietary assessment should include:

- Dietary intake including appetite.
- Contribution of oral supplements and enteral tube feeds.
- Knowledge and titration of PERT, including assessment of symptoms of malabsorption.
- Fat soluble vitamin supplementation.
- Use of non-prescribed supplements.
- Control of CF related diabetes.
- Other aspects of food intake, e.g. feeding behaviour problems or body image.

Nutritional management

Nutritional status has important prognostic significance, with a positive association being seen between body weight, height, BMI and survival (Corey *et al.*, 1988; Beker *et al.*, 2001; Stern *et al.*, 2008) and between nutritional status and lung function (Pedreira *et al.*, 2005). A diet that achieves and maintains good nutritional status is required to ensure that growth is optimised, resistance to infection maximised and outcome improved. Current recommendations state children and adolescents should achieve a BMI at or above the 50th percentile, adult females at or above 22 kg/m² and adult males at or above 23 kg/m² (Stallings *et al.*, 2008). Good nutrition education from diagnosis is needed in order to achieve these aims. Optimal PERT is an essential part of this education.

Pancreatic enzyme replacement therapy

The main aims of PERT are to:

- Enable a normal to high fat diet to be eaten.
- Control the signs and symptoms associated with maldigestion and malabsorption.
- Promote and maintain normal nutritional status and growth.
- Achieve optimal fat soluble vitamin and essential fatty acid status.

Types of enzyme preparations

The enteric coated, acid resistant microsphere and mini microsphere preparations are significantly more effective than the traditional powder based and enteric coated tablet formulations in correcting fat malabsorption. The enzymes are protected from inactivation by gastric acid and only release their activity when the pH rises above 5.5 in the duodenum, resulting in improved fat and nitrogen absorption (Littlewood *et al.*, 2006). In the USA, generic and prescribable proprietary PERT are available. Generic products should not be used in CF care (Borowitz *et al.*, 2009).

High strength enzyme preparations

High strength enzyme preparations became available in the mid 1980s. They were developed to improve PERT by

reducing the number of capsules taken per meal. In the early 1990s, there were concerns about the safety of some high strength preparations, which were linked with the development of fibrosing colonopathy (colonic strictures), particularly in children (Smyth *et al.*, 1994). As a result, the UK Committee on the Safety of Medicines (CSM, 1995) advised that:

- The total dose of lipase should not usually exceed 10 000 units/kg of body weight/day.
- Pancrease HL® and Nutrizym 22® should *not* be used in children with CF under 15 years.

It has been suggested that fibrosing colonopathy may be more closely related to the amount of methacrylic acid copolymer (MAC) coating in some preparations (Prescott & Bakowski, 1999). Consequently, in the UK the high strength preparations Creon 25000® and Creon 40000®, which do not contain MAC, are used for many adults and some paediatric patients. Changing to Creon 40000® has been shown to reduce total daily lipase dose with improvement in symptoms of malabsorption and an increase in body weight (Littlewood *et al.*, 2011). Patients must receive detailed advice and assessment before they change their enzyme preparation.

Enzyme dosage and administration

To date, there are no studies in infants, children or adults to determine the optimal dose of PERT or whether there is a dose–response association (Stallings *et al.*, 2008; Borowitz *et al.*, 2009). Enzyme therapy is based on historical recommendations and consensus statements published after the reports of fibrosing colonopathy. Enzyme dose should be based on fat intake and taken with all fat containing food and drinks consumed. There is large individual variation in the enzyme dosage required, but it should not usually exceed 10 000 units of lipase/kg/day. In the USA, dosage is calculated as units of lipase/kg/meal (Stallings *et al.*, 2008; Borowitz *et al.*, 2009). The recommendations are:

- Newborn infants – 2000–5000 units of lipase/120 mL of feed and with increasing feed volume, no greater than 2500 units of lipase/kg of body weight/feed.
- Younger than 4 years – 1000 units of lipase/kg of body weight/meal.
- Older than 4 years – 500 units of lipase/kg of body weight/meal, with a recommended maximum of 2500 units of lipase/kg of body weight/meal.

Alternatively, the dose can be based on the fat content of meals and snacks. Australian guidelines recommend doses of 500–1000 units of lipase/g of fat for an infant and 500–4000 units of lipase/g of fat for a child or adult. The lowest effective dose of enzyme should be used (Anthony *et al.*, 1999). Patients requiring >10 000 units of lipase/kg/day need assessment and further investigation.

Individual requirements for pancreatic enzymes depend upon a number of factors including:

- Degree of residual pancreatic function.
- Pharmacological characteristics of the preparation.

- Dissolution characteristics of the preparation – some patients may respond better to one product than another.
- Timing and method of enzyme administration.
- Fat content of the diet.
- Factors affecting pH within the gastrointestinal tract.

It is important to stress to patients that any dose adjustment should be dietetically or medically supervised to avoid inappropriate or excessive enzyme intake.

The method of enzyme administration is important. Microspheres must not be chewed or crushed as this will reduce enzyme efficacy. Microspheres should not be sprinkled on, or mixed with, the whole meal as exposure to hot food or food with a pH of >5.5 reduces efficacy. For infants and young children, microspheres should be mixed with a small amount of expressed breast milk, infant formula or a little semi solid food, e.g. apple purée, and given from a teaspoon with feeds. The capsules should be swallowed whole as early as possible; most children will manage this by 3–4 years of age (Sinaasappel *et al.*, 2002). Enzymes are best given in a divided dose with half before the meal and half during it, though this may vary between individuals and adjustment of the timing of administration may be necessary. Guidelines on PERT are summarised in Box 7.4.5.

Box 7.4.5 Guidelines for the use of pancreatic enzyme preparations

Enzymes should be taken with all fat containing meals, snacks and drinks

Enzymes should be taken with every meal, with ideally half the dosage being taken before and half during the meal

If meals last longer than 30 minutes, enzymes should be taken before, during and towards the end of the meal

The dose should be varied according to the fat content of food with extra enzymes taken with higher fat meals and snacks

Enzymes should not be taken with fat free snacks and drinks, e.g. soft drinks, fruit drinks, fruit, glucose polymer supplements, boiled or jelly sweets

Capsules containing enteric coated tablets or microspheres should be swallowed without being chewed (to avoid losing their effectiveness). For young children, or if swallowing is difficult, the capsules should be opened and the contents mixed with a little soft food or fruit purée and administered from a teaspoon. Granules must not be sprinkled over a meal. Under medical/dietetic supervision, the enzyme dose should be increased (e.g. by one to two capsules) if the stools are fatty, loose, offensive or frequent.

Adequate hydration is important, especially with higher strength enzyme preparations

Enzymes should be taken with all fat containing enteral tube feeds; they should not be added to the feed or routinely administered via the feeding tube.

Monitoring the effectiveness

Even with modern PERT, maldigestion and malabsorption may still occur. Factors that may contribute to inadequate PERT include:

- *Patients failing to recognise or report steatorrhea* – patients tend to become accustomed to what is a normal stool pattern for them and may fail to recognise symptoms of steatorrhea and that their enzyme dosage needs adjusting.
- *Inadequate education* – knowledge of enzyme titration according to dietary fat intake and timing of administration may be inadequate.
- *Lack of regular dietetic assessment* – regular assessment PERT is essential to achieve an appropriate balance between PERT and food intake (Littlewood *et al.*, 2006).
- *Non-adherence with guidance given* – patients may not take their PERT or adhere to advice given in respect of timing or dosage. People with CF should be encouraged to openly discuss any adherence issues they experience.
- *Other factors*, including low duodenal pH, e.g. due to excessive production of gastric acid or reduced pancreatic bicarbonate, can result in inappropriate release or inactivation of enzymes. Practical considerations such as enzyme storage and stock rotation are also important as enzymes denature over time.

The efficacy of PERT can be assessed by measurement of faecal fat and calculation of the coefficient of fat absorption or stool weight, although these are now mainly used as research tools in the UK. Faecal fat microscopy and steatocrit may also be used. More usually, effectiveness of PERT is monitored by assessment of nutritional status or growth and abdominal symptoms.

Nutritional requirements

Energy

The dietary energy requirements of people with CF are usually higher than those recommended for the general population. This is due to the increased energy expenditure resulting from inflammation and infection, and continuing energy losses due to malabsorption. It has generally been accepted that energy requirements for people with CF are 120–150% of the estimated average requirement for energy. More recently, energy intakes of 110–200% of those of the healthy population have been recommended (Stallings *et al.*, 2008). However, as a result of early diagnosis by newborn screening and the variability of disease expression, individual energy needs will vary greatly.

Protein

Protein requirements have not been well researched but it is generally accepted that the protein intake should be higher than average to compensate for loss of nitrogen in the faeces and sputum.

Fat

Fat restriction to reduce symptoms of steatorrhea is not necessary with modern PERT. Restricting fat compromises energy intake, fat soluble vitamins and essential fatty status. It is usually recommended that fat provide 35–40% of energy, although in practice studies shows that this is difficult to achieve, with intakes of between 30% and 35% more likely (White *et al.*, 2004). With increasing longevity and a greater variability in clinical condition, consideration needs to be given to dietary composition in relation to long term health. A relatively high fat intake should not solely be achieved by an excessive intake of saturated fat. Fats such as spreads and oils can be derived from monounsaturated sources. Olive oil can be drizzled on food to increase the energy density, instead of deep frying. Patients should be individually assessed and advised, and if overweight or obese, fat restriction would be appropriate. The dietary intake of the n-3 fatty acids should be as recommended for the general population. More research is required to determine the efficacy of intervention with pharmacological doses. The use of medium chain triglyceride oil preparations in cooking is no longer recommended as it is unpalatable and PERT is still needed to aid absorption.

Dietary fibre

The need for an energy dense diet means that the intake of fibre may be low. Recommendations for fibre intake in CF are limited. Further research in this area is needed due to the complexity of the CF gut.

Water soluble vitamins

Routine supplementation is unnecessary; diets should be assessed individually for dietary adequacy. Parenteral vitamin B₁₂ may be required following resection of the terminal ileum for meconium ileus (Sinaasappel *et al.*, 2002).

Fat soluble vitamins

Vitamins A, D, E and K should be provided from diagnosis onwards in pancreatic insufficient patients. Vitamin requirements vary, so regimens often combine a multivitamin preparation (or A and D capsules), an additional vitamin E supplement and a vitamin K supplement. To achieve adequate plasma levels of vitamin D, an additional separate vitamin D supplement is usually necessary to avoid vitamin A toxicity. Specific CF vitamin supplements are available, but often still need the addition of extra vitamin D and K.

Annual monitoring of plasma levels is recommended as a minimum for all patients. It is essential that all patients are individually assessed and that doses are adjusted depending on plasma levels. Pancreatic sufficient patients often require vitamin D supplementation to achieve adequate levels. Hypervitaminosis A and E have been reported in patients with CF following lung transplantation (Stephenson *et al.*, 2005) and higher plasma levels have

also been found in children and young adults compared with the general population (Huang *et al.*, 2006; Maqbool *et al.*, 2008). Deficiency is the primary concern in patients with CF, but with early diagnosis and improved treatments the consequence of high levels is also of concern.

Current recommendations for fat soluble vitamin supplementation in pancreatic insufficient patients are based on historical data and vary between countries (Sinaasappel *et al.*, 2002; Borowitz *et al.*, 2009; Sermet-Gaudelus *et al.*, 2010). The recommended starting doses per day are:

- **Vitamin A:**
 - Younger than 1 year: 1500 IU (455 µg) (Sermet-Gaudelus *et al.*, 2010).
 - Older than 1 year: 4000–10 000 IU (1200–3000 µg) (Cystic Fibrosis Trust Nutrition Working Group, 2002).
- **Vitamin E:**
 - Younger than 1 year: 10–50 mg.
 - Older than 1 year: 50–100 mg.
 - Adults: 100–200 mg (Cystic Fibrosis Trust Working Group, 2002).
- **Vitamin D:**
 - Younger than 1 year: 1000–2000 IU (25–50 µg).
 - Older than 1 year and adults: 1000–5000 IU (25–125 µg/day) (Sermet-Gaudelus *et al.*, 2011).
- **Vitamin K:**
 - Younger than 2 years: 300 µg/kg rounded to the nearest mg.
 - 2–7 years: 5 mg.
 - Older than 7 years: 10 mg (Cystic Fibrosis Trust, 2007).

Minerals and trace elements

Sodium

Cystic fibrosis results in an abnormally high concentration of sodium excreted in sweat, and sodium losses are increased in conditions causing excessive sweating, e.g. hot climates or extreme physical exertion. In these circumstances salt supplements are recommended.

Iron

Iron deficiency is common and increases with age (von Drygalski & Biller, 2008). It is related to disease severity, malabsorption and loss of iron in the sputum rather than dietary deficiency and there should be awareness of increased iron requirements.

Calcium

Reduced bone mineral density is common in adolescents and adults with CF. Negative calcium balance may be due to malabsorption, increased endogenous faecal losses of calcium (Schulze *et al.*, 2003) and vitamin D insufficiency. Attention to calcium intakes is important and supplementation may be necessary.

To meet the nutritional requirements of people with CF, a staged approach to nutritional intervention is rec-

ommended (Cystic Fibrosis Trust Working Group, 2002; Sinaasappel *et al.*, 2002).

First stage intervention: improving food and energy intake

Increasing meal frequency, choosing energy dense foods and using food fortification measures are the first stage of intervention. In the USA, behavioural intervention in conjunction with nutritional counselling is recommended in children 1–12 years of age to promote weight gain (Stallings *et al.*, 2008).

Second stage intervention: supplements

There should always be an emphasis on the use of normal food rather than supplements, but if intake remains poor despite encouraging a high energy diet, oral dietary supplements are the next stage of intervention. These include modular products, e.g. glucose polymer liquids and powders, fat emulsions or mixed fat and carbohydrate products, or sip feeds supplements. A systematic review (Smyth & Walters, 2000) highlighted the lack of evidence of efficacy for oral energy supplements in CF. However, this does not mean they are not of benefit to individuals.

A multicentre study of short term use of a high fat milk based supplement demonstrated significant weight gain in individuals with CF (Skypala *et al.*, 1998). In contrast, a small study comparing the use of oral supplements with dietary counselling over a 3-month period found no significant change in energy intake or nutritional status in either group (Kalnins *et al.*, 2005). In adults however, supplements have been shown to be effective in significantly increasing energy intakes when compared with diet alone (White *et al.*, 2004). A large, longer term randomised controlled trial of oral supplements in mild to moderately malnourished children with CF found no improvement in nutritional status or other clinical outcomes. It concluded '*oral supplements should not be regarded as an essential part of the management of mildly malnourished children with CF*' (Poustie *et al.*, 2006). However, the study did not consider the use of supplements in adult patients, the short term use in acute situations, in more severely malnourished individuals or those with end stage lung disease, or the impact of energy only supplements.

A CF specialist dietitian should carefully monitor the introduction, use and efficacy of supplements. The type and quantity of supplement recommended depends on the patient's age, preference and requirements. Supplements should be taken in addition to normal food to increase total daily energy intake and should not replace a meal. Ideally, they should be given with a snack between meals, as a drink after meals or later in the evening. Altering the type or flavour of the supplement may help to prevent taste fatigue.

Third stage intervention: enteral tube feeding

Enteral tube feeding is considered when dietary education, behavioural intervention and oral nutritional supplementation fail to improve nutritional status. Enteral

tube feeds can be provided via a fine bore nasogastric tube, gastrostomy or, more rarely, jejunostomy. In the UK, approximately 20% of patients are gastrostomy fed and 5% nasogastrically fed (Cystic Fibrosis Trust, 2011). There is no evidence to show which route is most effective; the choice depends largely on patient preference and the likely duration of supplementary feeding. Early reports of enteral tube feeding were limited by methodology, sample size and duration, but weight gain or improved growth was reported. Few studies have assessed efficacy of long term tube feeding in different age groups and a Cochrane Systematic Review reports no randomised controlled trials (Conway *et al.*, 1999).

Earlier intervention is associated with improved outcomes (Walker & Gozal, 1998; Oliver *et al.*, 2004). Gastrostomy feeding in children with mild respiratory compromise was shown to improve weight and height gain during the first year of feeding; this stabilised during the second year but no improvement in respiratory function was reported (Truby *et al.*, 2009). Studies do report stabilisation of lung function (Efrati *et al.*, 2006), but nutritional support may need to be long term in order for there to be significant benefits.

Enteral tube feeds are usually administered overnight and provide 30 – 50% of total energy requirements (Steinkamp & von der Hardt, 1994). Some patients may receive a greater proportion of their energy needs, if oral intake is particularly poor or nutritional requirements are exceptionally high.

Feed formulae

Whole protein, polymeric feeds are usually well tolerated in patients with CF. Adults and older children are usually given energy dense feeds (1.5–2 kcal/mL); however, occasionally a specialist high fat feed formulated for people with pulmonary disease may be used or additional fat added as a fat emulsion to increase fat intake and energy density. This allows smaller volumes of feed to be administered. Young children are usually given paediatric whole protein feeds providing 1.5 kcal/mL. Infants should be given a high energy infant formula.

Low fat elemental feeds are not usually required for patients with CF, although they are still widely used in some countries. It has been hypothesised that they are better absorbed in people with CF, but they are expensive, have a high osmolality and generally a lower energy density than whole protein feeds. Elemental formulae with a high proportion of MCT fat have been shown to improve weight gain even in patients with advanced lung disease (Williams *et al.*, 1999). There remains controversy as to whether these preparations require PERT, with one study showing that their absorption may be equivalent to that of whole protein formulae with enzyme replacement (Erskine *et al.*, 1998). Clinical practice varies and optimum feed type has yet to be established and may vary with clinical situations.

Enzyme administration during enteral tube feeds

Pancreatic enzymes are usually administered orally at the beginning of the feed and sometimes during or at the end

of the feed. Enzyme requirements are dependent on the rate of infusion, type and fat content of the feed. As the feed is continuously infused over a long period, lower doses of enzymes are required than would be normally administered with a meal containing the equivalent fat content. Increased gastric lipase production (Balasubramanian *et al.*, 1992) may also help fat digestion from continuously infused feeds. The method of enzyme administration varies between countries and the optimum pattern of enzyme administration remains to be established.

Problems with enteral tube feeding

Complications with tube feeding in CF are rare. Nasogastric tube displacement, although uncommon may occur due to coughing, vomiting or physiotherapy. Nocturnal hyperglycaemia requiring insulin therapy may occur in patients given night time feeds (Smith *et al.*, 1994). Careful monitoring of blood glucose levels are essential when feeds are introduced and periodically thereafter.

Parenteral nutrition

Parenteral nutritional support is not recommended for long term treatment, but may be useful for short term support when enteral tube feeding is contraindicated, e.g. after major gastrointestinal surgery or in severely ill patients awaiting transplantation (Sinaasappel *et al.*, 2002).

Special considerations

Infants

The success of National Newborn Screening Programmes for Cystic Fibrosis depends on the appropriate management of identified infants and improved outcomes. Management of the newborn infant diagnosed through newborn screening is, for many, different from the nutritional management of those diagnosed symptomatically. The focus is on maintaining health by preventing nutritional and respiratory complications (Borowitz *et al.*, 2009; Sermet-Gaudelus *et al.*, 2010). There is a lack of well designed clinical trials to support practice, hence management has developed mainly through clinical experience. In 2009, the North American CF Foundation developed recommendations for management of infants based on a systematic review of the evidence and expert opinion (Borowitz *et al.*, 2009). In 2010, The European Cystic Fibrosis Society Neonatal Screening Group used a modified Delphi Methodology to provide a consensus framework for the management of screened infants (Sermet-Gaudelus *et al.*, 2010).

Most infants will thrive if given breast milk or standard infant formula. Breast feeding should be encouraged. The routine use of hydrolysed formula is not recommended but it may be required for infants who have undergone surgical resection for meconium ileus or those with malabsorption unrelated to CF, e.g. cow's milk protein intolerance (Borowitz *et al.*, 2009; Sermet-Gaudelus *et al.*, 2010).

If fat malabsorption is adequately controlled, infants will usually thrive on energy intakes of 100–130 kcal/kg of body weight/day. If the infant is failing to thrive despite optimising their milk intake and PERT, energy intakes should be adapted to achieve normal growth. A higher energy infant formula should be prescribed. Alternatively, breast fed infants may be offered top up formula feeds.

All pancreatic insufficient infants should be commenced on PERT at a starting dose of 2000 units of lipase/100 mL of standard formula or breast feed. The dose should be increased if there are symptoms of malabsorption or inadequate weight gain, but the lipase intake should be kept below 10 000 units/kg of body weight/day (Sermet-Gaudelus *et al.*, 2010). Enteric coated microspheres/mini microspheres should be given on a teaspoon with all feeds mixed with a small amount of the infant's milk or a small amount of fruit purée. They should not be added directly to a bottle of feed.

Gastro-oesophageal reflux is common in infants with CF (Heine *et al.*, 1998). Unless treated, this may compromise growth and exacerbate respiratory symptoms. Treatments include thickening feeds, and using a prethickened infant formula and motility stimulants.

All pancreatic insufficient infants should be given fat soluble vitamin supplements in liquid form from diagnosis. Sodium chloride supplementation should be considered for all infants with CF and increased during hot weather or other times of increased salt loss, e.g. diarrhoea (Sermet-Gaudelus *et al.*, 2010).

Weaning foods should be introduced between 4 and 6 months of age, and a normal weaning diet should be established by the end of the first year. The dose of PERT should be adjusted to the fat content of the weaning food. Commercial weaning foods are low in salt and sugar; therefore, dietary advice is essential at this time.

Preconception

There is little evidence upon which to base recommendations for nutritional management of women with CF in the preconceptional period, during pregnancy and post partum. Recommendations are therefore largely based on the recommendations for the non-CF population, but are adapted and modified to incorporate knowledge and understanding of the nutritional requirements of CF. As nutritional status plays an integral role in the preconceptional period and throughout pregnancy, a thorough preconceptional nutritional assessment should be performed (Edenborough *et al.*, 2008). This should include:

- Assessment of weight, height and BMI.
- Dietary assessment and review of PERT, gastrointestinal symptoms and absorption.
- Assessment of glycaemic status by oral glucose tolerance test in the non-diabetic patient or optimising glycaemic control in those with CFRD.
- Increasing awareness of food safety issues.
- Measurement of fasting plasma vitamins A, D and E, and review of vitamin therapy (including non-prescription items).

Care should be taken to avoid excessive intakes of vitamin A because of the risk of teratogenicity. In practice, supplemental vitamin A is usually continued at a dose of <10 000 IU/day and plasma levels are closely monitored (Edenborough *et al.*, 2008).

Pregnancy

Due to increased life expectancy, pregnancy in women with CF is becoming increasingly common. Pregnancy is generally well tolerated although there are increased risks to both mother and child. Prepregnancy lung function and nutritional status are important predictors of foetal and maternal outcome (Lau *et al.*, 2011). Poor foetal outcomes have been associated with a poor prepregnancy weight (BMI <20 kg/m²) and a forced expiratory volume of <60% predicted values (Lau *et al.*, 2011). A high incidence of gestational diabetes has been reported (Lau *et al.*, 2011). Early participation of the MDT is essential to ensure an optimal outcome.

During pregnancy the primary nutritional aims are to:

- Achieve adequate weight gain – regular monitoring of nutritional status and weight gain is essential to optimise outcomes. Oral nutritional supplements or enteral tube feeding may be required.
- Minimise the impact of pregnancy related problems on food intake. Due to hormonal and mechanical changes in pregnancy, gastro-oesophageal reflux, heartburn, nausea, vomiting and constipation may occur more frequently. These can be more common in women with CF and can reduce food intake. Guidance on ways to alleviate these problems and improve nutrient intake are essential.

Successful breastfeeding in mothers with CF has been achieved (Gilljam *et al.*, 2000). Breast feeding increases maternal nutritional requirements. Individual advice about infant feeding according to the mother's clinical condition and circumstances should be given. Many drugs pass into breast milk and therefore may be contraindicated during pregnancy and lactation, or are contraindicated during breastfeeding (Edenborough *et al.*, 2008).

Cystic fibrosis related diabetes

Cystic fibrosis related diabetes (CFRD) is the most common comorbidity in people with CF and its prevalence increases with age. Data suggest 2% of children, 19% of adolescents and 40–50% of adults have CFRD (Moran *et al.*, 2009). Few people with CF have normal glucose tolerance and CFRD is part of a spectrum of glucose tolerance abnormalities (Moran *et al.*, 2010). Cystic fibrosis related diabetes shares features of type 1 and type 2 diabetes, but it is a distinct entity.

Cystic fibrosis related diabetes is primarily caused by insulin deficiency due to loss of insulin secreting beta cells within the islets of Langerhans. The causes are multifactorial (Nathan *et al.*, 2010), but obstruction of pancreatic ducts by abnormal, thick secretions causing progressive pancreatic damage is a major factor. In CF

there is also an element of insulin resistance (Hardin *et al.*, 2001).

Cystic fibrosis related diabetes mainly occurs in people with the most severe CF mutations that are associated with exocrine pancreatic insufficiency (Adler *et al.*, 2008). The importance of early detection, treatment and optimising control of CFRD cannot be overemphasised as CFRD is associated with deterioration in respiratory function and clinical and nutritional status, and increased morbidity and mortality. The negative impact of diabetes on nutritional decline appears to be more pronounced in those who are still growing during the prediabetic years (White *et al.*, 2009). Optimising control of CFRD is important as microvascular complications are increasingly recognised.

Patients with CFRD should be managed by a specialised multidisciplinary team with expertise in diabetes and CF. Oral diabetic agents are not as effective as insulin in improving nutritional and metabolic outcomes, and therefore insulin is the medical treatment of choice (Moran *et al.*, 2010).

The primary aim of treatment in CFRD is to maintain nutritional status. The maintenance of a diet high in energy, fat, protein and sodium to compensate for losses is important. This is in contrast to the management of type 1 and type 2 diabetes. The diet should also be healthy and well balanced. Some substitution of saturated fat with monounsaturated fat is advisable as long as this does not compromise total energy intake. The use of carbohydrate counting to guide insulin therapy can help to optimise control. If a patient with CFRD is malnourished, overnight enteral feeding with an adjusted insulin regimen can be given. All patients should receive individualised dietary review and advice at the time of the diagnosis of CFRD. Awareness of emerging issues, such as obesity, in some people with CF make this even more important. In a minority of patients, it may be necessary to consider energy restriction.

Cystic fibrosis associated liver disease

Cystic fibrosis associated liver disease (CFLD) occurs in 27–35% of patients and 5–10% will develop multilobular cirrhosis in the first decade of life. Portal hypertension often develops during the second decade and liver failure usually occurs in adulthood (Debray *et al.*, 2011). Liver disease may make it increasingly difficult to meet nutritional requirements. It further exacerbates malnutrition by increasing steatorrhoea, which is often unresponsive to increasing enzyme dosage. Oral intake may be reduced as a result of nausea, early satiety resulting from an enlarged liver and/or spleen and abdominal pain.

Nutritional support is an essential part of treatment of CFLD and optimising nutritional status is the primary goal. Close monitoring is essential, especially if the disease progresses to end stage ascites and encephalopathy. Nasogastric feeding may be required to meet energy requirements. Gastrostomy feeding is not recommended in advanced liver disease because of the risk of a gastric haemorrhage (Debray *et al.*, 2011).

Distal intestinal obstruction syndrome

Distal intestinal obstruction syndrome (DIOS) is caused by the accumulation of viscous mucus and intestinal contents that completely or partially block the intestinal lumen. Incomplete or impending DIOS is common and patients present with a short history of abdominal pain and/or distension and a faecal mass in the ileocaecum. Complete DIOS is less common, but in addition to the features of incomplete DIOS, the patient has a complete intestinal obstruction with vomiting of bilious material and/or fluid levels in the small intestine on abdominal X ray (Columbo *et al.*, 2011).

Risk factors for DIOS include a severe genotype associated with pancreatic insufficiency (though it does occur in pancreatic sufficient patients), a history of meconium ileus at birth, previous episodes of DIOS, poorly controlled fat absorption, dehydration and CFRD (Columbo *et al.*, 2011).

Both DIOS and incomplete DIOS are initially managed medically. Assessment of PERT and absorption should be undertaken, including knowledge of enzyme titration, timing and adherence with therapy. Advice about increasing fluid intake is also important. The role of increasing fibre intake is unclear (van der Doef *et al.*, 2011) and this should only be done with caution.

Lung or heart and lung transplantation

Lung transplantation has become a viable option for CF patients with end stage lung disease. Some may be declined for transplantation based on low weight as poor nutritional status is linked with increased mortality and poorer outcomes. Most patients will have had intensive nutritional input throughout life that makes nutritional management in the pretransplant period challenging or existing interventions more complex. Maximising oral intake can be difficult due to anorexia, dyspnoea, early satiety, dry mouth or taste changes due to oxygen or drug therapy. In addition, exceptionally high energy requirements, metabolic consequences of respiratory failure, presence of CFRD and need for non-invasive ventilation in some can make enteral tube feeding challenging. Some centres may use appetite stimulants at this time.

In the early postoperative period, a clean diet is usually recommended with awareness of food safety issues. Restoring and maintaining optimal nutritional status is a priority. In the long term, other nutritional problems may emerge, e.g. diabetes due to corticosteroids and other forms of immunosuppression, hyperlipidaemia, high plasma levels of the fat soluble vitamins, osteoporosis and renal failure.

Cystic fibrosis related low bone mineral density

Reduced bone mineral density is common in adolescents and adults with CF. Bone mineral content (BMC) and bone mineral density (BMD) are usually normal in well nourished children with good lung function, though several cross-sectional studies report low BMC/BMD in some children with CF (Sermet-Gaudelus *et al.*, 2011).

The aetiology of bone disease in CF is multifactorial. Risk factors include poor nutritional status and reduced lean body mass, vitamins D and K deficiency, poor calcium intake and negative calcium balance, delayed puberty, infection, inflammation, the use of corticosteroids (Sermet-Gaudelus *et al.*, 2011) and abnormal CFTR expression in bone cells (Haworth, 2010).

Bone mineral acquisition in childhood, especially during the pubertal growth spurt in adolescence, is a major determinant of adult bone health. It is therefore essential to implement prevention strategies and from diagnosis to address issues relating to bone health in people with CF. Dietetic management should focus on:

- Optimising weight gain and growth with particular attention to lean body mass.
- Optimising vitamin D and vitamin K status and supplementation protocols.
- Optimising skeletal accretion of calcium by attention to calcium intakes and supplementation where necessary.
- Encouraging appropriate physical activity with the support of the CF specialist physiotherapist.

Drug–nutrient interactions

The following should be noted:

- Vitamin A – hepatotoxic drugs, retinoids, tetracycline antibiotics, warfarin.
- Vitamin E – anticoagulant drugs, ciclosporin, warfarin.
- Vitamin K – warfarin.
- Calcium – bisphosphonates, quinolone antibiotics, tetracycline antibiotics.

7.5

Renal disorders

7.5.1 Acute and chronic kidney disease

Sue Perry and George Hartley

Additional contributors: Christel Lyell and Nicki Ruddock

Key points

- Nutrition has a central role in the management of acute and chronic kidney disease.
- This includes reduction of cardiovascular disease risk, monitoring of nutritional status and limiting the effects of reduced kidney function.
- Several dietary elements usually require consideration and may change over time.

Nutritional treatment has a central role in the management of both acute and chronic kidney disease. Dietetic interventions to reduce cardiovascular disease risk are important in early chronic kidney disease (CKD). Regular monitoring of nutritional status and limiting the effects of reduced kidney function are important considerations in acute kidney injury, progressive chronic kidney disease and established renal failure. As several dietary elements usually require consideration, an appreciation of both medical and dietetic aspects of care is required in order to produce appropriate and individualised dietetic treatment plans.

Each kidney contains up to 1 million nephrons; each nephron being a filtering unit of tiny blood vessels (glomeruli) attached to a tubule. The glomeruli normally filter approximately 100 mL of plasma/min. The rate at which this takes place is known as the glomerular filtration rate (GFR). The kidney has a number of important functions, including the excretion of waste products, electrolyte homeostasis (including sodium, potassium, calcium and phosphate), regulation of fluid, acid–base balance and metabolic processes; and hormone production, including erythropoietin and renin, and activation of vitamin D.

The glomerular filtration rate is the best index of overall kidney function. In clinical practice, serum creatinine

levels are used to monitor renal function as levels rise with decreasing GFR. However, the kidneys have a large functional reserve and serum creatinine levels only rise when at least 50% of kidney function is lost (GFR <60 mL/min). Creatinine is also subject to non-renal influences, which make it insufficiently sensitive to detect moderate CKD on its own. Therefore, an estimate of GFR (eGFR) is made using an equation that corrects for some of the more significant influences, such as age and weight. Serum creatinine also correlates with muscle mass and in those with increased muscle mass, GFR will be underestimated; in those with reduced muscle mass GFR will be overestimated.

Definitions of kidney disease

Chronic kidney disease is defined as either kidney damage (proteinuria, haematuria or anatomical abnormality) or GFR of <60 mL/min/1.73 m² present on at least two occasions for 3 or more months (Department of Health, 2004). Established renal failure (ERF) is an irreversible, long term condition for which regular dialysis treatment or transplantation is required if the individual is to survive (Department of Health, 2004). It is also known as end stage renal disease (ESRD) or kidney failure.

Acute kidney injury (AKI) is a sudden decline in kidney function, often occurring over hours or days. Many people make a complete recovery from AKI, but some are left with CKD or even ERF (Department of Health, 2004). It has now replaced the older term acute renal failure.

Chronic kidney disease

Diagnostic criteria and classification

In 2002 a classification system for CKD based on GFR was adopted worldwide (Table 7.5.1). There has been debate about the implications of having a reduced GFR, but the evidence suggests that if eGFR is <60 mL/min, there is an increased risk of mortality. As a normal GFR is approximately 100 mL/min, reduced kidney function can be explained to patients as a percentage of normal function (Table 7.5.1).

Aetiology

There is extensive clinical evidence that diabetes, hypertension and the presence of proteinuria are risk factors for progression of CKD (NICE, 2008a). The most common causes are shown in Table 7.5.2. Despite the wide range of causes of kidney injury, once there is a significant loss of nephrons, the result is a common pathway character-

ised by hypertension, proteinuria and progressive decline in GFR (Metcalf, 2007). The remaining nephrons develop glomerular hypertension and the GFR increases for each nephron (called hyperfiltration). This causes increased

Table 7.5.1 Stages of chronic kidney disease [source: National Clinical Guideline Centre (NCGC) 2008. Reproduced with permission of the National Clinical Guideline Centre]

Stage*	GFR (mL/min/1.73 m ²)	Description
1	≥90	Normal or increased GFR, with other evidence of kidney damage
2	60–89	Slight decrease in GFR, with other evidence of kidney damage
3A	45–59	Moderate decrease in GFR with or without other evidence of kidney damage
3B	30–44	
4	15–29	Severe decrease in GFR, with or without other evidence of kidney damage
5	<15	Established renal failure

*Use the suffix (p) to denote the presence of proteinuria when staging chronic kidney disease.
GFR, glomerular filtration rate.

Table 7.5.2 Common causes of chronic kidney disease (CKD)

Cause	Mechanism	Comments
Diabetic nephropathy	Part of systemic microvascular disease of diabetes The first sign is microalbuminuria, which presents when eGFR is normal	The leading cause of renal failure in the UK Approx. 50% of those with diabetes have proteinuria and reduced kidney function and 75% of these have hypertension
Hypertensive atherosclerosis	Long standing high blood pressure	A common cause of established renal failure
Renal artery stenosis	Often caused by atherosclerosis	May cause hypertension
Heart failure	Age, diabetes and smoking can all cause ischaemic heart disease and renal artery stenosis	Heart failure is frequently found with CKD
Obesity	A risk factor for CKD, acting partly through a link with diabetes and hypertension More likely to develop glomerular hyperfiltration and albuminuria	Obesity often causes hypertension, insulin resistance and CVD There is a strong association between abdominal obesity, metabolic syndrome and CKD
Polycystic kidney disease	Multiple cysts that gradually enlarge	Inherited, often causes established renal failure in middle age
Reflux nephropathy	Reflux of urine from the bladder back up the ureters	Often inherited
Glomerular disease	Many different types of glomerulonephritis May occur in children	Usually diagnosed by renal biopsy Usually proteinuria and/or haematuria.
Nephrotic syndrome	Caused by a wide range of glomerular diseases	Combination of heavy proteinuria, low serum albumin and fluid retention Often severe hyperlipidaemia
Microscopic vasculitis	Inflammation of the small blood vessels	For example, Wegener's granulomatosis
Myeloma	Bence Jones proteins precipitate in kidney tubules	Can cause acute kidney injury or CKD

CVD, cardiovascular disease; eGFR, estimated glomerular filtration rate.

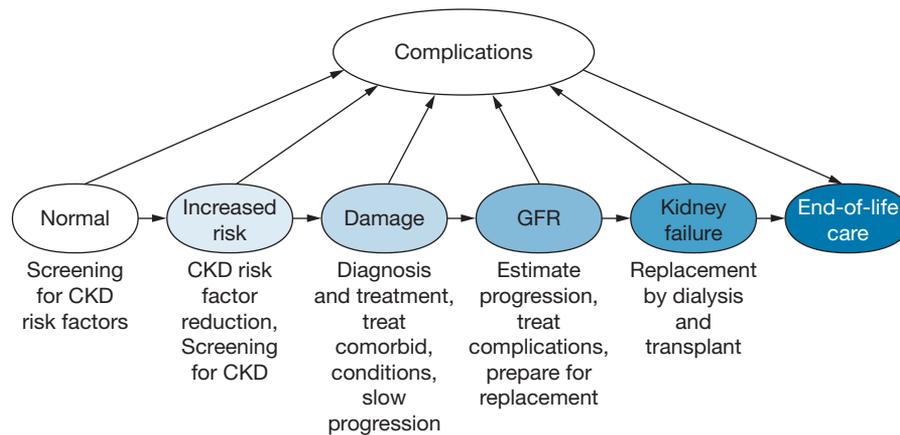

Figure 7.5.1 Overall health approach to chronic kidney disease (CKD) (source: Levey *et al.* 2007. Reproduced with permission of Macmillan Publishers Ltd)

glomerular permeability and excessive protein filtration. In addition, hypertension and hyperlipidaemia stimulate the abnormal production of growth factors and cytokines that, together with the glomerular hypertension, eventually lead to interstitial fibrosis and glomerulosclerosis (Metcalf, 2007). The rate of decline of kidney function is highly variable and depends on the cause as well as its treatment.

Nephrotic syndrome

This is the term for a group of symptoms, including proteinuria (>3.5 g/day), low blood protein levels (serum albumin <25 g/L), severe hyperlipidaemia and peripheral oedema. A wide range of glomerular diseases causes it and, although relatively rare in adults, it is important as it has serious complications. All patients should be referred to a nephrologist for further investigations, which often includes a renal biopsy (Hull & Goldsmith, 2008).

Disease consequences

The two main outcomes of CKD are loss of kidney function, leading to complications and kidney failure, and the development of cardiovascular disease (CVD) (National Kidney Foundation, 2002). There is a far greater likelihood of death from CVD than from CKD progression through to ERF. The cardiovascular risk is more apparent in younger patients, e.g. a 35-year-old man on dialysis has the same risk of a cardiovascular death as an 80-year old not on dialysis (National Kidney Foundation, 2009a). Although CKD becomes more prevalent with increasing age, people aged over 70 years who have a stable eGFR between 45 and 59 mL/min and no other evidence of kidney damage are unlikely to experience complications related to CKD. The greatest risks are to those who have progressive CKD.

For those who do reach ERF and start renal replacement therapy (RRT), mortality rates are very high. Five-year mortality rates in incident RRT patients are 50–73% for patients aged over 65 years of age (Zoccali *et al.*,

2010). The main cause of death continues to be CVD, although in addition to hypertension and hypercholesterolaemia, the presence of CKD mineral and bone disorders, and anaemia may complicate and accelerate vascular disease (Renal Association, 2010c,d).

Public health aspects and prevention

There has been a recent change in focus in renal medicine from the treatment of patients with ERF to the earlier identification and prevention of CKD. One reason is that CKD is more common than previously thought and is increasing in prevalence in the UK and around the world. The prevalence of CKD (stages 3–5) in the UK is approximately 8.5% (Stevens *et al.*, 2007). Another reason is the significant number of late referrals to nephrology services; currently between 20% and 30% of all referrals. These patients do not have the opportunity for preparation and choice regarding dialysis or conservative management. Late referrals also have a higher morbidity and mortality and a poorer quality of life on dialysis (Renal Association, 2009a). Dialysis treatment is expensive; 1–2% of the total NHS budget is spent on treating patients with ERF, although they comprise only 0.05% of the population (NHS Kidney Care, 2010).

In order to identify and treat patients earlier, Kidney Disease: Improving Global Outcomes (KDIGO) (Levey *et al.*, 2007) and the National Institute for Health and Care Excellence (NICE, 2008a) have recommended an overall health approach (Figure 7.5.1) and an integrated care strategy involving public awareness, professional education, policy influence, and improved care delivery systems, all underpinned by research.

This approach should help to identify those who:

- Have, or are at risk of developing, CKD.
- Need intervention to minimise CVD risk, and what that intervention should be.
- Will develop progressive kidney disease and/or complications of kidney disease, and how they can be managed.
- Need referral for specialist kidney care.

Table 7.5.3 Complications seen in chronic kidney disease (CKD) stages 3–5

Cardiovascular disease	Main cause of death in patients with CKD
Hypertension	Both a cause and a complication of CKD Elevated blood pressure is associated with a faster rate of decline in GFR
Dyslipidaemia	Very prevalent in CKD and is influenced by renal function and degree of proteinuria
Increased risk of diabetic complications	Poor glycaemic control is associated with faster rate of decline in GFR Increased risk of CVD and retinopathy in patients with both diabetes and CKD
CKD mineral and bone disorder	Caused by alterations in the control mechanisms for calcium and phosphorus homeostasis
Protein energy wasting	Serum albumin, dietary protein and energy intake may fall as GFR falls
Metabolic acidosis	Kidneys become unable to remove sufficient H ⁺ ions and serum bicarbonate levels fall
Hyperkalaemia	Can be life threatening, especially if K ⁺ >6.5 mmol/L
Fluid (and sodium) retention	Can be a problem, e.g. in nephrotic syndrome
Anaemia	Kidneys become unable to produce sufficient erythropoietin as GFR falls
Gout	Blood urate level rises as GFR falls, leading to increased risk of gout
Depression	As with any chronic disease, CKD may be associated with depression, especially if there are physical symptoms

GFR, glomerular filtration rate; CVD, cardiovascular disease.

Nutritional consequences and complications

Most of the complications seen in CKD have nutritional causes or consequences. They are most often seen in stages 4 and 5, although some may start to develop during stage 3 (Table 7.5.3).

Protein energy wasting

Undernutrition is a major problem in those with CKD stages 4 and 5, and is currently known as protein energy wasting (PEW) (Fouque *et al.*, 2008). It is associated with increased morbidity, greater healthcare requirements and reduced functional ability. Its onset and severity is related to GFR; below 60 mL/min there is a higher prevalence of impaired nutritional status, which ranges from 28% to 48% in patients with CKD stage 4 (Heimbürger *et al.*, 2000). Also, from this stage, serum cholesterol and serum albumin levels begin to decline. Low serum albumin is a strong predictor of adverse outcomes. However, the association between albumin and poor survival mainly reflects its associations with inflammation, comorbidity and fluid overload, as well as poor nutrition (Kaysen *et al.*, 2002; Jones, 2001).

Although one cause of protein energy wasting is an inadequate diet, other causes include chronic inflammation, intercurrent catabolic illnesses and metabolic acidosis (Stenvinkel *et al.*, 2000). Several criteria should be considered to diagnose PEW; these are biochemical criteria (including low albumin and/or cholesterol levels), low body weight, weight loss, reduced total body fat, loss of muscle mass and low protein or energy intakes. Additional measures of nutrition and inflammation, e.g. C-reactive protein (CRP), are also helpful (Fouque *et al.*, 2008).

Low protein and energy intakes become more common as GFR falls, particularly when GFR falls below 25 mL/min (Ikizler *et al.*, 1995). Uraemia is common at this stage,

causing nausea, lethargy and taste changes, which adversely affect appetite. Metabolic acidosis (low plasma bicarbonate) is also common at this stage, and is associated with increased protein catabolism and reduced synthesis of serum albumin (de Brito-Ashurst *et al.*, 2009).

Patients who are undernourished when they start dialysis are four times as likely to die within 2 years than those who are well nourished. Once dialysis starts, appetite and nutritional status usually improve. However, a gradual but significant decline is often seen in all nutritional markers with increasing years on dialysis (Chumlea *et al.*, 2003). A low percentage of body fat at the start of dialysis and fat loss over time have been found to be independently associated with higher mortality. In particular, a body mass index (BMI) of >23 kg/m² is associated with reduced mortality in dialysis patients and a BMI of <20 kg/m² is associated with the highest mortality rates (Leavey *et al.*, 2001).

Dyslipidaemia

Plasma triglycerides start to increase early in CKD and show the highest concentrations in those with nephrotic syndrome and in those receiving dialysis (NICE, 2008b). However, there is often a reduction of total, high density (HDL) and low density lipoprotein (LDL) cholesterol concentrations when GFR falls below 60 mL/min. Chronic inflammation is a common feature in dialysis patients and may cause PEW and progressive atherosclerotic CVD (Stenvinkel *et al.*, 2002). Surprisingly, on dialysis, obesity, hypercholesterolaemia and hypertension appear to be protective features that are associated with increased survival; this is known as reverse epidemiology. It appears that the adverse effects of PEW and inflammation are more dominant than traditional risk factors (Kalantar-Zadeh *et al.*, 2003). However, being overweight is not an advantage to patients with renal transplants, in

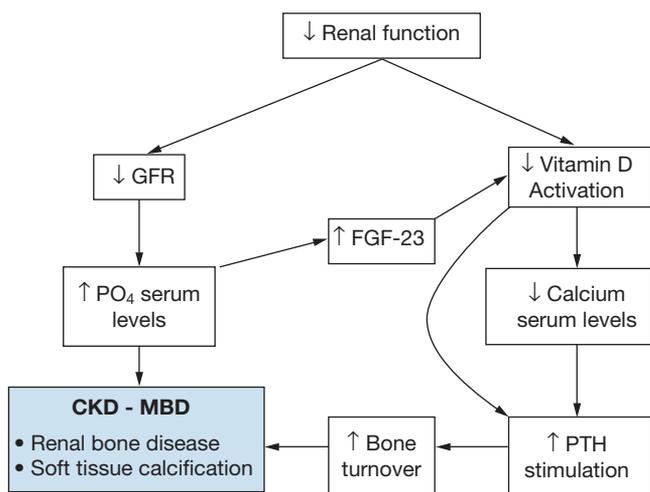

Figure 7.5.2 Bone and mineral metabolism in renal disease
PTH, parathyroid hormone; GFR, glomerular filtration rate; FGF-23, fibroblast growth factor-23; CKD-MBD, chronic kidney disease–mineral and bone disorder

whom obesity and hyperlipidaemia are quite common (Kalantar-Zadeh *et al.*, 2003).

Mineral and bone disorders

As CKD advances and kidney function declines, mineral homeostasis becomes progressively impaired. Hyperphosphataemia develops from CKD stage 4 onwards as the excretion of phosphate can no longer match dietary intake. Serum levels of the phosphate regulating fibroblast growth factor 23 increase as GFR falls. This inhibits the activation of vitamin D by the kidneys (Gutierrez *et al.*, 2005), resulting in low circulating levels and hypocalcaemia. This stimulates parathyroid hormone (PTH) production by the parathyroid gland, a condition known as secondary hyperparathyroidism. Without therapeutic intervention, CKD mineral and bone disorder (CKD-MBD) will develop (Figure 7.5.2). This is a relatively new term that defines the complex syndrome that includes both renal bone disease (renal osteodystrophy) and soft tissue calcification (Kidney Disease: Improving Global Outcomes CKD-MBD Work Group, 2009).

The condition is associated with adverse outcomes. Traditionally, hyperphosphataemia and secondary hyperparathyroidism have been associated with increased morbidity from renal osteodystrophy, skeletal and bone pain, and fractures. However, more recently, it has also been associated with increased mortality in dialysis patients (Block *et al.*, 2004; Covic *et al.*, 2009) and concerns over vascular calcification (especially involving the coronary arteries) have increased. Observational studies show that coronary artery calcification is common and extensive in dialysis patients (Goodman *et al.*, 2000; Guerin *et al.*, 2000) and that it is linked to an increase in cardiovascular mortality rates (London *et al.*, 2003).

Hyperkalaemia

Hyperkalaemia has potentially adverse cardiac effects, causing arrhythmias and cardiac arrest. It can be life

threatening, especially if potassium levels are above 6.5 mmol/L. Patients may present with associated muscle weakness and feel generally unwell, or they may be completely asymptomatic. Hyperkalaemia is rarely caused by renal dysfunction alone until GFR has fallen below 30 mL/min (Bakris *et al.*, 2000). Some patients may develop hyperkalaemia as early as CKD stage 3, usually as a result of the side effects of taking medications such as angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). If serum potassium levels are 6.0 mmol/L or above, and other drugs that promote hyperkalaemia have been discontinued, ACE inhibitors or ARBs should be stopped (NICE, 2008). At this point, other causes of raised potassium levels, including diet, should be investigated. These include:

- Potassium sparing diuretics, e.g. spironolactone.
- Metabolic acidosis.
- Uncontrolled diabetes or insulin deficiency.
- Catabolism as a result of trauma or weight loss.
- Constipation.
- Dehydration.
- Sudden decline in residual renal function.
- Blood transfusion.
- Haemolysed blood sample.

Controlling serum potassium is particularly important during haemodialysis.

Fluid and sodium retention

As kidney function deteriorates, the ability to excrete excess sodium is reduced and sodium retention can occur. Serum sodium level is a poor indicator of sodium status, but a better indicator of hydration. Hence, hypernatraemia and hyponatraemia usually indicate dehydration and overhydration respectively. Excess dietary sodium leads to increased thirst, which can compound problems of fluid balance.

Fluid retention is unlikely in early CKD, apart from conditions such as nephrotic syndrome when fluid retention is common. When urine output is reduced and fluid intake exceeds output, fluid accumulates in the body, causing hypertension and oedema. Severe fluid overload, or even mild overload in individuals with heart failure, can result in pulmonary oedema and shortness of breath. Although ankle swelling can indicate fluid overload, patients may have several excess litres of fluid without oedema being clinically apparent. Acute changes in body weight usually represent changes in fluid balance in these patients. Clinical examination of the patient by medical staff or bioelectrical impedance is useful in determining fluid status.

Nutritional assessment

Nutritional monitoring should take place regularly in all patients with progressive CKD from stage 4 onwards, as PEW becomes more frequent. The use of a variety of nutritional markers is recommended (Fouque *et al.*, 2008; Renal Association, 2010b). A full nutritional assessment should include the following.

Anthropometry

As a minimum, (oedema free) body weight, percentage weight change and BMI should be measured. Careful interpretation of weight change is important; a history of oedema or rapid weight loss or gain may be due to changes in fluid status. Attention should be paid to dry weight for those with oedema or on dialysis. For longitudinal measures, the use of skinfold callipers to assess mid upper arm circumference (MUAC) and triceps skinfold thickness are useful. In haemodialysis patients, high MUAC is a predictor of greater survival, particularly in those with low BMIs (Noori *et al.*, 2010).

Biochemistry

Serum cholesterol, urea, creatinine, eGFR, potassium, phosphate, serum albumin, CRP, urinary protein loss and fluid status should be measured (Renal Association, 2010b; 2011b).

Clinical history

This should include appetite, comorbidities and presence of oedema.

Dietary intake

A 24-hour recall or 3-day food diary should be used to assess dietary protein and energy intake.

Functional assessment

This assesses the ability to conduct the activities of daily living. Measurement of handgrip strength has been found to correlate well with lean body mass (Heimbürger *et al.*, 2000).

Subjective global assessment

This has been validated for use in patients with ERF and is linked with adverse outcomes and mortality (Enia *et al.*, 1993). In dialysis patients, the 7-point subjective global assessment may validly distinguish different degrees of PEW associated with increasing risks of mortality (de Mutsert *et al.*, 2009). In addition, social and economic factors should be taken into account, e.g. patients living alone can be at greater nutritional risk.

Ideal body weight (IBW) should be calculated from height and ideal BMI, which would be:

- 20 kg/m² for those with an actual BMI of <20 kg/m².
- 25 kg/m² for those with a BMI >25 kg/m².
- Actual BMI if 20–25 kg/m² (Renal Association, 2010b).

Management stages 1–3

Clinical management

The medical management of CKD mainly consists of interventions to slow the rate of decline in renal function and limit any associated complications, such as CVD. In addition, specific treatments such as immunosuppressive therapy for autoimmune disorders may also be required. The medical management of all patients with CKD stages 1–3 should include reduction of all modifiable cardiovascular risk factors including:

- Strict control of hypertension (blood pressure 140/90 mmHg; 130/80 mmHg in diabetes mellitus).
- Tight glucose control in diabetes (HbA_{1c} 48–58 mmol/mol).
- Achieving a healthy weight (BMI 20–25 kg/m²).
- Lipid lowering (total cholesterol <4 mmol/L; LDL <2 mmol/L).
- Smoking cessation if appropriate.
- Regular exercise.
- Limiting alcohol intake (men <3 units/day; women <2 units/day).

Of these, the interventions that have been found to be particularly effective at reducing the progression of CKD are strict blood pressure control, use of ACE inhibitors or ARBs, strict glucose control in diabetes and the use of statins (National Kidney Foundation, 2002).

Uncomplicated CKD stages 1–3 can usually be managed in primary care. Serum creatinine and eGFR should be regularly monitored, as should proteinuria and albuminuria. Most people in this category will not develop ERF during their lifetime and information provided should concentrate on cardiovascular risk reduction. However, those with progressive CKD, such as rapidly declining eGFR (>5 mL/min/year) or significant proteinuria are likely to require nephrology referral.

Hypertension

There is strong evidence that lowering blood pressure reduces cardiovascular risk and progression of CKD (NICE, 2008a). Interventions that inhibit the renin angiotensin aldosterone system activity, such as ACE inhibitors or ARBs, provide cardiovascular and renal protection (together with a reduction in proteinuria) (National Kidney Foundation, 2002). However, they can cause hyperkalaemia.

Hyperlipidaemia

Statins have been found to be safe and effective at reducing cardiovascular mortality. They should be considered for primary prevention in all CKD stages 1–4 and transplant patients with a >20% risk of CVD over 10 years (Renal Association, 2010c).

Alcohol, smoking and exercise

Clients should be encouraged to exercise, achieve a healthy weight and stop smoking to reduce CVD risk (NICE, 2008b; Renal Association, 2010c). A low or moderate alcohol intake is recommended as heavy alcohol intake is linked with hypertension.

Dietetic management

Most of the evidence for dietetic treatment of early CKD comes from research that focused on dietetic interventions to reduce CVD. There is evidence that good glycaemic control in those with diabetes, weight reduction in those with obesity and nutritional support in those with PEW improve patient outcomes. The main aims of dietetic treatment in these patients are to reduce the progression both of CKD and CVD.

Protein

Protein restriction has been found to help alleviate uraemic symptoms and was thought to possibly delay the progression of renal disease (Bennett *et al.*, 1983), although evidence for this is inconclusive (Levey *et al.*, 1996; NICE, 2008a). The risk of developing PEW in patients following low protein diets has led to concern about their use (Kopple *et al.*, 1997). There is insufficient evidence to recommend an optimal protein level, but it is generally considered that dietary protein intake should not be <0.8g/kg/day (SIGN, 2008).

Energy

Energy requirements are not increased. As many patients with early CKD have diabetes or hypertension and obesity is common, weight management is an important part of the dietetic treatment. Those with a high risk of or with CVD should modify their fat intake and include oily fish once a week in their diet.

Obesity

Weight loss programmes have been shown to reduce proteinuria, blood pressure and rate of renal decline (Navaneethan *et al.*, 2009). Weight reduction also has beneficial effects on associated risk factors, including insulin resistance, diabetes, dyslipidaemia and left ventricular hypertrophy (Abrass, 2004). Patients who may benefit the most from weight loss are those with a BMI of greater 30 kg/m², type 2 diabetes or an increased waist circumference (regardless of BMI) (Teta, 2010; Renal Association, 2010b).

Modifications of lifestyle, physical activity and individualised dietary advice tailored to food preferences are initial measures. For sustainable weight loss, a gradual decrease in energy intake by 500–600 kcal/day is recommended. This should be accompanied by close dietetic supervision to avoid exacerbation of uraemic symptoms (Teta, 2010). High protein diets for weight loss may be unsafe for patients with CKD. Protein intake exceeding 20% of total energy is not recommended, because of the potential detrimental effects on kidney function (Friedman, 2004). Pharmacological measures are generally unsafe, except for orlistat, which has been used with some success. Bariatric surgery may help in severe obesity (see Chapter 7.13.3).

Diabetes

Strict glycaemic control has been found to both delay the onset and slow the progression of microvascular complications in type 1 diabetes [Diabetes Control and Complications Trial (DCCT) Research Group, 1993]. In type 2 diabetes, improved glycaemic control appears to provide a similar benefit.

Sodium

Advice to reduce dietary salt intake to <6g/day has been shown to achieve a modest reduction in blood pressure in those with hypertension and in those with diabetes (Suckling *et al.*, 2010). The Dietary Approach to Stop Hypertension Sodium (DASH) trials showed that increas-

ing fruit and vegetable, wholegrain and fish intake, and a low salt diet combined with lower intakes of fat, saturated fats, sugar and red meat led to lower blood pressures compared with a control group. However, this trial did not include adults with CKD. Due to the potential for increased potassium and phosphate levels, patients with CKD may not be able to adhere to the DASH diet, although the principle of salt reduction is still recommended (SIGN, 2008) (see Chapter 7.14.4).

Given the impact of sodium reduction on blood pressure, the current recommended intake of salt is 6g (100mmol of sodium)/day (Renal Association, 2011b). Most dietary sodium consumed is from salt added to processed food and patients may need help in how to interpret the varying information on food labels. A small amount of salt may be used in cooking, but no extra salt should be added at the table. Herbs and spices should be encouraged, but salt substitutes should be avoided due to their potassium content (SIGN, 2008).

Infrequently, some patients with later stages of CKD lose excessive amounts of sodium in the urine. Dietary sodium intake in these individuals should not be restricted as they may become salt and fluid depleted.

Fluid

Most patients do not need to change from the usual recommendation and an adequate fluid intake should be encouraged to promote excretion of waste products. Some may need a higher fluid intake, such as those with kidney stones or those with a salt losing enteropathy. However, those with a tendency to fluid retention, such as those with nephrotic syndrome, may need to limit both their salt and fluid intakes (see CKD stage 5 (haemodialysis) for further information).

Potassium

Dietary potassium should not be restricted only in those with raised serum levels, as many foods containing potassium are required for a healthy balanced diet. Both dietary restrictions and serum potassium levels should be regularly monitored (NICE, 2008) (see CKD stage 4 for further information).

Phosphate

Dietary intake of phosphate is rarely limited at this stage of CKD.

Nephrotic syndrome

Traditionally, high protein diets have been advocated to correct for urinary protein losses. However, studies have demonstrated that a high protein diet was ineffective in correcting hypoalbuminaemia (Mansy *et al.*, 1989). Moreover, the increased protein intake tends to further increase proteinuria, whereas low protein diets (<0.8g/kg/day) have a slight antiproteinuric effect (Giordano *et al.*, 2001). However, as muscle wasting can be a problem in these patients, a low protein diet is not recommended. In practice, a dietary protein intake of 0.8–1g/kg of IBW/day is suggested. Dietary management of nephrotic syndrome requires the consideration of the following:

- Obesity – careful assessment is essential due to generalised oedema.
- Lipids, including lipid lowering drugs and a cardioprotective diet.
- A diet containing 100 mmol of sodium (<6 g of salt)/day will help to minimise hypertension and fluid overload.
- Fluid may need to be restricted (together with salt restriction) when gross oedema is present.
- Dietary protein intake should be limited to 0.8–1.0 g/kg of IBW.
- Ensure adequate energy intake during periods of acute deterioration.

Management of stage 4

Clinical management

In addition to the reduction of modifiable cardiovascular risk factors, treatment of renal anaemia, metabolic acidosis and CKD–MBD become an important part of management. Nephrology reviews usually include measurement of eGFR, haemoglobin, calcium, phosphate, potassium, bicarbonate and PTH. Ideally, these patients should be managed in a dedicated clinic by a multidisciplinary team (Renal Association, 2009a).

Patients with progressive CKD should also be offered an appropriate education programme aimed at improving their understanding of their condition and the treatment options; RRT (haemodialysis, peritoneal dialysis or a transplant) or conservative care (NICE, 2008a; Renal Association, 2009a). It can take up to 1 year to prepare fully for RRT, but this programme should enable a planned start using an established access (such as a fistula for haemodialysis or a peritoneal dialysis catheter) or by pre-emptive renal transplantation.

Renal anaemia

Treatment is with iron and erythropoiesis stimulating agents (ESAs) as required, with regular monitoring of both serum ferritin and haemoglobin levels.

Metabolic acidosis

Sodium bicarbonate supplementation is recommended to correct metabolic acidosis. This may also help to

reduce protein catabolism and retard the progression of CKD (de Brito-Ashurst *et al.*, 2009).

Mineral and bone disorder

Management of CKD–MBD involves the correction of biochemistry by limiting dietary phosphate together with the use of various agents, including phosphate binders, vitamin D compounds and calcimimetics. In some cases, surgical removal of the parathyroid glands may be required. It can be difficult to achieve an effective combination of different therapies, and frequent monitoring of blood levels and adjustments may be required. To help achieve adequate phosphate control, phosphate binders may be required in addition to any dietary restriction. These work by limiting the absorption of phosphate from the gastrointestinal tract. Although they are used in patients with CKD stage 4, most of the evidence regarding their effectiveness comes from their use in patients on dialysis. Both calcium carbonate (Slatapolsky *et al.*, 1986) and calcium acetate (Schiller *et al.*, 1989) have been used as phosphate binders. They are inexpensive and, compared to non-calcium containing binders, are relatively well tolerated (Navaneethan *et al.*, 2011), but there are concerns that their use is associated with vascular calcification (Goodman *et al.*, 2000; Guerin *et al.*, 2000; London *et al.*, 2003). Newer agents such as sevelamer hydrochloride/carbonate and lanthanum carbonate are significantly more expensive, but offer the potential advantage of being calcium free. In practice, a mixture of both calcium and non-calcium containing binders are used, but care should be taken to avoid high calcium levels and to limit the intake of calcium from phosphate binders (National Kidney Foundation, 2003).

Alfacalcidol is an active vitamin D analogue that is also used in the management of CKD–MBD. It can be effective at suppressing PTH levels, but it also promotes calcium and phosphate absorption, leading to an increase in their serum levels. Careful biochemical monitoring is therefore required, and its use balanced against other effects (Table 7.5.4). Where PTH levels remain high, tertiary hyperparathyroidism has developed. Treatment involves either a parathyroidectomy or cinacalcet therapy. Cinacalcet is a calcimimetic agent that increases the sensitivity of calcium sensing receptors in the parathyroid gland, thereby inhibiting PTH secretion. It is expensive and NICE

Table 7.5.4 Recommended bone biochemistry levels in chronic kidney disease

	Serum phosphate (mmol/L)	Serum calcium* (mmol/L)	Parathyroid hormone (PTH)
CKD 3–5 patients (not on dialysis)	0.9–1.5	Kept within normal reference range	Consider treatment where levels are progressively increasing and remain persistently higher than upper reference limit
Dialysis patients (stage 5D)	1.1–1.7	2.1–2.5	Between two and nine times upper limit of normal Marked changes in levels in either direction within range should prompt initiation or change in therapy

*Adjusted for albumin concentration.

(2007) currently recommends that cinacalcet be reserved for individuals in whom surgery is contraindicated.

Dietetic management

The aim is to promote a healthy well balanced diet, taking into account the nutritional treatment of comorbidities. Other factors, particularly the monitoring of both serum electrolyte levels and nutritional status, become more important in order to provide appropriate and timely dietetic advice.

By CKD stage 4, complications such as fluid and electrolyte imbalance, metabolic acidosis, anaemia and uraemia are common. Though these have an adverse effect on nutrition, wellbeing and blood levels can vary greatly between individuals. Some patients experience hyperkalaemia with mild renal impairment, whilst others will maintain normal levels even in advanced disease. Careful review of each patient is required. Dietary recommendations depend on biochemistry, normal dietary intake, comorbidities and nutritional status.

The National Institute for Health and Care Excellence (NICE, 2008a) recommends that where dietary intervention is indicated, the risks and benefits of dietary protein restriction should be discussed within the context of education, detailed dietary assessment and supervision. In addition, those with progressive CKD should be offered dietary advice concerning potassium, phosphate, protein, calorie and salt intake. Any dietary changes also need to consider other dietary restrictions a person might be following. It is important to consider the overall nutritional adequacy of the diet, bearing in mind that a restrictive diet may increase the risk of PEW.

Protein

As with earlier stages of CKD, there is debate as to the optimal level of protein intake. High protein intakes are associated with high phosphate intakes as foods that contain protein usually contain phosphate. Due to the prevalence of hyperphosphataemia, it is advisable to avoid high protein intakes and to aim for a protein intake of 0.75–1.0 g/kg of IBW (SIGN, 2008; Renal Association, 2010b). A higher protein intake may also increase metabolic acidosis. As uraemia becomes more likely at this stage, protein intake may decline and should be regularly monitored.

Energy

Energy expenditure is similar to that of healthy individuals (Monteen *et al.*, 1986). An intake of 35 kcal/kg/day should be adequate for most patients (Kopple *et al.*, 1986), but 30 kcal/kg may be more appropriate in those over 60 years of age when energy expenditure is reduced. However, it is important to ensure an adequate energy intake in order to prevent negative nitrogen balance and weight loss. Careful interpretation of weight change is important, as a history of oedema or rapid weight change may be due to changes in fluid status.

Sodium and fluid

A daily sodium intake of 100 mmol/day (6 g of salt) is recommended at this stage for most patients. However,

sodium bicarbonate given to correct acidosis may also contribute significantly to sodium intake. Only patients with resistant oedema (such as those with nephrotic syndrome or heart failure) are likely to need advice regarding both sodium and fluid intake. If required, the fluid allowance is usually between 500 and 1000 mL/day plus the previous day's (24-hour) urine output.

Potassium

Hyperkalaemia becomes increasingly common as GFR falls. Dietetic advice to treat hyperkalaemia can allow ACE inhibitors or ARBs to be continued, facilitating the optimal treatment of hypertension and proteinuria (NICE, 2008a). However, as potassium levels at the lower end of normal are not advisable, it is important to ensure that the diet is not too restrictive. The lowest mortality risk may be between 4.1 and 5.5 mmol/L (Korgaonkar *et al.*, 2010). The aim of a low potassium diet is to control serum potassium levels within an acceptable range whilst encouraging a well balanced diet. The level of potassium restriction should be individualised according to dietary intake, blood levels and medical treatment, but intakes of approximately 1 mmol/kg of IBW may be required. In practice, this involves limiting or avoiding those foods with high potassium content. Non-essential foods should be limited or avoided first, e.g. coffee and chocolate. Fruit, vegetables and potatoes contain significant amounts of potassium, as do meat, fish and milk, but as the latter are important components of most diets, they should not be restricted unnecessarily. Cooking methods may need to be adapted, e.g. boiling potatoes and vegetables lowers their potassium content. There is evidence that some people have been found to have low serum vitamin C levels on a low potassium diet (Pollock *et al.*, 2005). Nowadays, people should be able to consume up to five 80-g portions of fruit and vegetables daily, but should also be provided with appropriate education on limiting or avoiding those that are particularly high sources of potassium, e.g. bananas and dried fruit.

Patients with diabetes should be advised that pure fruit juice, milk or chocolate are not the best treatment for hypoglycaemia when following a low potassium diet. Table 7.5.5 gives an example of a first line low potassium diet that could be used until personalised dietary advice can be provided. The skill of the dietitian is in limiting those foods that are high in potassium and have the least nutritional value, whilst considering patient preference and nutritional adequacy.

Phosphate

Hyperphosphataemia becomes increasingly common when GFR falls below 40 mL/min. A low phosphate diet is an important part of its treatment, although phosphate binders are often required, as discussed earlier. Foods contain phosphate in organic or inorganic forms. Inorganic phosphate is more readily absorbed than organic phosphate, and phytate (found in fibre rich foods) may also reduce phosphate absorption further (Kalantar-Zadeh *et al.*, 2010). Organic phosphate is naturally found in foods that are high in protein, but usually only 40–60%

Table 7.5.5 First line potassium lowering dietary advice [source: The British Dietetic Association 2013. Reproduced with permission of The British Dietetic Association (www.bda.uk.com)]

	Foods high in potassium – reduce intake of the following	Lower potassium alternatives
Fruit	Avocado, bananas, dried fruit, e.g. apricots, currants, dates, figs, prunes, raisins, sultanas	Fruit should be limited to a maximum of three portions/day A portion is 80g or about a handful
Vegetables	Vegetables that have not been boiled, e.g. steamed, stir fried or raw Beetroot (fresh), sundried tomatoes, tomato purée	Two to three small (80g) portions of other vegetables Boil vegetables if possible Limit salads to one small bowl/day
Starchy foods	Jacket/baked potatoes Oven, microwave or retail chips Manufactured potato products, e.g. hash browns, frozen roast potatoes, potato waffles, potato wedges Unboiled sweet potato, cassava, plantain, taro, yam	Boiled potatoes, potatoes that have been par-boiled, then roasted or fried Boiled sweet potatoes, cassava, plantain, taro, yam Have no more than one serving of potato or starchy vegetable/day Pasta, rice, noodles, breads.
Snacks	Potato crisps/snacks, nuts, chocolate, fudge Biscuits and cakes containing lots of nuts, dried fruit or chocolate	Corn or maize based snacks Boiled, chewy and jelly sweets Marshmallows, mints, popcorn Biscuits and cakes not containing dried fruit, nuts or chocolate
Drinks	Coffee, malted milk drinks, (e.g. Horlicks, Ovaltine), drinking chocolate, cocoa, fruit and vegetable juices, smoothies Limit milk to 400 mL ($\frac{2}{3}$ pint)/day or 200 mL ($\frac{1}{2}$ pint) milk plus one yogurt/day Beer, cider, stout and wine	Tea, herbal tea, squash and cordial, mineral water, flavoured water, fizzy drinks Spirits are generally lower in potassium than other alcoholic drinks Remember to keep within safe limits for alcohol intake
Salt substitutes	Do <i>not</i> use salt substitutes, e.g. Lo-salt, So-Lo, Low Sodium salt	Other seasonings, e.g. pepper, herbs, spices

NB: This is initial advice only and should only be used until a registered dietitian can provide personalised dietary advice.

of the phosphate is absorbed from the gastrointestinal tract. Any restriction of dietary phosphate is likely to limit the intake of meat, fish, poultry, eggs and milk. Hence, foods with a high protein to phosphate ratio should be encouraged to ensure that protein intake is not compromised by phosphate restriction (Kalantar-Zadeh *et al.*, 2010). Consideration should be given to the individual's nutritional status, and care taken to ensure an adequate protein intake.

Inorganic phosphates are found in food additives and some highly processed foods and carbonated drinks. As over 90% of inorganic phosphate may be absorbed, their intake should be limited. Encouraging fresh foods rather than processed foods is likely to reduce both phosphate and sodium intake. Table 7.5.6 lists high phosphate foods that may be recommended in first line advice. Current UK guidelines recommend that serum phosphate levels be maintained between 0.9 and 1.50 mmol/L for CKD stages 4 and 5 (not on dialysis) (Renal Association, 2011b).

Management of stage 5 (established renal failure)

Clinical management

Once eGFR falls below 15 mL/min and uraemia, fluid overload or PEW persist despite medical treatment, RRT should commence if the patient has opted to dialyse. Ideally this should be planned so that dialysis can start with an arteriovenous fistula or peritoneal dialysis cath-

eter. Those patients who have opted not to dialyse should continue to have conservative management of their renal failure. In all cases, regular monitoring of renal function is an essential part of the continuing care of these patients.

Dietetic management

The aims will vary depending on the mode of RRT or if the patient is managed conservatively. There have been more studies in patients on dialysis than in earlier stages of CKD, particularly focusing on the treatment of PEW and CKD-MBD as these are both associated with increased morbidity and mortality. Recently, the haemodialysis population has shown a demographic shift from predominantly undernutrition to overnutrition (Kramer *et al.*, 2006) and this will need to be taken into account when providing dietetic advice.

Management of haemodialysis

Clinical management

Haemodialysis is the main mode of dialysis in most developed countries. In 2007 it was the established mode of dialysis in the UK in about two-thirds of patients (Renal Association, 2009b). In haemodialysis, blood is circulated through a machine that passes it through very small tubes made from a semi permeable membrane. Surrounding these tubes is the dialysate, which consists of sterile water and electrolytes. Blood cells and proteins are too pass

Table 7.5.6 First line advice on foods high in phosphate whose intake should be reduced

Dairy foods	Cheese spread, processed cheese Condensed milk, evaporated milk, milk shakes Malted milk drinks, e.g. Horlicks, Ovaltine Hard cheeses, e.g. cheddar Soft cheeses, e.g. Brie Limit milk to 300 mL (½ pint)/day
Meat, fish and nuts	Offal, e.g. liver, kidney, pâté Herring, kippers, pilchards, sardines, whitebait Crab, fish paste, scampi Nuts and seeds
Cereals and snacks	Chocolate, fudge Cakes, biscuits and cereals containing chocolate, nuts or seeds, e.g. muesli, cereal bars Baking powder, rock cakes and scones
Processed foods and drinks	Food additives containing phosphates or phosphoric acid; check labels on processed foods and carbonated drinks Examples of foods that may have these additives include ham, sausages, breaded chicken, cake mixes, instant sauces and dark carbonated drinks

NB: This is initial advice only on which foods to limit and should only be used until a registered dietitian can provide personalised dietary advice.

through the pores in the membranes, but small molecules such as urea, water and electrolytes pass through into the dialysate. In this way, excess water and uraemic toxins are removed and electrolyte and acid–base balance are restored. However, amino acids, glucose, vitamins and trace elements may also be removed by dialysis. The best access to the patient's blood is via an arteriovenous fistula, though a central venous catheter (usually into the internal jugular vein) can be used when access is needed immediately. Haemodialysis usually takes place three times per week, but several forms of more frequent haemodialysis (such as daily) have recently been evaluated and are associated with improved outcomes (Renal Association, 2009b). It is usually hospital based; although some patients dialyse at home.

Dietetic management

The main aims of the dietetic management of haemodialysis are:

- Regular monitoring of nutritional status in order to be able to prevent or treat PEW.
- Regular monitoring and dietetic advice to help maintain electrolytes within acceptable ranges.
- To help control fluid balance.
- To promote a healthy well balanced diet taking into account nutritional treatment of comorbidities.

Dietetic assessment should be provided at the start of dialysis in order to identify those who require nutritional supplementation as well as those who need fluid removal, and to balance this with advice on any dietary restrictions that may be required. After 6–8 weeks of dialysis, many patients notice an improvement in symptoms and dietary advice may need to change. For stable patients, nutritional changes are likely to be gradual after this. Multidisciplinary working is a vital part of ensuring appropriate treatment for these patients (Renal Association, 2010b).

Regular dietetic monitoring is likely to be beneficial and may lead to both a significant reduction in the proportion of patients with PEW and a significant decrease in phosphate levels (Campbell *et al.*, 2009).

Protein

In haemodialysis, protein requirements are increased, partly due to the loss of amino acids through the dialysis filter and the fact that dialysis itself can increase protein catabolism (Fouque *et al.*, 2007). A safe level of protein intake is likely to be at least 1.1–1.2 g/kg of IBW in order to achieve nitrogen balance (Fouque *et al.*, 2007; Renal Association, 2010b; British Dietetic Association Renal Nutrition Group, 2011). At least 50% of protein should be of high biological value (National Kidney Foundation, 2000). However, high protein intakes of >1.4 g/kg may not improve survival and may be harmful (Shinaberger *et al.*, 2006).

Energy

Energy expenditure does not appear to be increased (Cuppari & Avesani, 2004). Recommended energy intake is 30–35 kcal/kg of IBW/day for all patients depending upon age and physical activity (Renal Association, 2010b). Studies have reported that energy intakes are often lower than this, and may be as low as 20–25 kcal/kg/day (Rocco *et al.*, 2002). It has also been shown that energy intake may be insufficient, particularly on dialysis days. Even if protein intake is adequate, an inadequate energy intake is likely to result in a negative nitrogen balance. When assessing energy intake, a food diary that includes a dialysis day, a non-dialysis day and a weekend day as a minimum or several dietary interviews can be helpful (Fouque *et al.*, 2007).

Obesity

Current evidence suggests that a BMI of >23 kg/m² is protective for these patients. However, obese patients on

dialysis who are eligible for a kidney transplant should be encouraged to lose weight. Transplants are rarely undertaken in those with a BMI of $>35 \text{ kg/m}^2$ as graft survival appears to be decreased in obese patients.

Diabetes

Intensive glucose control in type 2 diabetes may have less of a protective effect against cardiovascular events in these patients (Reaven *et al.*, 2009). Achieving an HbA_{1c} of $<58 \text{ mmol/mol}$ in elderly patients with type 2 diabetes may have a modest effect on outcome and needs to be weighed against the risk of hypoglycaemic events. Haemodialysis *per se* has no significant long term effect on glycaemic control in insulin treated type 2 diabetic patients.

Sodium and fluid

Most patients show a progressive reduction in urine output. For most patients, limiting sodium and fluid intake is required to control blood pressure and to prevent excessive fluid weight gains. In haemodialysis, very high fluid weight gains between dialysis sessions [intradialytic weight gain (IDWG)] are associated with increased mortality risk, particularly cardiovascular risk (Kalantar-Zadeh *et al.*, 2009). However, patients with very little fluid weight gain between dialysis sessions are at highest risk of death as this is associated with poor nutritional status and may reflect poor oral intake (Lopez-Gomez *et al.*, 2005).

It is very difficult to ignore thirst as the overriding stimulus is plasma osmolality, to which serum sodium contributes the most (Tomson, 2001). Patients with poorly controlled diabetes may also be extremely thirsty. Reducing sodium intake suppresses thirst and therefore excessive IDWG. Patients on a low sodium diet (with advice to drink only when thirsty) have been found to gain significantly less weight than those on a standard diet and fluid intake (Rigby-Matthews *et al.*, 1999). A low sodium diet also improves blood pressure control and may result in the withdrawal of antihypertensive treatment (Krautzig *et al.*, 1998). Hence for most patients, the focus should be on limiting salt intake rather than on fluid intake.

When fluid needs to be considered, the current guidelines for fluid intake vary from 500 to 1000 mL in addition to daily urine output in order to achieve an IDWG of 2–2.5 kg or 4–4.5% dry body weight (Fouque *et al.*, 2007). In order to achieve this, drinks and food with a high fluid content (sauces, soup, ice cream, etc.) should be counted as part of a daily fluid allowance. The water content in other foodstuffs such as fruit and vegetables is not counted. Drinking from a full small cup is usually more helpful than using a part filled larger cup or mug. However, any fluid allowance given should be reassessed regularly as residual renal function (urine output) is likely to change. Reducing sodium and fluid in addition to both potassium and phosphate, whilst ensuring that protein and energy intake is adequate, is difficult and a stepwise approach to educate the patient is most important (Fouque *et al.*, 2007).

Potassium

Hyperkalaemia is a common indication for emergency dialysis in patients already on haemodialysis and 3–5% of deaths in dialysis patients have been attributed to hyperkalaemia. The highest mortality rate is when potassium levels exceed 5.6–6.0 mmol/L (Kovesdy *et al.*, 2007). Serum potassium levels (measured at the start of dialysis) should be 4–6 mmol/L (Renal Association, 2009b). Dietetic advice to reduce dietary potassium intake should be provided when serum potassium levels approach 6 mmol/L, but other causes for hyperkalaemia should be investigated and corrected. For these patients, a daily intake of potassium of 50–70 mmol (1950–2730 mg) or 1 mmol/kg of IBW may be required (Fouque *et al.*, 2007).

However, low potassium levels may lead to an increased mortality rate, especially when pre-dialysis levels are lower than 4 mmol/L (Kovesdy *et al.*, 2007). Hypokalaemia towards the end or immediately after dialysis may be corrected by relaxing dietary potassium or by increasing the dialysate potassium concentration. Information regarding dietary advice required for a low potassium diet is described earlier.

Phosphate

The use of a phosphate restricted diet in combination with oral phosphate binders is now well established in the management of hyperphosphataemia and secondary hyperparathyroidism in patients on dialysis. Use of phosphate binders, vitamin D compounds and calcimimetics is described earlier. Limiting phosphate intake to 800–1000 mg (27–32 mmol)/day (adjusted for dietary protein needs) is recommended when serum phosphate levels or PTH are elevated (Fouque *et al.*, 2007). The recommended serum phosphate level is 1.1–1.7 mmol/L (measured at the start of each dialysis session) (Renal Association, 2011b). Low phosphate levels are associated with increased mortality as are high phosphate levels in dialysis patients. Some patients may have PEW and CKD-MBD; the association between low serum phosphate levels and increased mortality rate may be due to a decline in protein intake and worsening PEW (Shinaberger *et al.*, 2008). Dietary advice required for a low phosphate diet is described earlier.

Management of peritoneal dialysis

Clinical management

Peritoneal dialysis is a form of dialysis in which dialysis fluid is introduced into the peritoneal cavity via a peritoneal dialysis catheter in the patient's abdomen, where it draws waste products and excess water out of the blood using the peritoneal membrane as a filter. Most people dialyse every day either by manual exchanges performed four to five times a day [continuous ambulatory peritoneal dialysis (CAPD)] or overnight using a machine [automated peritoneal dialysis (APD)]. The fluid must stay inside the peritoneal cavity for a period of time (a dwell) to allow removal of waste products and fluid. Different dialysis regimens can be prescribed to maximise an individual's dialysis to ensure efficiency.

Dietetic management

The main aims of the dietetic management of peritoneal dialysis are:

- Regular monitoring of nutritional status to prevent or treat PEW.
- Regular monitoring and dietetic advice to help to maintain electrolytes within acceptable ranges.
- To help control fluid balance.
- To promote a healthy well balanced diet taking into account nutritional treatment of comorbidities.

Dietetic assessment should be undertaken at the start of dialysis to make a baseline assessment. Any symptoms of uraemia at this time usually start to recede and appetite improves. As residual renal function is relatively preserved in this patient group and dialysis is performed each day, some diet and fluid restrictions may be more relaxed.

Protein

Protein requirements are increased to compensate for protein losses into the dialysis fluid. The actual amount of protein lost by individuals is variable and is dependent on the properties of their peritoneal membrane and the dialysis regimen. Recommendations for protein requirements for this group have become more conservative over time with increasing evidence to suggest neutral nitrogen balance can be achieved at much lower intakes than previously recommended. Current consensus suggests aiming for a protein intake of 1.2 g of protein/kg of IBW (Renal Association, 2010b) although intakes of between 1.0 and 1.2 g of protein/kg of IBW may be adequate for many individuals with no adverse effect on nutritional status (Dombros *et al.*, 2005, British Dietetic Association Renal Nutrition Group, 2011).

Energy

Energy requirements are 30–35 kcal/kg of IBW, although older, less active patients may achieve neutral energy balance with intakes less than this. Monitoring actual body weight will help to assess if energy intake is appropriate for an individual. Unlike other renal patient groups, energy intake is obtained by the absorption of glucose from the peritoneal dialysis fluid as well as from diet. Glucose acts as an osmotic agent to ultrafiltrate fluid (UF) from the patient, so while it is in contact with the peritoneal membrane, not only does it facilitate fluid removal but it is also absorbed, hence contributing to total energy intake.

The amount of energy obtained from the peritoneal dialysis fluid is dependent on the amount of glucose in the bags (increased in some bags to increase UF) and the characteristics of the individual's peritoneal membrane. In CAPD, approximately 60% of the daily dialysate glucose load is absorbed in those with a normally functioning membrane (Dombros *et al.*, 2005), which can be 300–800 kcal/day. Those using high glucose concentration bags will regularly be absorbing large amounts of energy, which may cause undesirable weight gain.

To minimise glucose absorption (and therefore non-nutritive energy), other bags are available that use alterna-

tive osmotic agents, e.g. icodextrin (a non-absorbable glucose polymer) and amino acids. Icodextrin is often used to maximise UF, particularly for longer dwells, and amino acid bags can be indicated in those with poor nutritional intake. These may be useful glucose sparing strategies for those with obesity or diabetes. Glucose absorption from the peritoneal dialysis fluid can make meeting other dietary requirements more difficult as there needs to be a higher concentration of nutrients in the recommended reduced dietary energy intake.

Obesity

The high energy load provided by the treatment can cause weight gain. Central obesity can worsen or develop in some peritoneal dialysis patients, together with an increased risk of hyperlipidaemia and insulin resistance (Renal Association, 2010a). Practically, it can also be difficult to achieve an adequate dialysis dose in those patients with a high body weight. As for haemodialysis, there may be a protective element to having a higher BMI; however, this will affect the individual's suitability for a transplant.

Diabetes

Glycaemic control can become more difficult to manage due to the glucose absorbed from the peritoneal dialysis fluid. This may require an increase in insulin or oral hypoglycaemic drugs (Reaven *et al.*, 2009). Some individuals may have a set dialysis regimen against which diabetes medications can be titrated; however, many patients alter dialysis regimens to address their fluid balance on a day to day basis so tight glycaemic control can become challenging.

Sodium and fluid

The fluid requirement for those on peritoneal dialysis depends on an individual's residual renal function (urine output) and the UF achieved by peritoneal dialysis. Whilst limiting fluid helps prevent fluid overload, an appropriate dialysis regimen individualised to best match the UF potential is the most important predictor of adequate fluid balance. The use of high glucose bags is associated with detrimental changes in peritoneal membrane function, which can occur over time as well as with weight gain and poor glycaemic control in diabetes (Renal Association, 2010b). Limiting sodium and fluid intake helps to minimise the need for their use.

Potassium

Most people who have peritoneal dialysis are able to have a normal potassium intake. For some, the removal of potassium by the dialysis can be so efficient that a high potassium intake is required to maintain normal potassium levels. High serum potassium levels may indicate ineffective dialysis. Monitoring potassium levels will inform what level of potassium in the diet is required.

Constipation

Constipation is associated with peritoneal dialysis catheter malfunction and peritonitis, which can result in

peritoneal dialysis failure. Constipation needs to be dealt with in a proactive, preventative manner. Laxatives are often taken regularly, but if changing the diet, fibre should be increased gradually and the potassium and fluid content of the diet should also be considered to ensure that target potassium levels are achieved and fluid overload is prevented (Lee, 2011).

Phosphate

The same dietetic principles apply to patients on peritoneal dialysis as for those on haemodialysis, and the same phosphate levels are recommended.

Protein energy wasting

Although felt to be diminishing, PEW is still prevalent, particularly amongst those with other comorbidities. In peritoneal dialysis, several factors have been found to be associated with PEW. The frequency of gastrointestinal symptoms is high, varying from diarrhoea, constipation, abdominal pain, delayed gastric emptying, and nausea and vomiting (Cano *et al.*, 2007b). Management of these symptoms may help improve appetite and food intake. For those who have fluid in their peritoneal cavity in the day, bloating and a feeling of satiety may also be experienced. Inadequate dialysis has been implicated in contributing to PEW (Churchill *et al.*, 1996; Paniagua *et al.*, 2002) and the level of residual renal function is thought to be directly related to nutritional intake independent of dialysis dose (Caravaca *et al.*, 1999; Wang *et al.*, 2001). The peritoneal membrane characteristics are also associated with PEW and fluid overload caused by poor volume management is also associated with poorer nutritional status (Wang *et al.*, 2003; Cheng *et al.*, 2005). Although some of these factors are difficult to manage or cannot be altered, it is important they are considered when formulating clinical treatment plans to address PEW.

Complications

A serious but uncommon complication of peritoneal dialysis is encapsulating peritoneal sclerosis (EPS). It is characterised by bowel obstruction and marked sclerotic thickening of the peritoneal membrane. Symptoms such as anorexia, nausea, vomiting and weight loss are common. In cases with milder gastrointestinal features, nutritional status may be maintained by ensuring adequate food intake with oral nutritional supplements and antiemetics as required. However, more severe cases may warrant enteral tube feeding if the gastrointestinal tract allows or parenteral feeding when it is impossible to establish adequate nutrition using the gut.

Management of kidney transplantation

Clinical management

Renal transplantation is the most common solid organ transplant procedure and is considered the gold standard for RRT as a successful transplant can lead to the restoration of renal function. Survival following renal transplantation is better than that for age matched individuals remaining on the transplant waiting list (Wolfe *et al.*,

1999). The longer patients receive dialysis, the greater their risk for post transplantation morbidity and mortality.

A transplant is considered to be the first choice for patients who are considered fit for major surgery and for chronic immunosuppression (Renal Association, 2011c). During a kidney transplant, the donor kidney is usually placed in the iliac fossa and the existing kidneys are not removed. Almost all transplants will provoke a powerful immunological rejection response in the recipient, which will destroy renal tissue; therefore immunosuppression is needed to avoid rejection.

Acute rejection generally occurs days to weeks after surgery. Chronic rejection, however, occurs slowly over months or years and leads to progressive loss of renal function. Eventually, as transplant function declines, the patient is likely to suffer symptoms of advancing kidney failure. As with patients with CKD, dietary changes may be required at some stage.

The most frequently used immunosuppressive agents are tacrolimus and ciclosporin. Other immunosuppressives used are mycophenolate mofetil, azathioprine, sirolimus and corticosteroids. Some of their adverse effects have nutritional implications, as shown in Table 7.5.7.

The medical and dietetic management of transplantation can be divided into three main periods and the aims for medical management are:

- *Pretransplant* – to correct or improve complications of ERF in order to optimise outcome.
- *Immediate post transplant phase* – to prevent acute rejection, optimise graft function and minimise infection.
- *Later post transplant phase* (from 3–6 months after surgery) – to preserve good graft function and prevent the long term consequences of immunosuppression, including premature CVD (Renal Association, 2011d).

Dietetic management

The main aims are:

- *Pretransplant phase* – to correct or improve nutritional status and CKD-MBD, and to treat obesity.
- *Immediate post transplant phase* – to monitor nutritional status and ensure adequate protein and energy intake, monitor electrolyte levels and treat as appropriate, and provide food safety advice.
- *Later post transplant phase* – to provide adequate, but not excessive, protein intake and to promote a healthy well balanced diet, taking into account nutritional treatment of comorbidities to reduce CVD risk.

Pretransplant phase

The aim of pretransplant nutritional management is to optimise outcomes in the early and the late transplant period. Ideally, a multidisciplinary team (MDT) approach should be taken, including diet, lifestyle changes and medication to aid in the correction or improvement of PEW, dyslipidaemia, obesity, CKD-MBD and hypertension. The presence of these comorbidities is predictive of related complications in the post transplant period.

Table 7.5.7 Drug–nutrient interactions

Medication	Nutrient interactions	Nutritional implications
ACE inhibitors/ARBs	Enhanced hypotensive effect when given with alcohol	Can cause hyperkalaemia
Potassium sparing diuretics, e.g. spironolactone		Can cause hyperkalaemia
Atorvastatin, simvastatin	Grapefruit juice can increase the plasma concentration of statins	
Ciclosporin, tacrolimus	Grapefruit juice can increase the plasma concentration of these medications	Hyperkalaemia Hypercholesterolaemia
Sirolimus		Hyperlipidaemia Hypokalaemia
Erythropoetin		Correct iron or folate deficiencies before starting Supplemental iron may improve the response
Corticosteroids		Weight gain Glucose intolerance Lipid abnormalities Osteoporosis
Calcium based phosphate binders, e.g. calcium acetate, Calcichew	Interacts with iron tablets. Do <i>not</i> take iron tablets within 2 hours of taking these medications	May cause hypercalcaemia
Alfacalcidol, calcitriol		May cause hypercalcaemia
Cinacalcet		May cause hypocalcaemia

ACE inhibitors, angiotensin converting enzyme inhibitors; ARB, angiotensin receptor blocker.

Poor nutritional status during the pretransplant period is associated with higher post transplant morbidity and mortality (Chan *et al.*, 2011). It has been shown that obesity may lead to increased risks post transplant, particularly if the BMI is $>35 \text{ kg/m}^2$ (Holley *et al.*, 1990, Gill *et al.*, 1993, Pischon & Sharma, 2001, Gore *et al.*, 2006). Although studies suggest that moderate obesity does not affect major transplantation outcomes (Johnson *et al.*, 2002; Howard *et al.*, 2002), it is still reasonable to recommend that obese transplant candidates aim to reach a more desirable BMI.

Immediate post transplant phase

A successful kidney transplant enables previous dietary restrictions to be relaxed. However, some patients find it hard to relax their diet and fluid intake.

Protein and energy

In the first 4 weeks after transplantation, a diet providing 1.2–1.3 g of protein/kg of body weight may prevent negative nitrogen balance (Teplan *et al.*, 2009; Chan *et al.*, 2011). An energy intake of 30–35 kcal/kg is advised as it helps to ensure positive nitrogen balance (Teplan *et al.*, 2009, Danovitch, 2005).

Sodium and fluid

A low sodium diet may help those with post transplant hypertension and fluid overload (Danovitch, 2005). As kidney function improves, patients become polyuric and need encouragement to drink lots of fluid. This may be difficult for a patient who has spent years on dialysis trying to reduce their fluid intake; encouragement and reassurance are essential.

Potassium

Hyperkalaemia is associated with ciclosporin and tacrolimus, especially during the immediate post transplant period when dosages are high. This may be exaggerated by graft dysfunction. Treatment may require limitation of dietary potassium.

Phosphate

Hypophosphataemia is very common during the early weeks post transplant due to phosphaturia (Kasiske *et al.*, 2000). Oral phosphate supplementation may be needed where profound hypophosphataemia persists despite a liberal dietary intake. Phosphate binders should be discontinued as renal function improves to avoid severe hypophosphataemia.

Food borne infections

Transplant patients, even those who are not nutritionally compromised, may be susceptible to an increased incidence of infection. During the early post transplant period and in periods of acute illness, the likelihood of food borne infection is high due to significant suppression of the immune system (Chan *et al.*, 2011). Although there is no evidence to support the use of restrictive clean diets, it is prudent to provide general food safety advice to kidney transplant recipients (Chan *et al.*, 2011). Providing education on food safety may help minimise the risk for contamination. This may help to reduce the risks of infection with the following:

- *Listeria monocytogenes* – raw milk, soft cheeses and hot dogs.
- *Nocardia asteroides* – decaying vegetables.

- *Salmonella* – associated with undercooked, contaminated meat, poultry and eggs, as well as raw milk. Raw seafood and raw fruit and vegetables also present an increased risk.
- *Legionella* – contaminated or unsafe water supply (Danovitch, 2005).

Long term dietetic management

Protein

It has been shown that 0.8g/kg/day of protein intake as well as limiting sodium intake can stabilise long term renal function and maintain an adequate nutritional status in the kidney transplant recipient (Bernardi *et al.*, 2003). High protein intakes should be discouraged because of the dangers of protein induced hyperfiltration. For stable patients, a normal protein intake of 0.8–1.0g/kg of IBW should be the aim.

Energy

Energy intake and expenditure should be balanced to maintain desirable body weight and to prevent weight gain. For stable transplant patients who require weight reduction, a daily energy intake of 25 kcal/kg of IBW is a reasonable starting point.

Nutritional consequences and complications

Long term immunosuppression is associated with several nutrition related problems; these are obesity, dyslipidaemia, glucose intolerance, hypertension and CKD-MBD.

Obesity

Weight gain and obesity are common. This may be due to several factors, including a feeling of wellbeing after transplantation with increased food intake, improved quality of life (physical and psychological), freedom from dietary restrictions, a sedentary lifestyle, hyperphagia and higher body fat accumulation related to corticosteroids. Obesity is associated with CVD events and mortality (National Kidney Foundation, 2009b). Diet and other behaviour modifications have been shown to help reduce weight over the short term (National Kidney Foundation, 2009b).

Dyslipidaemia

Cardiovascular disease remains the main cause of long term mortality in the transplant population. There is no reason to believe that the management of complications of atherosclerotic CVD is different from that for the general population (National Kidney Foundation, 2009b). A diet in line with the latest lipid management guidelines for the general population is likely to benefit transplant recipients with dyslipidaemia (Chan *et al.*, 2011), although statins are usually required.

New onset diabetes mellitus

This is common and may reflect increased dietary intake, weight gain and the use of immunosuppressive agents, specifically corticosteroids, tacrolimus, sirolimus and, to a lesser extent, ciclosporin. The incidence of new onset diabetes mellitus after transplantation (NODAT) is highest

in the first 3 months after transplantation. Its presence is associated with poorer outcomes, including increased graft failure, mortality and CVD (National Kidney Foundation, 2009b). Diet, weight loss if appropriate and exercise provide the basis for the initial management (Davidson *et al.*, 2003). Oral hypoglycaemic agents or insulin may also be required.

Hypertension

Hypertension is an important risk factor for CVD as well as graft survival. Weight loss and exercise in the obese hypertensive patient may also play an important role in its treatment. Hypertensive patients are likely to benefit from limiting sodium intake to 2–3g/day (Chan *et al.*, 2011).

CKD-MBD

CKD-MBD is common in transplant recipients. Calcium, phosphate and vitamin D metabolism are influenced by several factors resulting from the earlier period of CKD. Corticosteroids may cause osteoporosis, which may further affect MBD management. Hypercalcaemia is common and is usually due to hyperparathyroidism that persists from the preceding period of CKD (National Kidney Foundation, 2009a,b). Hypophosphataemia may persist and dietary phosphate intake should be individualised according to blood levels. A supplement of Vitamin D (or analogue) may also be required.

Management for those receiving conservative management

The number of people who choose not to have dialysis continues to rise, possibly as a result of an ageing population with multiple comorbidities. For these patients, regular review is important and the focus of care is symptom management. The main aims are to provide all aspects of clinical care, with the exception of dialysis, including the management of anaemia, together with ongoing support by the MDT in liaison with community and palliative care services. Little is known about the appropriate level of nutritional intervention for this patient group and there are no documented recommendations. Realistically, an approach that promotes enjoyment of food and mealtimes combined with symptom control would appear prudent.

Nutritional support in protein energy wasting

Early identification of any decline in nutritional status and its proactive management is essential as correcting established malnutrition is difficult. Assessment of oral intake should be part of a full assessment of nutritional status and medical causes should also be identified and treated. Once the appropriate nutritional plan is in place, regular monitoring is essential in order to evaluate the effectiveness of the intervention. The frequency of monitoring will depend on individual needs.

First line dietetic advice should be to fortify the existing diet with additional nutrient dense foods, relax any

current dietary limitations (dependent on current biochemistry) and provide individualised advice. The use of sugary foods and sweet drinks should be encouraged, when appropriate, and fats are also a useful source of energy. Both mono- (MUFAs) and poly-unsaturated fatty acids (PUFAs) should be encouraged in all patients; however, high fat foods such as pastries, biscuits and cakes should not be discouraged in poor eaters or it will be difficult to meet energy requirements. As cholesterol levels are often lower in CKD stages 4 and 5, it is debatable as to whether a strict cardioprotective diet is as important at this time.

It has not yet been established if provision of nutritional support to patients prior to developing ERF leads to reduced morbidity and mortality, although there is some evidence that it improves nutritional markers in those on haemodialysis. A diet consisting of 45 kcal/kg and 1.5 g of protein/kg/day has been found to promote weight gain and improve albumin levels in malnourished haemodialysis patients (Kuhlmann *et al.*, 1999). Oral nutritional supplements should be added if oral intake cannot be improved following dietetic intervention (Renal Association, 2010b). Glucose polymers (powders/liquids) and fat emulsions are ideal for increasing energy in patients with poor appetites who are unable to take adequate energy via normal food. If electrolyte levels are high, renal specific supplements that are low in electrolytes should be considered (Cano *et al.*, 2006) (see Chapter 6.3).

Enteral tube feeding should be considered if the nutrient intake remains suboptimal despite oral supplements, although percutaneous endoscopic gastrostomy feeding is difficult in patients on peritoneal dialysis due to complications such as peritonitis. Other types of nutritional support that may be used are:

- *Intraperitoneal amino acids (IPAAAs)* – sometimes used in CAPD and provide amino acids via dialysis. It is normal practice to insist that a high energy snack is eaten at the time of infusion, although evidence for this is limited (Jones *et al.*, 1998).
- *Intradialytic parenteral nutrition (IDPN)* – a form of parenteral nutrition given via the venous return whilst on haemodialysis. Again, evidence for this is limited (Cano *et al.*, 2007a; Bossola *et al.*, 2010).

A meta analysis found that both oral and enteral nutritional support improved protein and energy intake, and increased serum albumin in haemodialysis patients (Stratton *et al.*, 2005). This view is supported by a further review of the use of oral nutritional supplements and IDPN (Bossola *et al.*, 2010). The conclusion was that the long term use of oral nutritional supplements is safe and may be useful in terms of improvement of nutritional parameters such as serum albumin and body weight. However, it remains to be clarified if their use is associated with increased survival. Intradialytic parenteral nutrition was also found to improve serum albumin and body weight, but did not influence survival. Percutaneous endoscopic gastrostomy feeding has been successful in those on haemodialysis, but the numbers of patients in

the studies were low. It requires frequent monitoring but can lead to increases in weight and albumin levels; however, levels of phosphate have been found to be low at times (Holley & Kirk, 2002) (see Chapter 6.4).

Considerations for long term dietetic care of patients

Nutritional treatment in these patients can be complex because several nutrients often need to be managed simultaneously, the diet needs to change over time and comorbidities may need to be taken into account. The complexity of a regimen has been one of the most frequently identified barriers to patient compliance (Mitch & Klahr, 1993). Although a stepwise approach to educating the patient is important, giving knowledge alone does not necessarily lead to a change in behaviour. Behavioural change techniques are appropriate for patients with CKD as they can enhance patient motivation by reducing resistance to change. It can be helpful to explain why the diet may differ from a healthy diet and why this is of benefit. It has been found that people with CKD appreciate advice on what they can have to eat rather than lists of what they should avoid (Department of Health, 2004) (see Chapter 1.3).

Priorities may change over time, e.g. a moderate salt intake and cardioprotective diet that is important in early CKD is likely to be a lower priority if there is a greater need for nutritional support, when ensuring a high energy intake and adequate protein may mean foods that are higher in fat, sugar and salt are included in the diet. Cardiovascular death in later stages of CKD is more likely to be due to non-traditional risk factors such as phosphate control. Good glycaemic control is crucial in preventing or delaying the progression of early CKD in those with diabetes, but in ERF, opinion suggests that less strict glycaemic control may be preferable because this may reduce the risk of hypoglycaemia. In early CKD, weight loss is helpful in most obese patients, but on haemodialysis, obese patients currently fare better. As with the dietetic treatment of other chronic diseases, assessing the patient's motivation as well as their dietary understanding is important, together with jointly agreeing goals.

Micronutrients

The metabolism and status of micronutrients is altered in renal failure, but absolute requirements for trace elements have yet to be established. Iron deficiency is common, especially when erythropoietin therapy is used. Unfortunately, oral supplementation is ineffective and parenteral iron is often required. Zinc and selenium levels are also reduced, but routine supplementation is not recommended (Gilmour *et al.*, 1998). Deficiencies in vitamin C, thiamine, riboflavin and pyridoxine may occur in individuals who are following a low protein diet. Chronic kidney disease results in a rise in vitamin A levels by up to 20% above baseline, primarily because of an increase in retinol binding protein; however, toxicity is rare because the vitamin is bound to the protein and is

Table 7.5.8 Dietary components and renal disease

	Protein	Energy	Potassium	Phosphate	Sodium and fluid
Significance in renal disease	Sufficient needed to avoid protein energy wasting Lower intake may delay progression of CKD (contentious)	Sufficient required to maintain energy balance and prevent protein energy wasting	Hyperkalaemia may cause cardiac arrhythmias/arrest	Hyperphosphataemia involved with development of CKD–mineral and bone disorder	Excess intake leads to fluid overload and hypertension
Acute kidney injury	≥1.0 g/kg body weight (BW) (see text)	Matched to requirements (see text)	As required (see text)	As required (see text)	As required (see text)
CKD stages 1–3	>0.8 g/kg BW	Aim to achieve ideal weight	Unlimited unless hyperkalaemic	No limitation	100 mmol of sodium (rarely fluid overloaded)
Nephrotic syndrome	0.8–1.0 g/kg ideal body weight (IBW)	30–35 kcal/kg IBW	Not limited unless hyperkalaemic	Not limited unless hyperphosphataemic	100 mmol of sodium + fluid limited if overloaded
CKD stage 4	0.75–1.0 g/kg IBW	30–35 kcal/kg IBW	Unlimited unless hyperkalaemic	Intake usually limited to 27–32 mmol if phosphate or PTH levels raised	100 mmol of sodium + fluid limited if overloaded
Haemodialysis	Minimum 1.1–1.2 g/kg IBW	30–40 kcal/kg IBW	Intake usually limited to approx. 1 mmol/kg BW	Intake usually limited to 27–32 mmol (adjusted for protein needs) – see text	100 mmol of sodium + fluid limitation usually required
Peritoneal dialysis	Minimum 1.0–1.2 g/kg IBW	30–35 kcal/kg of IBW (including glucose absorbed from dialysate)	Not limited unless hyperkalaemic	Intake usually limited to 27–32 mmol (adjusted for protein needs) – see text	100 mmol of sodium + fluid limitation usually required
Transplant	0.8–1 g/kg long term	Aim to maintain desirable weight	Not limited unless hyperkalaemic	Hypophosphataemia is common	80–120 mmol of sodium

Recommended intakes are for daily amounts.
CKD, chronic kidney disease; PTH, parathyroid hormone.

therefore inactive. Studies of vitamin E status in renal failure report contradictory findings. There is no evidence that supplements of vitamin B₁₂, folic acid, biotin, pantothenic acid, vitamins A or E are routinely required to correct deficiencies in any group of patients. High dose supplements of folic acid, pyridoxine and vitamin B₁₂ show no benefit on cardiovascular morbidity or mortality and are not recommended.

There is some evidence that patients on low potassium diets can become vitamin C deficient. However, a high intake of vitamin C (2 g/day) is associated with hyperoxalosis and this may result in oxalate containing kidney stones. A lower dose (100 mg/day) does not appear to alter serum oxalate in patients on dialysis (Gilmour *et al.*, 1998).

Abnormal renal metabolism, inadequate intake and/or gastrointestinal absorption and dialysis losses account for vitamin deficiencies amongst dialysis patients (Fouque *et al.*, 2007). The European Society of Parenteral and Enteral Nutrition (ESPEN) has recommended that due to dialysis induced losses, water soluble vitamins should be supplied; folic acid (1 mg/day), pyridoxine (10–20 mg/day) and vitamin C (30–60 mg/day). Haemodialysis does not

induce significant trace element losses; however, supplementation of zinc (15 mg/day) and selenium (50–70 mg/day) may be useful in depleted patients (Cano *et al.*, 2006). The provision of water soluble vitamins has been associated with significantly lower mortality rates, but few UK units prescribe these (Fissell *et al.*, 2004). It is currently recommended that haemodialysis patients be prescribed supplements of water soluble vitamins (Renal Association, 2010b). However, there are no recommendations regarding vitamin supplementation for peritoneal dialysis patients. The limited research in this area suggests there may be deficiency of some B vitamins and vitamin C. Individual dietary assessment will help establish if supplementation is necessary. For those with a successful renal transplant, regular supplementation is not needed (Martins *et al.*, 2004). Table 7.5.8 summarises the requirements of the major nutrients to be considered in renal disease.

Acute kidney injury

Acute kidney injury (AKI) describes the disorder where kidney function abruptly deteriorates. It has now replaced

Table 7.5.9 Causes of acute kidney injury

Location	Cause	Example
Prerenal	Reduced intravascular volume	Blood loss, gastroenteritis, diuretics, hypoalbuminaemia, burns
	Cardiac failure	
	Vasodilatation	Sepsis
	Increased resistance to renal blood flow	Renal artery disease Renal vein thrombosis
Renal	Hepatorenal syndrome*	
	Glomerular disease	Primary renal disease or as part of a multisystem disorder (includes any cause of acute glomerulonephritis)
	Intrarenal vascular disease	Vasculitis Atheroembolic disease Haemolytic uraemic syndrome
Post renal Obstruction to the flow of urine can be at any level from the intrarenal tubules to the urethra	Tubulointerstitial disease	Acute tubular necrosis: post ischaemic (prerenal)** Toxic agents: drugs, poisons, X ray contrast Acute interstitial nephritis: infective, infiltration, (e.g. lymphoma), drug reaction
	Intrarenal obstruction	Crystals: uric acid, oxalate, calcium Abnormal proteins, e.g. myeloma
	Ureteric obstruction (needs to be bilateral unless only one functioning kidney)	
	Bladder outflow obstruction	Prostate or bladder tumours, calculi
	Urethral obstruction	Tumours, strictures

*The hepatorenal syndrome is an incompletely understood syndrome in which acute kidney injury occurs in association with liver failure. The liver failure is the primary lesion and renal function generally improves as the hepatic failure recovers.

**Acute tubular necrosis can result from any prerenal cause of renal failure if of sufficient duration and intensity. In hospital this is most commonly seen in the context of sepsis, trauma, major surgery and cardiac failure.

the term acute renal failure. The definition of AKI has changed in recent years, and detection is now mostly based on monitoring creatinine levels, with or without urine output. Criteria such as RIFLE (Bellomo *et al.*, 2004) and AKIN (Mehta *et al.*, 2007) have been used to diagnose AKI. Recently, Kidney Disease: Improving Global Outcomes (KDIGO, 2012) has produced a clinical practice guideline for AKI, which includes a globally acceptable definition by merging aspects of both RIFLE and AKIN and by defining its severity in three stages. This should enable the incidence, management and outcomes of AKI to be compared.

In general terms, AKI differs from CKD in that the decline in renal function is more rapid, taking place over hours or days, and is also potentially reversible. It covers a broad spectrum of conditions and clinical settings. Forms of kidney injury can be mild or severe and the condition of individuals may vary from being mobile around the ward with single organ failure to being cared for in the critical care unit with multiorgan failure. Renal replacement therapy may or may not be required. Causes of AKI are shown in Table 7.5.9. There is an overlap between the first two groups as any prerenal cause can lead to ischaemic damage to the kidney, causing the pathological acute tubular necrosis.

Disease process and consequences

Acute kidney injury is estimated to affect 7% of general hospital admissions (Nash *et al.*, 2002) and up to 20% of critically ill patients (Hegarty *et al.*, 2005). It is more likely to develop in individuals with pre-existing CKD, and is more common in older individuals. Patients may present with a reduced urine volume or with general symptoms such as nausea and vomiting. More serious presentations include pulmonary oedema, pericarditis, confusion or depressed levels of consciousness. It may also be detected incidentally following blood tests performed either routinely or to investigate other complaints.

Mortality rates range from 10% in uncomplicated AKI to 80% in patients with multiorgan failure (Cosentino *et al.*, 1994). Individuals die from their underlying disease and complications, rather than from renal failure. Poor nutritional status is associated with higher mortality rates (Mault *et al.*, 1983), but survival rates improve as nutritional support is increased (Abel *et al.*, 1973; Bartlett *et al.*, 1986; Rainford, 1981).

Management

The medical and nutritional management of the patient with AKI are closely linked and are dependent upon the

Table 7.5.10 Nutritional requirements in acute kidney injury

	Non-catabolic (no RRT)	Non-catabolic (on IHD)	Catabolic (on IHD)	Catabolic (on CRRT)
Protein (g/kg/day)	1.0	1.2	1.5	Up to max of 1.7 in hypercatabolism
Energy	Not affected by acute kidney injury Tailored to individual requirements and clinical state			
Fluid	Usually restricted, unless on CRRT			
Electrolytes	Monitor and adjust intake as required Will vary depending on disease state and type of treatment Solutions used in CRRT contain electrolytes			
Micronutrients	Requirements are not well documented Fat soluble vitamin and antioxidant status is low CRRT has negative effect on balance of some vitamins and trace elements. Consider supplementation – see text			

IHD, intermittent haemodialysis, RRT, renal replacement therapy; CRRT, continuous RRT.

patient's clinical state. Consequently, treatment regimens will need to be tailored to the particular needs of the individual.

Medical management

Unless the patient presents with a life threatening indication for urgent RRT, e.g. pulmonary oedema, severe hyperkalaemia or pericarditis, initial treatment will be aimed at the underlying cause of renal failure. This will involve efforts to preserve renal function, together with investigations to elucidate the cause of renal failure. Since the kidneys are dependent upon an adequate blood supply, measures to restore the circulating blood volumes and blood pressure are important. Other important general measures include aggressive treatment of sepsis and measures to improve cardiac function if impaired. Patients with an intrinsic renal cause for AKI will need further investigation, possibly including a renal biopsy, to ascertain whether any specific therapy is needed. More general management includes withdrawal of potentially nephrotoxic agents from the patient's therapy. Where the patient's urinary tract is obstructed, prompt relief of the obstruction may preserve renal function.

If the cause of AKI cannot be reversed, then it is likely that RRT will become necessary. A number of treatment options are available, and the modality chosen will reflect clinical need together with the facilities available locally. Intermittent haemodialysis, as discussed earlier in CKD, can be used in AKI patients who are stable. Dialysis treatment will usually undertaken on alternate days or in some cases daily. If the patient is oliguric, fluid balance becomes a critical aspect of management since intermittent haemodialysis provides limited opportunity for fluid removal. For individuals with cardiovascular instability, continuous RRT (CRRT) is the most suitable mode of RRT. It provides efficient correction of blood biochemistry and the steady removal of fluid, making it suitable for treating the sickest of patients. Continuous RRT can take a number of different forms, with haemofiltration being commonly employed. This technique involves blood passing across a filter to remove waste products and electrolytes. A

sterile replacement solution infusion maintains fluid balance. Running continuously over the day, CRRT enables large volumes of fluid to be removed.

Dietetic management

The general aim is to maintain nutritional status, whilst limiting the complications of renal failure. Early intervention is preferable since the timescale is much shorter in AKI than in CKD. A patient's nutritional requirements are influenced by a number of factors, and can vary greatly between individuals (Table 7.5.10). Individualised assessment will enable the nutritional prescription to be matched to the patient's needs. It is recommended that a dietitian conducts this assessment (Renal Association, 2011a).

Acute kidney injury has no effect on an individual's energy requirements (Schneeweiss *et al.*, 1990). Even in patients with AKI and multiorgan failure, measured energy requirements are only 20% above resting values (Bouffard *et al.*, 1987). Whilst absolute protein requirements are not well documented, they are influenced by the patient's clinical condition together with any RRT that they may receive.

Common causes of non-catabolic AKI include dehydration, nephrotoxins and urinary obstruction. In these cases, protein turnover rates are not increased and daily intakes of 1.0g of protein/kg of body weight where RRT is not required, and 1.2g/kg of body weight where intermittent haemodialysis is used, are recommended (Cano *et al.*, 2006). Oral diet alone or with the addition of nutritionally dense supplementary sip feeds will frequently be sufficient to meet nutritional needs in these patients. If not, artificial nutritional support should be implemented. Wherever possible, this should be provided via the enteral route. Nutritionally dense feeds, with or without a reduced electrolyte content, are useful when the control of fluid balance and/or serum phosphate and potassium levels is an issue.

Fluid and electrolyte intake should be individualised according to blood biochemistry and fluid status. Frequent monitoring of blood biochemistry is essential to

guide provision. Indications for potassium, phosphate, sodium and fluid restriction are similar to those in CKD. However, allowing a more liberal phosphate intake may be a better management approach if it helps to promote food intake. In the short term, maintaining a good nutritional intake is more of a priority than achieving serum phosphate control. Dietary restrictions are likely to be required until renal function begins to improve. When this happens, patients may become polyuric. An increased fluid intake (adequate to cover the large urine volumes and insensible losses) should then be maintained. As serum potassium and phosphate levels normalise, any dietary restrictions can be lifted.

Causes of catabolic AKI include sepsis and trauma; protein turnover rates in these patients are increased and negative nitrogen balance results. Patients will frequently have multiorgan failure and be managed in an intensive care unit. They present complex therapeutic challenges and require a broad appreciation of the management of nutrition in critical illness. Such issues are beyond the scope of any discussion, but major considerations in relation to AKI are outlined (see also Chapter 7.17.1).

Artificial nutritional support will usually be required. Where the enteral route cannot be used, parenteral nutrition support should be considered. Energy should be provided as a balance of carbohydrate and fat since patients will have both impaired glucose tolerance and reduced lipid clearance (Druml *et al.*, 1983). Nitrogen should be sourced from a standard mixture of essential and non-essential amino acids (Brown *et al.*, 2010) as some non-essential amino acids become conditionally essential in AKI and critical illness.

During CRRT, care is needed to avoid the potential over provision of energy from hidden sources. The metabolism of glucose and lactate contained in some of the solutions used during CRRT may result in significant energy gains. This area is explored in more detail elsewhere (Hartley, 2011). Continuous RRT also has a negative influence on nutrient balance with significant losses of amino acids (Davenport & Roberts, 1989; Frankenfield *et al.*, 1993; Davies *et al.*, 1991). Protein intakes should be increased to compensate for these losses and the patient's catabolic rate (Brown *et al.*, 2010). A daily protein intake up to a maximum 1.7g/kg for hypercatabolic individuals on CRRT is currently recommended (Cano *et al.*, 2006; 2009; Renal Association, 2011a). To achieve these high protein intakes in enterally fed patients without excessive energy, protein rich supplements can be added to feeds to increase the nitrogen to calorie ratio.

Continuous RRT allows feed volumes and electrolyte intake to be liberalised; clearance rates are so great that intravenous supplementation with phosphate and other electrolytes may be required. However, technical advances have led to the development of newer solutions that should result in less supplementation being required. Frequent monitoring of blood levels is essential. Micronutrient losses on CRRT may also be significant. Documented daily ultrafiltrate losses include 100 mg of vitamin C (Bellomo & Boyce, 1993), 290 µg of folate (Fortin *et al.*, 1999), 4 mg of thiamine and 0.97 µmol (77 µg) of sele-

nium (Berger *et al.*, 2004). These losses are superimposed upon the low antioxidant status reported in AKI (Druml *et al.*, 1998; Story *et al.*, 1999). Since the losses of vitamin C, thiamine and selenium exceed the amounts provided by commonly used parenteral sources and for some of these nutrients in many enteral feeds, selective micronutrient supplementation may be needed. Cases of severe oxalosis have been reported in individuals with AKI receiving daily vitamin C supplements of 500 mg intravenously (Friedman *et al.*, 1983) or 5000 mg orally (Mashour *et al.*, 2000); megadoses of vitamins should be avoided.

7.5.2 Renal stones

Karen Thomsett and Sharon Underwood

Key points

- In developed countries 80% of renal stones are composed of calcium salts, usually calcium oxalate.
- Fluid intake is the most important factor in the dietary treatment of stones.
- Intake of calcium, protein and sodium should also be considered in the management of calcium stones.
- Evidence is limited regarding the efficacy of individual dietary components or of multicomponent dietary strategies for preventing stone recurrence.
- There is increasing evidence to show a link between obesity, metabolic syndrome and diabetes with stone formation.

In developed countries most urinary stones are renal stones; bladder stones are less common. Diagnosis is rarely difficult as the condition is painful, ranging from dull loin pain if the stone is in the renal pelvis to agonising colic if it is lodged in the ureter. Urolithiasis refers to stones originating in the urinary system, including the kidneys and bladder. Nephrolithiasis indicates the presence of calculi in the kidneys.

Generally 80% of stones are composed of calcium salts, usually calcium oxalate and less commonly calcium phos-

phate (Daudon *et al.*, 1995). The remaining 20% are composed of uric acid magnesium ammonium phosphate (struvite) or cystine. Stones with any other composition are very rare (<1% of total occurrence). Until recently, renal stones in developing countries were considered to be different from those in industrialised countries. In developing countries, phosphate and urate stones predominated. However, the epidemiology of renal stones is changing worldwide, with a predominance of calcium oxalate stones (Daudon *et al.*, 2004) (Table 7.5.11).

Table 7.5.11 Main classifications of kidney stones

Type of stone	Occurrence (%)	Composition
Calcium oxalate ± calcium phosphate	75	Calcium oxalate, calcium phosphate
Struvite (infection stones)	15	Magnesium ammonium phosphate (triple phosphate)
Pure calcium phosphate	5–7	Calcium phosphate
Uric acid	5–8	Uric acid

In the UK, kidney stones affect up to 5% of the population, with a lifetime risk of passing a kidney stone of about 8–10%. The rate doubles if there is a family member with a history of stone disease. The peak age is 20–50 years with a male to female ratio of about 2:1 (Parmar, 2004). Globally, the incidence is increasing across gender, age and race; prevalence appears to have doubled over the past 30 years and is associated with the socioeconomic status of the population. The overweight and obese are more likely to get stones (Romero *et al.*, 2010) and this association is greater in females. Kidney stones are associated with a small, but significant, increase in the risk of chronic and end stage renal disease, with young women being at greater risk (Tonelli *et al.*, 2012). Renal stones recur and the likelihood that another stone occurring within 5–7 years is 50% (Asplin *et al.*, 1996).

Stones result from nucleation; a phase change when dissolved substances become solid. This requires supersaturated urine; the greater the concentration of two ions, the more likely they are to precipitate. The concentration of ions depends on the urinary pH, ionic strength and solute concentration. Both environmental and nutritional factors have been shown to affect stone nucleation and growth by their effects on urinary constituents and pH. Nucleation is followed by retention of the initial nucleus crystal, growth, aggregation and retention (Basavaraj *et al.*, 2007).

Calcium stones

Calcium oxalate is the main component of 80% of kidney stones (Parmar, 2004). Increased urinary calcium (>300 mg/day in men and >250 mg/day in women or >4 mg/kg of body weight/day) leads to precipitation of insoluble calcium salts and inactivates urinary inhibitors. Inhibitors include citrate, magnesium and the organic substances glycosaminoglycans, prothrombin F1 fragment and Tamm–Horsfall glycoprotein. Promoters of stone formation include low urine volume, low urine pH, calcium, sodium and oxalate (Basavaraj *et al.* 2007). Anatomical factors can influence stone formation.

In 80% of cases there is no underlying cause and the stone can be described as idiopathic. In the remaining 20%, the stone is secondary to other renal factors.

Idiopathic calcium stone disease

This is a syndrome of normal plasma calcium and unexplained hypercalciuria, which is distinguished from primary hyperparathyroidism by normal serum calcium levels. There are three subtypes (Paliouras *et al.*, 2012):

- Absorptive hypercalciuria – increased urinary calcium excretion due to increased intestinal absorption.
- Renal leak hypercalciuria – a primary tubular defect leading to decreased calcium reabsorption.
- Resorptive hypercalciuria – a primary increase in bone mineral turnover.

Contributory factors include:

- *Gender* – men are particularly susceptible and account for 85% of cases.
- *Age* – idiopathic calcium stones occur most commonly occur between 20 and 49 years of age; the incidence rises in the fourth decade.
- *Ethnicity* – the risk is highest for Caucasians, followed by Asians and Hispanics, and then Blacks.
- *Low urine volume* – the risk is greater in people who do not drink sufficiently and in those who work in hot climates or conditions, as a result of the increased likelihood of dehydration.
- *Social class* – the incidence is greater in social classes I and II, possibly associated with a higher intake of dietary animal protein.
- *Dietary factors* that have been suggested to be associated include high intakes of calcium, protein, sodium and possibly vitamin D, sucrose and fructose. A low intake of fluid plays a pivotal role in stone formation, and poor intake of fibre, notably phytate, has been linked with stone formation. However, some of these associations remain equivocal.
- *Obesity* – stone formation is positively associated with a higher urinary oxalate (Taylor & Curhan, 2008b).
- *Increased intestinal absorption of calcium* – the cause is unknown but stones may result from either increased synthesis of 1,25 dihydroxycholecalciferol or the presence of calcitriol intestinal receptor sites (Dretler, 1998). Intestinal hyperabsorption of calcium raises serum calcium (remaining within the normal range), which reduces endogenous parathyroid hormone (PTH) production. This leads to decreased renal tubular reabsorption of calcium and higher urinary excretion in order to maintain a normal serum calcium level.
- *Impaired tubular reabsorption of calcium* – secondary hyperparathyroidism stimulates calcitriol synthesis and increases intestinal calcium reabsorption (Pak, 1998).
- *Hyperoxaluria* – increased urinary oxalate excretion (>45 mg/day) significantly increases stone risk. Given the low oxalate content of most common foods, a variable absorption rate and bioavailability (10–100%), and the influence on oxalate absorption and urinary oxalate excretion by other variables, e.g. fluid intake, the impact of dietary oxalate on urinary excretion remains questionable.

- *Hypocitraturia* – citrate binds to calcium anions in the tubular lumen, increasing their solubility and inhibiting the nucleation of calcium oxalate crystals. In addition, citrate also inhibits crystal aggregation and growth. Citrate excretion is regulated by urinary pH with acidosis reducing renal excretion. Dietary factors associated with hypocitraturia include a low intake of fruit and vegetables and high intake of sodium and protein. Some medications have been implicated, notably thiazide diuretics and angiotensin converting enzyme (ACE) inhibitors (Melnick *et al.*, 1998).
- *Acidic urinary pH* promotes the precipitation of calcium phosphate and, to a lesser extent, calcium oxalate.
- *Hyperuricosuria* – total urinary uric acid output is usually normal in stone formers, but the concentration is increased. This is thought to reduce the activity of urinary inhibitors.

Role of diet in idiopathic calcium stone formation

Calcium

For many years it was assumed that a high calcium intake increased the risk of stone formation. However, severe calcium restriction (<400mg/day) does not reduce the frequency of new stone formation in patients with recurrent urolithiasis and may be detrimental as negative calcium balance and secondary hyperoxaluria can occur (Parmar, 2004). A large prospective study found a 34% lower incidence of stone occurrence amongst men on a high calcium diet (Curhan *et al.*, 1993). However, this study was carried out on healthy subjects and may not be applicable to patients with existing stones. Several more recent studies have shown that an adequate calcium intake is associated with decreased stone formation. Curhan *et al.* (2004) found that in previously non-stone forming younger women, a higher intake of calcium was related to a lower risk of kidney stone formation.

Protein

The influence of excessive protein has become clearer in recent years, but the mechanism remains complex. Following a protein load there is a brief period of metabolic acidosis and, although urinary pH *per se* is not a major risk factor, calcium phosphate and, to a lesser degree, calcium oxalate are less soluble in acid conditions. Dietary protein has been found to increase oxaluria and uricosuria, which are associated with urolithiasis (Borghi *et al.*, 2002).

Sodium

Urinary sodium excretion correlates with urinary calcium excretion (Parmar, 2004). A high sodium diet increases calcium excretion and consequently the risk of stone formation. Hypercalciuric patients may be more sensitive to the calciuric effect of a sodium load. High sodium intake also increases the saturation of monosodium urate, the crystals of which can act as a basis for calcium crystallisation.

Vitamin D

The role of excessive vitamin D intake in stone formation is controversial. There is a correlation between plasma vitamin D and calcium excretion; therefore, patients should be discouraged from self medication multivitamin preparations or fish liver oil capsules containing vitamin D. However, a large epidemiological study found a lower incidence of renal stones in men with a high intake of vitamin D (Curhan *et al.*, 1993). A review by Parivar *et al.*, (1996) found that there was no conclusive evidence linking excessive dietary vitamin D intake or prolonged exposure to sunlight with a higher incidence of urolithiasis. It has been shown that combined calcium and vitamin D supplements can increase the risk of stones (Yalamanchili & Gallagher, 2012). Prospective studies are needed to clarify the relationship between vitamin D and kidney stone formation and whether nutritional vitamin D supplementation increases the risk of stone occurrence.

Fluid

A low fluid intake results in low urinary output with an increase in the concentration of ionic particles and the saturation level of various salts, increasing the likelihood of precipitation.

Fibre

There are conflicting epidemiological studies on the role of fibre intake on urolithiasis risk, largely as a result of the different definitions and analytical methods used to estimate fibre intake. Phytate binds to calcium and exhibits a strong inhibitory effect on urinary crystallisation of calcium salts such as calcium oxalate and calcium phosphate. Until further studies are conducted, no conclusions can be made on any role of fibre in stone formation.

Diagnosis of idiopathic hypercalciuria

A range of tests and assessments are required to establish the likely cause and type of stone.

24-Hour urine collection

An accurate 24-hour urine collection will provide information on the elevated amounts of excretory products. The urine must be collected while consuming the usual diet and fluid intake, and the urine quantity passed measured.

Biochemistry

Serum concentrations of calcium, sodium, oxalate, uric acid, electrolytes and PTH should be measured.

Imaging studies

These include:

- Plain X ray helps identify the composition, size and shape of stones.
- Renal ultrasonography – is frequently used as the first investigation to identify calculi.

- Computerised tomography is more sensitive and establishes the size, number and position of the stones and the extent of obstruction.
- Plain renal tomography helps identify stones not detected by other means.

Dietary history

A diet history helps to ascertain the past and present intake of all relevant nutrients to establish if hypercalciuria is due to diet or hyperabsorption. Hypercalciuria on a low or normal calcium diet (<700 mg/day) indicates hyperabsorption.

Social history

Patients should be asked about past and present occupations to establish whether their working environment is likely to have caused long periods of dehydration and/or increased insensible losses, e.g. miners, long distance lorry drivers and heavy metal workers. Caucasians who have worked abroad in a hot climate are at similar risk. Prolonged bed rest, e.g. following limb fracture, can also be a contributory cause as this results in mobilisation of calcium from the bones and leads to hypercalciuria. Previous history is important as a stone may have formed in the past and been growing slowly.

Dietary treatment of idiopathic hypercalciuria

The necessity of dietary restrictions to treat idiopathic hypercalciuria and, more importantly, to prevent the recurrence of stones is controversial.

Calcium

Calcium restriction is not indicated in patients with idiopathic hypercalciuria who have normal intestinal absorption of calcium. A decreased calcium intake will result in the preferential absorption of oxalate and increased oxaluria. Increasing dietary calcium decreases urinary oxalate excretion by binding with oxalate in the intestine (Pak *et al.*, 2005) and dietetic advice should take this into account. For example, black tea is a good source of oxalate, but adding milk (containing calcium) decreases oxalate absorption significantly. Dark chocolate increases urinary excretion of oxalate compared with milk chocolate (De O G Mendonca *et al.*, 2003).

Many studies support the theory that increasing calcium intake will beneficially decrease urinary oxalate excretion (Lemann *et al.*, 1996; Coe *et al.*, 1992). Reduced bone mineral content (BMC) has been reported in idiopathic stone formers who have been following a low calcium diet (352 ± 20 mg) for 10 years (± 0.7 years) (Fuss *et al.*, 1990a). The reduction in BMC was as pronounced as that observed in hyperparathyroid stone formers. Although comparison with normal subjects showed that idiopathic renal stone formers had lower than average BMC, whether or not they restricted calcium intake, those on a low calcium diet were found to have lower BMC in the distal radius than those on a free diet (Fuss *et al.*, 1990b). This may be due to one or more of the following causes:

- Idiopathic hypercalciuria, if not compensated by an adequate calcium supply, will lead to negative calcium balance.
- Hypophosphataemia in idiopathic renal stone formation is associated with increased resorption and decreased formation of bone.
- Elevated circulating levels of 1,25 dihydroxyvitamin D can induce bone resorption and result in negative calcium balance, especially if associated with a low calcium diet (Fuss *et al.*, 1990a).

The role of calcitriol (1,25 dihydroxycholecalciferol) remains uncertain. Studies have shown that calcitriol potentiates the loss of bone mineral by aggravating the negative calcium balance caused by a low calcium diet (Coe *et al.*, 1992). Calcitriol and its analogues are able to reduce the production of PTH, which explains the failure of serum PTH levels to rise if dietary calcium is low.

Oxalate

The majority of urinary calculi contain oxalate, which suggests that dietary oxalate intake should be reduced. However, approximately 60% of urinary oxalate is endogenous, being produced from the metabolism of glycine, glycolate and hydroxyproline or synthesised from glyoxalate metabolism (Holmes & Assimos, 1998). Normally, in hepatic peroxisomes, glyoxalate is metabolised to glycine and glycolate by alanine glyoxylate aminotransferase (AGT) and glyoxalate reductase hydroxypyruvate reductase (GRHPR), respectively. Inherited defects of these enzymes lead to oxalate hyperproduction. *Oxalobacter formigenes* (a Gram negative anaerobic enteric bacterium) assists oxalate homeostasis by using oxalate for its biosynthesis and promoting oxalate secretion. Its absence from the intestinal lumen is associated with increased oxalate absorption and oxalate calcium nephrolithiasis (Hatch *et al.*, 2006). Supplementation with ascorbic acid increases urinary oxalate levels and grapefruit juice increases excretion of both oxalate and citrate in the urine (Baxmann *et al.*, 2003).

Total oxalate is found as two main fractions, soluble and insoluble. The soluble oxalate fraction contains oxalic acid and the water soluble salts of sodium and ammonia. When bound to calcium, iron and magnesium oxalate become insoluble and absorption is limited. About 30% of ingested oxalate is degraded by anaerobic intestinal microflora, with the rest being absorbed in the small and large intestine. Absorption ranges from 10% to 100% (Grieff *et al.*, 2013).

The effectiveness of dietary restriction of oxalate alone is equivocal; restrictions should be confined to patients who normally have a high consumption of oxalate rich foods and should address other dietary recommendations, including optimising fluid intake, controlling calcium intake and reducing sodium intake (Table 7.5.12).

Body weight

Lemann *et al.* (1996) showed that weight is a major determinant of urinary oxalate excretion in healthy adults. In addition, Taylor & Curhan, (2008b) showed a relationship

Table 7.5.12 Principal dietary sources of oxalate (Kasidas & Rose, 1980; Harvard School of Public Health, 2007) There are limited data available and much of the information is conflicting. The oxalate content of food varies considerably between plants of the same species, possibly as a result of differences in soil quality, ripeness, climate or method of harvesting and storage, and methods used for analysis.

Food	Oxalic acid content (mg/100g)
Beetroot – pickled	500
Beetroot – boiled	675
Carob powder	73
Chocolate	117
Cocoa	623
Nuts – most nuts are high in oxalate*	
Almonds	435
Pecans	202
Peanuts	187
Parsley (can be used in small amounts)	100
Rhubarb	600–860
Spinach	600–750
Swiss chard	645
Tea infusion (mg/100 mL) – black tea without milk	55–78
Wheatgerm	269

*Analysis of pistachio and chestnuts show they have very low levels of gastric soluble oxalate and are suitable in moderation (Ritter *et al.*, 2007).

Foods that contain moderate amounts of oxalate and should be taken in limited quantities include berries such as gooseberries, raspberries and strawberries; okra; sweet potato; potato.

between higher weight and higher urinary oxalate. Weight, body mass index (BMI) and urinary creatinine were all positively and independently associated with urinary oxalate. Although the reasons for these associations are unclear, it is likely that endogenous oxalate production increases with body weight. Therefore, modest weight reduction in overweight stone formers may be beneficial. Weight reduction should be supervised as rapid or extreme weight gain or loss may precipitate stone development (Stoller & Bolton, 1995).

Fluid

There is consensus that an oral fluid intake sufficient to produce a urine output of at least 2L/day (ideally 3–3.5L of fluid intake) is adequate hydration for stone patients. A high intake of fluid has been shown to be effective when used as the only method of stone prevention (Borghesi *et al.*, 1996; Preminger *et al.*, 2007). A review by Kleiner (1999) stressed that dietitians should promote and monitor fluid intake among patients. The importance of extra fluids in hot weather and hot climates should be stressed. Drinking water from a water softener is not recommended as the mineral content, e.g. calcium, is reduced and the sodium is correspondingly increased.

Sodium

A high sodium intake leads to increased urinary sodium and calcium excretion due to inhibition of reabsorption in the proximal tubule and the Loop of Henle. Sodium intake should be reduced to 80–100 mmol/day and dietary intake can be monitored by urinary analysis.

Protein

A high dietary intake of protein can increase the excretion of calcium and uric acid, and decrease the excretion of citrate. Protein restriction to 0.8–1.0 g/kg/day in patients with idiopathic hypercalciuria has been shown to reduce urinary excretion of urea, calcium, uric acid and oxalate, and increase urinary citrate excretion (Giannini *et al.*, 1999). These effects are thought to be due to a reduction in bone resorption and renal loss of calcium due to the decreased exogenous acid load.

Citrate

Citrate is a naturally occurring urinary stone inhibitor that binds calcium in solution to form highly soluble calcium citrate complex. This complex decreases the ionic concentration of calcium and hence the relative saturation of calcium oxalate and calcium phosphate in the urine. However, the benefits from large intakes of citrus fruit and vegetables may be offset by the resultant hyperoxaluria caused by the consequent increased intake of dietary oxalate.

Fish oils

Eicosapentanoic acid (EPA) has been reported to decrease urinary calcium excretion in people with idiopathic hypercalciuria who have erythrocyte ion transport abnormalities and different erythrocyte membrane lipid composition compared with healthy controls (Curhan & Curhan, 1997). There may be a group of patients for whom fish oil supplementation could correct this defect; however, evidence to date is inconclusive. A study by Yasui *et al.* (2001) showed that a highly purified preparation of EPA reduced urinary calcium in patients with urinary stones. However, a prospective study found no association between the intake of n-3 fatty acids and the risk of kidney stone formation (Taylor *et al.*, 2005). Epidemiological studies demonstrated reduced incidence of nephrolithiasis associated with consumption of EPA (Dyerberg *et al.*, 1975). Eicosapentanoic acid is believed to have a protective role in the prevention of nephrolithiasis by reducing urinary calcium and oxalate excretion through alteration of prostaglandin metabolism (Ortiz-Alvarado *et al.*, 2012).

Vitamin C

Vitamin C is excreted in urine in its unmetabolised form and as oxalate. There is considerable uncertainty as to the definitive effect of vitamin C on stone formation. In a large study, there was no increased risk associated with high intakes of vitamin C (Curhan *et al.*, 1999). This contrasts with a recent prospective study that showed that the use of ascorbic acid supplements (1000 mg) increased the risk of calcium oxalate stones in men (Thomas *et al.*,

2013). This may not be generalisable to women who have a reduced risk of stone formation, but dietary advice to avoid supplemental vitamin C is prudent.

Other dietary factors

Cranberry juice

In normal subjects, 500 mL of cranberry juice for 2 weeks has been shown to decrease oxalate and phosphate excretion, while increasing citrate excretion (McHarg *et al.*, 2003). In addition, there was a decrease in the relative supersaturation of calcium oxalate, which tended to be significantly lower than that induced in the control group given water alone. The authors concluded that cranberry juice had antilithogenic properties and, as such, deserves consideration as a conservative therapeutic protocol in managing calcium oxalate urolithiasis. However, Gettman *et al.* (2005) showed that cranberry juice exerted a mixed effect on urinary stone formation; it increased the risk of calcium oxalate and uric acid stone formation, but decreased the risk of brushite (calcium phosphate) stones. Current advice should be to avoid cranberry juice and its products until further research proves otherwise. It should be noted that cranberry juice is contraindicated in patients taking warfarin (see Chapter 5.3).

Sucrose and fructose

A high sucrose intake has been shown to increase urinary calcium excretion independent of calcium intake, although the mechanism is unknown. A positive association between sucrose intake and new kidney stone formation has been shown in women but not men (Curhan *et al.*, 2004). Taylor & Curhan (2008a) prospectively examined the relationship between fructose and incident stones in women and men, and concluded that fructose intake was independently associated with an increased risk of incident kidney stones. At present, the evidence is insufficient to recommend restriction of sucrose and/or fructose *per se*. However, intake should be addressed in the context of reducing body weight and thus the incidence of the metabolic syndrome and diabetes, which are associated with stone formation.

Non-dietary treatment of idiopathic hypercalcaemia

Thiazide or hydrochlorothiazide diuretics appear to act on the renal tubules, causing greater reabsorption of calcium and restoring parathyroid function, intestinal calcium absorption and urinary calcium excretion to normal. Potassium citrate or bicarbonate, given with the thiazide, prevents hypokalaemia and improves the excretion of citrate (Pak, 1994). Potassium phosphate may suppress calcitriol synthesis and thus decrease calcium absorption (Parmar, 2004).

Secondary calcium stone disease

Secondary calcium stone disease usually results from one of the following conditions.

Primary hyperparathyroidism

The treatment of primary hyperparathyroidism is a parathyroidectomy. Parathyroid hormone levels should

always be measured when assessing patients with stones. If parathyroidectomy is delayed or unsuccessful, a low calcium diet may be prescribed to lower plasma and urine calcium levels. In some cases, surgical removal of the stone may be required.

Medullary sponge kidney

In medullary sponge kidneys, tiny cysts form in the medulla (the inner part of the kidney) causing a sponge like appearance. These cysts keep urine from flowing freely through the tubules. Hypercalcaemia, incomplete distal renal tubular acidosis and hypocitraturia are common. Increasing fluid intake is vital.

Renal tubular acidosis

This is a rare condition, caused by primary or secondary damage to the renal tubules in which acid urine cannot be produced because of a failure of bicarbonate reabsorption; therefore, calcium phosphate stones are formed. Renal tubular acidosis can be treated by alkalis and/or diet to normalise serum bicarbonate and pH. A diet rich in animal protein will increase the urinary acidity, so a reduction in animal protein intake may be helpful. Some patients may choose to make radical changes to their diet and become vegetarian or vegan to reduce their symptoms. They may require advice to ensure a nutritionally balanced diet.

Primary hyperoxaluria

Type 1 primary hyperoxaluria is an autosomal recessive condition that is caused by an inborn error of glyoxylic acid metabolism. Glyoxylic acid is normally transaminated to glycine or glycolic acid, but if the necessary enzymes are absent, oxalic acid will be produced. Two enzyme deficiencies, and hence two forms of primary hyperoxaluria, have been identified: absence of alanine glyoxylate aminotransferase (type 1) and of D-glycerate dehydrogenase (type 2). The majority of cases are type 1. Type 3 currently has no identified enzyme deficiency.

The full biochemistry of oxalic acid and glyoxylic acid metabolism is not known, but in patients with primary hyperoxaluria the production and excretion of oxalic acid is greatly increased. Calcium oxalate is insoluble so renal stones readily occur and in addition, oxalosis (systemic oxalate deposition) in the heart, bones, joints, eyes and other tissues is common. When this occurs the prognosis is very poor.

Treatment of primary hyperoxaluria comprises:

- *Pyridoxine supplements* – the only known effective treatment for primary hyperoxaluria. It is a cofactor in the alanine glyoxylate pathway and reduces oxalate production by inducing enzyme activity (Parmar, 2004). Although not all patients respond to pyridoxine, it remains the main treatment. Magnesium supplementation in conjunction with high dose pyridoxine results in reduced urinary oxalate excretion.
- *Increased fluid intake and increasing urinary volume* to 3 L/24 hours should be encouraged.
- Patients may be advised to follow a *low oxalate diet*, although there is no substantial benefit in the long

term for those with primary hyperoxaluria. A list of foods high in oxalate that should be avoided is shown in Table 7.5.12.

- In those with hypercalciuria, *oral citrate supplements*, given in conjunction with the use of thiazide diuretics is beneficial. Oral phosphate supplements may also be considered.
- *Oxalobacter formigenes* may be given orally as it degrades oxalate.
- *Dialysis* can be used to remove oxalate.
- *Combined liver and kidney, isolated liver or isolated renal transplantation* are options that may have to be considered.

Secondary hyperoxaluria

There are several causes of secondary hyperoxaluria:

- *Iatrogenic* – hyperoxaluria may occur as a result of the treatment used for idiopathic hypercalciuria.
- *Intestinal bypass, bariatric surgery and bowel disease* – enteric hyperoxaluria can result from fat malabsorption by the small bowel from any cause, including resection, e.g. ileostomy formation, intrinsic disease as seen with Crohn's disease, jejunioileal bypass and Roux-en-Y gastric bypass (Lieske *et al.*, 2008). If this results in steatorrhoea, calcium will bind with fatty acids in the gut and be unable to bind with oxalate; as a result, more oxalate will be passively absorbed. Treatment focuses on reducing dietary oxalate to reduce hyperoxaluria, and decreasing intake of fat to reduce steatorrhoea. Medium chain triglyceride oil has no effect on oxalate absorption and therefore can be used to increase energy intake if required. Oral calcium supplements have also been used to precipitate oxalate in the intestinal lumen, and cholestyramine may be used to bind fatty acids, bile acids and oxalate. Oral citrate supplements and a high fluid intake can also be beneficial.
- *Excessive vitamin C intake* (doses >1000 mg) has been implicated as a risk factor for stone formation as a result of ascorbate being metabolised to oxalate, which is then excreted in the urine.
- Vitamin D overdose will cause increased intestinal absorption of calcium.
- Prolonged immobilisation leads to bone reabsorption and consequent hypercalcaemia and hypercalciuria.

Uric acid stones

Uric acid is produced by the biochemical conversion of dietary and endogenous purines. People with diabetes are more prone to forming uric acid stones (Lieske *et al.*, 2006). Factors that lead to uric acid calculi formation include (Pak *et al.*, 2001):

- *Persistently acidic urine* – uric acid stones are associated with obesity, the metabolic syndrome and type 2 diabetes, and such patients have been found to have a lower urinary pH with a decreased rate of ammonium excretion, postulated to be due to renal tubule insulin resistance (Maalouf *et al.*, 2007).

Table 7.5.13 Principal dietary sources of purines (Clifford *et al.*, 1976; Wood, 1996)

Meat sources	Fish sources	Other sources
Liver	Anchovies	Yeast and extracts
Heart	Crab	Beer
Kidney	Fish roes	Asparagus
Sweetbreads	Herring	Cauliflower
Meat extracts, e.g. Oxo	Mackerel	Mushrooms
	Sardines	Beans and peas
	Shrimps	Spinach
	Sprats	
	Whitebait	

- *Hyperuricosuria* (>750 mg/day of uric acid).
- *Low urine volume*.

Treatment

Dietary modification

Weight loss, where applicable, is advocated with encouragement to follow a vegetarian diet that will reduce protein intake and promote urine alkalinity. A high protein intake increases the acid load that the kidneys buffer. Patients with uric acid stone disease have a defect in the production of this buffer, resulting in acidic urine, which increases the amount of less soluble uric acid. Elderly people often have a defect in this buffering process and hence have a higher incidence of uric acid stones (Rodman, 1991). Therefore, it is wise to recommend a decrease in protein consumption for all stone formers; particularly sources of protein that also have high purine content.

Patients should be advised to avoid foods rich in purine (Table 7.5.13). However, the necessity for severe restriction has been superseded by the use of allopurinol, and potassium citrate can be given to increase urinary pH and so prevent precipitation of uric acid (Parmar, 2004).

Fluid intake

As with all types of stones, a high fluid intake, sufficient to produce a daily urine output of at least 2L is desirable. Patients with chronic diarrhoea or high ileostomy outputs have an increased risk of uric acid stones due to the loss of fluid and alkali that allows uric acid supersaturation. In patients with chronic diarrhoea syndromes, the use of potassium salts to replace alkali can cause intestinal irritation and therefore sodium bicarbonate may be the preferred treatment. The aim is to reach a urine pH of above 6 when uric acid is unlikely to be supersaturated. In patients with an ileostomy, the amount of fluid required to maintain an adequate urine output may result in excessive stoma output; a balance may have to be achieved between the two.

Potassium or sodium citrate

These are used to increase urinary pH to 6–6.5, but are often contraindicated in end stage kidney disease due to a risk of hyperkalaemia and disorders of coagulation.

Allergic reactions, e.g. skin rash, are common. The use of sodium citrate is counter intuitive due to sodium's association with an increased risk of stone formation.

Struvite (infection) stones

These stones contain magnesium ammonium phosphate and calcium phosphate, and are more common in women than men. Recurrent infection of the urinary tract with a urea splitting organism and anatomical predisposition are the main causes. The organisms break down urea, producing ammonia and resulting in more alkaline urine. Magnesium ammonium phosphate and calcium phosphate are extremely insoluble in alkaline conditions and once urinary pH exceeds 7.2, struvite will precipitate spontaneously with a rapid rate of growth. Staghorn, a calcareous cast of the collecting system, is a common feature of this stone type (Moe, 2006).

Treatment

Diet has no role in the treatment of struvite stones.

Surgery

The best treatment of struvite calculi is stone removal. However, bacterial penetration of small residual calculi may still occur and long term antibiotics will be required.

Eradication of the infection

The best prevention for struvite calculi is to eradicate the source of the infection by antimicrobial therapy. After clearance of the struvite calculi, 3 months of oral culture specific antibiotic treatment is recommended.

Urease inhibitor

It has been shown that it is possible to inhibit the action of the urea splitting enzyme urease in the bacteria in the kidney, thus preventing ammonia release, by using acetohydroxamic acid (1g/day). Data on usage for 2 or more years do not show a sufficient significant difference between patients and controls to recommend treatment for all patients. The inhibitor must be given with antibiotics as it has no antibacterial effect. Approximately 20–30% of patients are unable to tolerate acetohydroxamic acid because of side effects, including deep vein thrombosis and haemolytic anaemia (Parmar, 2004).

Cystine stones

Cystine stones occur in a very rare autosomal recessive genetic disorder affecting the renal tubular reabsorption of cystine, arginine and ornithine, and resulting in increased concentration of cystine in the urine (Table 7.5.14). Cystine is relatively insoluble in urine, with a limit of solubility at pH 7.5 and 37°C of 243mg/L (Coe *et al.*, 2005), so homozygous cystinurics readily precipitate cystine and stone episodes in this population usually occur by 20 years of age. Heterozygotes (asymptomatic carriers) may excrete up to 10 times as much cystine as normal, but do not form cystine stones.

Table 7.5.14 Urinary concentration of cystine

Patient group	Cystine concentration (μmol/L)
Normal	10–100
Heterozygous cystinurics	200–600
Homozygous cystinurics	1400–4200

Treatment

Dilution of urine

The patient should be advised to drink enough fluid to pass at least 3L of urine/day. A fluid plan should be advised to ensure an adequate regular intake, particularly at bedtime and during the night. This treatment is seen as a very simple way of preventing recurrence of stones but in practice, compliance can be difficult. Salt restriction significantly reduces urinary cystine excretion (Jaeger *et al.*, 1986). Care should be taken that hyponatraemia does not result from very high fluid intake.

Alkalinisation of urine

Urine alkalinisation with citrate increases the solubility of cystine and may decrease stone formation (Anderton, 1998). Potassium citrate is preferred to sodium citrate or sodium bicarbonate if sodium restriction is imposed concurrently. Urine alkalinisation may be used when penicillamine therapy is not well tolerated.

Medication

The sulphhydryl group in the chelating agent D-penicillamine reacts with cystine to form a more soluble complex in urine. The treatment carries a high risk of side effects, including rashes, thrombocytopenia, neutropenia, proteinuria and nephrotic syndrome. Alpha-mercaptopyropionylglycine (α -MPG) or mercaptamine has been used as an alternative to penicillamine. It has similar side effects but is better tolerated (Lindell *et al.*, 1995). Captopril is used as it forms captopril-cystine disulphide, which is 200 times more soluble than cystine. However, its effectiveness in the treatment of cystinuria has not been consistently shown (Sloand & Izzo, 1987).

Diet

Salt restriction reduces cystine excretion (Rodriguez *et al.*, 1995) so a no added salt diet (80–100mmol/day) or lower should be advised. Further dietary treatment is a last resort. Restriction of animal protein is associated with reduction in intake of the cystine precursor methionine as well as cystine, so a diet low in methionine will reduce urinary cystine. However, such a diet is restrictive and difficult to follow because animal protein from meat, fish, cheese, eggs and milk has to be limited to 30g/day. Additional protein requirements must be met from vegetable protein.

Melamine stones

In 2008, 294 000 infants in China were affected by melamine contaminated infant formula with 5000 hospitalised and six deaths. Melamine was used as a nitrogen bulking agent to artificially increase the apparent protein content. Renal damage was thought to be the result of kidney stones formed from melamine and uric acid or from melamine and its cocrystallising chemical derivative, cyanuric acid (Zheng *et al.*, 2013).

Ketogenic diet

Nephrolithiasis has been observed in children receiving the ketogenic diet. The prevalence ranges from 3% to 10%, in comparison to one in several thousand in the general population. Analysis of the stones shows a varied picture, with uric acid stones predominating (Furth *et al.*, 2000). Major causative factors include hypercalciuria due to increased bone demineralisation with acidosis, hypocitraturia and acidic urine (see Chapter 3.8).

7.6

Neurological disease

7.6.1 Parkinson's disease

Karen Green

Key points

- Parkinson's disease (PD) is a progressive neurodegenerative disorder and the most common form of parkinsonism.
- Parkinson's disease can have a considerable impact on nutritional intake as a result of both the effects of the disease and side effects of drug treatment.
- Nutritional inadequacies should be identified and corrected as early as possible. Dietetic intervention may be necessary to prevent undesirable weight gain or loss.
- Up to 95% of people with PD will develop swallowing difficulties that need to be addressed promptly by the dietitian and speech and language therapist to prevent weight loss and malnutrition.

Parkinson's disease (PD) is a chronic and relentlessly progressive neurodegenerative disease; it is the primary and most common form of parkinsonism. Parkinsonism is an umbrella term used to cover a range of conditions, which share the main symptoms of slow movement, possible tremor, rigidity and problems with walking [Parkinson's UK (PUK), 2011]. The prevalence of PD in Europe has been estimated at between one in every 800 and one in every 1500 population (von Campenhausen *et al.*, 2005); in the UK, one in every 500 people has PD. This currently equates to approximately 120 000 people in the UK (PUK, 2011). It is characterised by the signs and symptoms listed in Table 7.6.1, which can be remembered by the mnemonic TRAP.

Other motor symptoms include hypomimia (lack of facial expression), dysarthria (speech difficulty), dysphagia, sialorrhoea (excessive secretion of saliva) and poor manual dexterity. Non-motor symptoms include cognitive impairment, depression, dementia, sleep disorders, orthostatic hypotension, fatigue and olfactory dysfunction (loss of taste and smell function). Gastrointestinal dysfunction is receiving increasing attention and recognition as an important clinical component of PD (Pfeiffer,

2011). These symptoms are usually more apparent in the advanced stages of the disease.

Diagnostic criteria and classification

Onset of PD at ages over 50 years is considered to be late onsets PD. Around 5–10% of individuals are diagnosed before the age of 50 years. Parkinson's disease is classified as juvenile onset when diagnosed under the age of 20 years, or early onset when diagnosed between 20 and 50 years of age (Calne, 2001).

Disease process

Part of the disease process develops as cells are destroyed (by an unknown trigger or event) in parts of the brain stem, particularly the crescent shaped cell mass known as the substantia nigra. Nerve cells in the substantia nigra send out fibres to tissue located in both sides of the brain. There the cells release an essential neurotransmitter known as dopamine that helps control movement and coordination (Lang & Lozano, 1998). Loss of dopamine in the corpus stratia is the primary defect in PD, and

Table 7.6.1 Signs and symptoms of Parkinson's disease (PD)

Feature (TRAP)	Description	Effect
Tremor at rest	Involuntary shaking of the upper and lower limbs, e.g. hands, fingers and legs. Classical PD tremor is the pill rolling tremor	It is most apparent when the affected part is at rest or the person is under stress Although tremor is rarely disabling, it is one of the symptoms that bothers patients most
Rigidity	Muscles remain in a constantly contracted state, causing symptoms such as muscle stiffness, weakness or aching	Patients are less aware of impaired movement but this may be obvious to a carer, e.g. raising the patient's arm results in ratchet-like jerky movements (cogwheel rigidity)
Akinesia	Slowness of movement, which is often the most disabling feature of the disease	Normal activities such as washing and dressing may take hours There may also be slowness in speech and delayed reaction to conversation
Postural instability	Impaired balance and coordination result in general unsteadiness in movement, particularly while turning; and increased risk of falls	Patients often develop a forward lean or sometimes a stooped posture with the head bowed and the shoulders dropped Gait disturbance becomes more obvious; some patients may halt in mid stride, sometimes toppling over as a result, others may shuffle along with knees flexed and ultimately some may be unable to walk unaided

symptoms usually appear when at least 80% of the dopamine is lost. As a result, dopamine deficiency affects the nerves and muscles controlling movement and coordination, and may also be responsible for associated cognitive decline.

Genetics

It has been reported that men are more likely to develop PD than women (Baldereschi *et al.*, 2000). A prospective study showed men were 1.5 times more likely than women to develop PD (Alves *et al.*, 2009). The genetic components of some forms of PD have been identified, and it can be inherited in both a recessive and dominant manner.

Disease consequences

Parkinson's disease is associated with disability, morbidity, institutionalisation, high demand on healthcare input and mortality (Mutch *et al.*, 1986; Shulman *et al.*, 2001; Parashos *et al.*, 2002; Elbaz *et al.*, 2002; Leibson *et al.*, 2006; Aarsland *et al.*, 2009). Due to the progressive nature of the disease, it is generally expected that the signs and symptoms of the disease will become more pronounced each year. The natural history of PD is very variable and it is extremely difficult to accurately predict how, or how quickly, the disease will progress in a specific individual. However, Poewe & Wenning (1996) reported that approximately 80% of people who are diagnosed late will become significantly disabled or die within 10–14 years of diagnosis.

Public health aspects and prevention

Although the cause of PD remains unknown, a number of factors that increase the risk of developing this disease have been identified, including early diet, genetics and environment. Other factors that may prevent or slow

down PD development and progression have also been found, e.g. antioxidants, levodopa and non-steroidal anti-inflammatory drugs (NSAID). Free radicals, unstable and potentially damaging molecules generated by normal chemical reactions in the body, are thought to contribute to nerve cell death, thereby leading to PD (Dexter *et al.*, 1994; Alam *et al.*, 1997). In normal circumstances free radical damage is kept under control by antioxidants that protect cells from this damage. Vitamins E and C, coenzyme Q10 (CoQ10), nicotinamide adenine dinucleotide (NADH) and Ginkgo biloba have been shown to have antioxidant properties and it has been speculated that their supplementation may provide some protection against PD (Beal, 1998; Fariss & Zhang, 2003; Etminan *et al.*, 2005). However, to date, there is limited research to support these claims.

Nutritional consequences

The symptoms associated with PD vary from individual to individual; therefore, each individual will experience varying degrees of nutritional inadequacies as a consequence of the disease. Some of the most commonly reported nutritional consequences of the disease are discussed below.

Weight loss

This is a major feature of the disease, whether it is progressive weight loss or obvious malnutrition. Approximately half of all sufferers will experience unintentional weight loss and about three-quarters will experience eating difficulties of some kind (Cushing *et al.*, 2002; Palhagen *et al.*, 2005). It has been reported that women are more prone to weight loss than men (Durrieu *et al.*, 1992). Weight loss can result from reduced energy intake, which has been attributed to increased lethargy, olfactory dysfunction, dysphagia and gastrointestinal dysfunction. In addition, the decline in cognition can lead to lowered

energy intake by affecting interest in food and eating habits. Cognitive impairment in PD can vary depending on which part of the brain is impaired and the timing of onset and progression of the disease (Stennis Watson & Leverenz, 2010). Beyer *et al.* (1995) found that as the disease progresses, individuals with PD were four times more likely to lose 4.5 kg more than age matched controls. This is mainly attributed to subtle chronic rather than acute bouts of energy imbalance in the form of decreased energy intake (Toth, 1999).

The nutritional effects of poor food intake may also be exacerbated by increased energy expenditure as a result of tremor or rigidity (Levi *et al.*, 1990) although one study found that resting energy expenditure (REE) was 15% lower in PD patients compared with healthy controls due to decreased physical activity (Toth, 1999). However, dyskinesia can use up more energy than the PD patient consumes and this can contribute to severe weight loss, possibly as a result of increased energy consumption by skeletal muscle.

Up to 95% of people with PD will develop swallowing difficulties (Logemann *et al.*, 1997). This needs to be addressed promptly by both the dietitian and speech and language therapist to prevent and/or treat weight loss and malnutrition as appropriate. The risk of aspiration is often overlooked in people living with PD and as a consequence, pneumonia is a commonly reported cause of death in this group (Robbins *et al.*, 2008; Miller *et al.*, 2009a,b).

The on-off syndrome can occur in patients on long term antiparkinsonian medication, which causes sudden alterations in or loss of functional ability. The main feature of the off period is increased muscle tone (rigidity), and of the on period, increased involuntary movements (dyskinesias). Off periods, also known as motor fluctuations, are unpredictable and may last for a few minutes or many hours. Drug adjustment is often titrated in an attempt to overcome this problem; however, at some stage this syndrome affects the patient's ability to prepare meals and, feed themselves, and thereby increases the risk of the patient developing malnutrition, leading to weight loss.

Autonomic failure

Autonomic failure has been found in 47% of patients with PD (Allcock *et al.*, 2004) and the associated symptoms can impact on the maintenance of appropriate nutritional intake. For further details of the mechanism of autonomic failure and its nutritional consequences and dietary management, see Chapter 7.6.3.

Bone health and osteoporosis

Hypovitaminosis D is highly prevalent in people living with PD (Sato *et al.*, 1997; Evatt *et al.*, 2008) and disease severity and bone density have been shown to be correlated (Sato *et al.*, 1997). Patients with PD have been found to have a defect in the renal synthesis of 1,25 dihydroxy vitamin D (1,25 [OH]₂D) (Jackson *et al.*, 2007). Some researchers have suggested that people living with PD should be supplemented with 1 alpha hydroxyvitamin D3 (vitamin D3), the more active form of vitamin D,

which can help increase bone density and dramatically lower the risk of fracture in these patients (Boonen *et al.*, 2007). This is essential for patients who are bed bound or immobile. Calcium and vitamin D status should therefore be assessed early in the disease to prevent or decrease the incidence of osteoporosis.

Constipation

This is a commonly reported feature of PD (Cassani *et al.*, 2011), with the number of PD patients experiencing constipation ranging from 20% to 89% (Edwards *et al.*, 1991; Stocchi *et al.*, 2000; Siddiqui *et al.*, 2002; Kaye *et al.*, 2006). It is thought that constipation occurs as a result of:

- Reduced peristalsis causing delayed gut transit time.
- Lack of fibre intake due to difficulties chewing fibrous foods.
- Lack of fibre when following a texture modified diet, e.g. puréed food.
- Lack of fluid intake as a response to problems with urgency and frequency of micturition or incontinence.
- Reduced mobility.
- Side effect of some antiparkinsonian medications.

Weight gain

In contrast to the weight loss that develops as part of this disease itself, weight gain has been noted to occur following deep brain stimulation surgery (DBS) (Tuite *et al.*, 2005). Sauleau *et al.* (2009) found that 38% of their patient group was overweight, with a body mass index (BMI) of 26–29.9 kg/m² 6 months post DBS. This was attributed to the improvement in motor control, rather than improvement in energy intake. Weight gain may also occur in individuals treated with dopaminergic agonists, sometimes as a result of impulse control difficulty with compulsive eating (Nirenberg & Waters, 2006). For further information about DBS, see Clinical management later.

Nutritional assessment

Nutritional assessment should include the following aspects.

Anthropometry

Weight, height, BMI and Malnutrition Universal Screening Tool ('MUST') score (or an alternative validated nutritional screening tool) are used to determine nutritional status, and baseline measurements recorded to allow progress to be monitored. Other measurements, e.g. mid upper arm circumference (MUAC), should be considered, although severe rigidity or motor fluctuations may make these impossible.

Biochemistry

There are no specific tests that track the progress of PD; however, during periods of illness in a hospital setting,

e.g. aspiration, inflammatory markers will help monitor the clinical status of the patient.

Clinical assessment

Clinical observations will vary depending on the setting in which patients are treated. However, it is worth noting fluid balance (dehydrated or overloaded), bowel movements (frequency and consistency), temperature (apyrexial or pyrexial), swallowing difficulties, motor function (on-off periods) and drug regimens. Consider any comorbidity when devising an individually tailored care plan.

Dietary assessment

Food charts in a hospital setting or food diaries in a community setting are important. There may be difficulties communicating with the patient for various reasons, including on-off periods, speech difficulties or poor memory due to dementia. The appropriateness of the method of nutritional support the individual is currently receiving and their tolerance to the prescribed regimen should be considered. This will help when devising and updating the care plan. Focus should be on total energy intake versus requirements, and any food avoidance or changes to dietary intake should be noted.

Economic and social assessment

Links with carers and community teams who are involved in the patient's care at all levels should be made where appropriate to ensure streamlined holistic care. The focus should be living arrangements, and difficulties with obtaining food, meal preparation and cooking.

Management

Clinical management

Although there is no treatment capable of slowing or stopping the progression of the disease, current treatments can effectively relieve the symptoms, especially in the early years. Many people who are adequately treated notice very little or no progression of symptoms over the first few years. However, within 5–10 years of onset, symptoms will disrupt activities of daily living (ADL). Clinical management is therefore directed at minimising the symptoms and disabilities of the patient.

Drug management

The type of medication used varies between individuals according to the nature and severity of symptoms. Many of the available medications have significant side effects; therefore, the aim of drug therapy is to find a balance between effective symptom control and avoidance of side effects. The following are commonly used drugs in the management of PD:

- Levodopa – Madopar® (co-beneldopa), Sinemet® (co-careldopa), Stalevo® and Duodopa®.

- Dopamine agonists – Ropinirole®, Cabergoline®, Apomorphine®.
- Selegiline.
- Anticholinergics: Benhexol®, Orphenadrine®, Bztropine®.
- Amantidine.
- Catechol-O-methyltransferase (COMT) inhibitors – Entacapone®, Tolcapone®.

Levodopa is used to replace or mimic dopamine in the brain and, in conjunction with COMT inhibitors, to limit the conversion of levodopa to dopamine in the peripheral tissues, thereby facilitating a greater proportion of levodopa to cross the blood–brain barrier. Dopamine agonists, which mimic dopamine, are usually the first drugs prescribed for those diagnosed with juvenile onset PD (Uitti *et al.*, 1999). It is also used alongside levodopa. The efficiency of drug therapy tends to diminish with time and the duration of benefit after each dose becomes progressively shorter; this is known as end dose failure.

Surgical procedures

Deep brain stimulation is a surgical procedure used to treat the debilitating symptoms of PD, such as tremor, rigidity, stiffness, slowed movement and walking problems. Currently, the procedure is used only for patients whose symptoms cannot be adequately controlled with medications. It uses a surgically implanted, battery operated medical device, a neurostimulator, which is likened to a heart pacemaker and about the size of a stopwatch. It delivers electrical stimulation to targeted areas in the brain that control movement, blocking the abnormal nerve signals that cause tremor and PD symptoms. Research is ongoing to ascertain the effectiveness of DBS in the longer term.

Nutrition management

Both the treatment and effects of PD may compromise nutritional intake and nutrition management aims to:

- Identify nutritional inadequacies at an early stage.
- Implement measures to correct deficiencies or nutrition related problems.
- Find ways to minimise any practical difficulties associated with eating or swallowing.
- Prevent undesirable weight gain or loss.
- Lessen the impact of drug therapy side effects on dietary intake.
- Regular monitoring of nutritional status throughout the progression of the disease.

No special diet is required for PD in the early stages of the disease; however, it is important to establish and maintain good eating habits throughout the course of the condition (Glynn, 2003). Information should be provided on how to adopt the Healthy Eating Guidelines (Food Standards Agency) (see Chapter 4.2) and incorporated by Parkinson's UK into its booklet *Diet and Parkinson's*; this will help prevent undesirable weight gain.

As the disease progresses, more specific diet therapy may be needed to help overcome problems that affect nutritional intake and status.

Weight loss and poor oral intake

Guidance on how to optimise nutrient intake with nutrient dense foods, food fortification measures or imaginative use of nutritional supplements may be necessary. Other strategies to help overcome problems such as anorexia, sensory impairment and fatigue may also be helpful (see Chapter 6.3). Due to a lack of research on energy requirements in PD, advice is based on best practice and clinical experience. It is not unheard of for patients exceeding 3000 kcal/day to maintain an ideal weight, and others lose weight. Calculating requirements is based on Schofield's equation. Weight gain factors range from 600 to 1000 kcal in addition to basal metabolic rate (BMR) to promote weight gain, if necessary, or 25–35 kcal/kg ideal body weight (NICE, 2006b), especially in underweight patients.

Dysphagia

As stated earlier, this problem needs to be addressed promptly to prevent weight loss and malnutrition. Significant problems with swallowing require expert assessment from a speech and language therapist and guidance regarding food texture modification (see Chapter 7.3). If altered texture diets, e.g. puréed diets, may be nutritionally inadequate and not sufficiently energy dense to meet the patient's nutritional requirements, additional use of energy dense nutritional supplements may be indicated to prevent weight loss. However, these may be contraindicated in patients who require thickened fluids. Prethickened nutritional supplements available on the market include Fresubin Thickened Stage 1 & 2 (1.5 kcal/mL) (Fresenius Kabi) and Nutilis Complete Stage 1 (2.4 kcal/mL) (Nutricia), and would benefit patients with dysphagia and weight loss.

Bone health

Evidence suggests that people living with PD should be routinely supplemented with 1000–1500 mg of calcium (e.g. Calchicew) and 10–15 µg (400–600 IU) of vitamin D (Ad-Cal D3 Forte) daily (Sato *et al.*, 2001). However, more recent research has proposed that these older studies used low cut-offs to define vitamin D deficiency, and that intake should exceed 20 µg (800 IU) of vitamin D to prevent falls and for optimal skeletal health (Bischoff-Ferrari *et al.*, 2006; Knekt *et al.*, 2010). Dietary sources of calcium and vitamin D should also be encouraged if possible. The treating neurologist should know if patients want to increase their vitamin D beyond current guidelines, and agree this with them.

Constipation

Dietary advice is aimed primarily at softening and increasing the bulk of the stool. This should be the first treatment strategy and it usually works in most PD patients.

Fluid

Patients should drink a minimum of 1.2 L (six to eight glasses) of fluid/day as a minimum and in addition to water provided by food. Factors such as physical activity, age and weather can affect this requirement. Fluids that can be suggested are water, cordial fruit juice, prune juice, vegetable juice, tea, coffee, smoothies and drinking yoghurt. People living with PD often have a weaker sense of thirst and, if necessary, should be helped and encouraged to drink at regular intervals throughout the day.

Fibre

Fibre rich foods that are easy to manage, e.g. high fibre breakfast cereals, wholemeal bread, easy to peel fruit (e.g. bananas or satsumas), dried fruit and golden linseeds are suitable. Golden linseeds should be introduced into the diet slowly, e.g. start with 1 teaspoon/day up to maximum of 1 tablespoon/day over a week, and can be added to foods such as breakfast cereal, yoghurts or soups. The use of vegetables, peas, beans and lentils as meal components should be encouraged. The common practice of adding bran to foods should not be encouraged, as this is more likely to create problems than solve them. Advice on increasing fibre (18–24 g/day) and fluid (up to 2.5 L/day) simultaneously should be given to prevent exacerbating symptoms of constipation.

Protein manipulation

Advising advanced PD patients with motor fluctuations to manipulate protein consumption has become very common. This practice in any form, i.e. protein restriction, reduction or redistribution, is not supported by convincing and well designed randomised controlled trials. Most of the evidence comes from small pilot trials. It is well documented that patients who follow a protein restricted diet (PRD) experience an increase in total energy expenditure (Barichella *et al.*, 2007; Cereda *et al.*, 2009), resulting in weight loss over time (Riley & Lang, 1988; Paré *et al.*, 1992; Barichella *et al.*, 2006). The long term adequacy of protein controlled dietary regimens has not been established. Protein requirements are based on more than 0.8 g of protein/kg of ideal body weight (IBW) (Wolfe *et al.*, 2008) or using the dietary reference values. Timing of medications around meal times should be addressed to avoid protein–levodopa interaction.

In the absence of curative treatment, the management of PD remains largely palliative despite the huge advances that have been achieved in medical knowledge. The National Institute for Health and Care Excellence (NICE, 2006a) advises, '*Palliative care should be applied throughout the course of the disease and not limited to the terminal end of life period*'. Achievement of best quality of life for patients and their carers and families is the goal of palliative care. The palliative stage of the disease is defined by:

- Inability to tolerate dopaminergic therapy.
- Unsuitable for surgery, e.g. DBS.
- Presence of advanced comorbidity (MacMahon & Thomas, 1998).

Medication may be stopped due to lack of drug efficacy and increasing sensitivity to side effects such as hallucinations. Active and aggressive nutritional support may also be withdrawn if it causes discomfort or distress. Regular contact with the palliative care team is advised at this stage and it is very important that there is good, effective and open communication within the multidisciplinary team (see Chapter 7.16).

Drug–nutrient interactions

Levodopa (L-dopa) and protein

Large neutral amino acids in dietary proteins compete with L-dopa for intestinal absorption and transport across the blood–brain barrier. This limits L-dopa's efficacy and is responsible for the occurrence of motor fluctuations. Taking levodopa 45 minutes before meals, with a carbohydrate such as a cracker or a biscuit, can help to stop this happening. Reducing the amount of protein is not advised as it is an important part of a balanced diet.

7.6.2 Motor neurone disease

Elaine Cawadias and Alan Rio

Key points

- Motor neurone disease (MND) patients require coordinated care from a multidisciplinary team that includes dietetic expertise. Nutritional assessment, guidance and monitoring should commence at the earliest possible stage of the disease.
- Body weight loss of greater than 10% from prediagnosis weight is a clinical indicator for oral nutritional supplementation.
- Clinical indicators for gastrostomy are dysphagia, weight loss and inadequate energy intake; if indicated, it should be started early in the disease course.
- Prior to gastrostomy placement, MND patients require detailed assessment by the multidisciplinary team to assess the benefits and risks.
- Patients with respiratory failure require acclimatisation to non-invasive positive pressure ventilation before gastrostomy.

Motor neurone disease (MND), also known as amyotrophic lateral sclerosis (ALS), is the name given to a group of closely related disorders characterised by degeneration of the motor neurones in the brain, brain stem and spinal cord. This degeneration leads to weakness and wasting of muscles. Early symptoms of MND include awkwardness in fine finger movement and dexterity, wasting in the limbs, foot drop, neck weakness and stiffness in the fingers. Cramping and fasciculations (muscle twitches) in the forearm, upper arm and shoulder girdle may also appear.

As symptoms progress, hand, arm or leg weakness, together with generalised hyperflexia (increased reflex action), can occur. Abductors, adductors and extensors of fingers and thumb become weak, giving rise to the appearance of the skeletal hand. Over time, upper limb weakness may progress to leave the patient with flail arm syndrome; in some patients, spasticity of the limbs may develop. The disease can also affect the neck, tongue, pharyngeal and laryngeal muscles, leading to dysphagia.

The course of the illness, irrespective of its site of onset and pattern of evolution, is progressive. The disease is quite variable with no two people having the same illness trajectory or experiences. It does not affect the senses, and touch, taste, sight, smell and hearing are all preserved. Cognitive function usually remains intact but there is increasing evidence of a dementia component or frontotemporal dementia (FTD), which may have implications for patient decision making and choices concerning treatment options and interventions. Criteria for the diagnosis of FTD syndromes in ALS have been proposed (Strong *et al.*, 2009).

The progression of the disease can be profound and highly distressing for patients and carers; support and forward planning are key elements of care. As the disease accelerates, physical tasks, speech, swallowing and ultimately breathing may become affected. The course of the disease varies according to the site of onset but prognosis is poor, with survival estimated at 2–5 years from symptom onset. In some patients the disease progression is rapid and survival may only be a matter of months. Death is usually due to ventilatory failure (Victor & Ropper, 2001).

Motor neurone disease can affect any adult at any age, the highest incidence being in the 50–70-year age range, with males affected slightly more frequently than females. The incidence of MND in the UK is approximately 2 per 100 000 and prevalence is about 7 per 100 000. Current estimates suggest that approximately 5000 people in the UK have MND (MNDA, 2000).

The cause of MND is unknown in 90–95% of cases and is termed sporadic. Approximately 5–10% of patients will have the familial form of MND (FALS). A number of genetic mutations have been identified, including *SOD1*, *TDP43* and *FUS*. About 20% of FALS is caused by the *SOD1* mutation, with the remaining known mutations accounting for about 65%. The most common inheritance pattern for FALS is autosomal dominant, with each offspring having a 50% chance of inheriting the gene.

Types

The physical effects of the disease depend on which motor neurones are affected. Neurological lesions may primarily occur in the upper motor neurones (from the brain to the spinal cord, termed bulbar onset and affecting swallowing function), lower motor neurones (from the spinal cord to muscles, termed spinal onset and affecting limbs) or both.

It can be difficult to diagnose MND in the early stages as its initial symptoms may be indistinguishable from those of other neurological disorders. Diagnosis can therefore take up to 18 months due to the complexity of the investigations and the need for an accurate diagnosis. Clinical diagnostic tools include electromyography (EMG), nerve conduction studies (NCS), physical neurological examination, magnetic resonance imaging (MRI) and cerebral spinal fluid protein (Leigh *et al.*, 2003). The El Escorial criteria for ALS/MND are often used, with certainty of diagnosis being termed as clinically possible, probable or definitive (World Federation of Neurology Research Group on Neuromuscular Disease, 1994). Motor neurone disease is broadly classified into the following types, although as the disease progresses they become less distinguishable and may overlap.

Amyotrophic lateral sclerosis

This is the most common form of the disease (about two-thirds of cases), typically occurring between 40 and 70 years of age. It involves both upper and lower motor neurone lesions causing muscle weakness and wasting, spasticity (stiffness), hyperactive reflexes (jerking of limbs) and fasciculations. Bulbar onset ALS is seen in about 20% of cases. Symptoms include changes in speech (articulation, volume) and swallowing (food and/or fluids). Limb onset is more common, with symptoms including foot drop, leg, hand or arm weakness. Most patients with limb onset will eventually develop some bulbar symptoms. Survival time from diagnosis is approximately 2–5 years, though 8–10% survive 10 years (Mitsumoto & Munsat, 2001).

Progressive muscular atrophy

This is a rarer form of the disease, accounting for only about 7.5% of MND cases. It tends to occur at a younger age (often below the age of 50 years) and is much more common in men than women (ratio of 3–4:1). It is predominantly a degeneration of lower motor neurones causing:

- Diminished or absent tendon reflexes.
- Muscle weakness and wasting.
- Fasciculation, often starting in the small muscles of one hand.
- Weight loss.

The 5-year survival time is 72% in patients with onset under the age of 50 years and 40% in those with onset over the age of 50 years.

Table 7.6.2 Multidisciplinary team roles in the management of motor neurone disease

Team member	Role
Dietitian	Nutritional support, texture modification, artificial nutrition and hydration, tube feeding and aftercare, continuing support
Speech and language therapist	Speech and swallow assessment, assisted communication aides, texture modification, postural modification for safe feeding, liaison with team regarding timing of alternative feeding methods
Clinical nurse specialist	Educational role, symptom management control, psychological support, coordinated patient care, liaison with community team, advice on tube feeding aftercare
Occupational therapist	Assessment of functional ability, adaptive aides including cutlery and feeding devices, advice on moving and hoisting, support with adjusting to changing lifestyle
Physiotherapist	Exercise, mobility, head support, neck collar, assisted cough, respiratory care including chest clearance and NIPPV use
District nurse	Continuing support, nursing care, feeding tube care, medication, liaison with palliative care and hospice teams
Pharmacist	Medication, alternative methods of administration, i.e. oral versus tube, solid/crushed/liquid, side effects

NIPPV, non-invasive positive pressure ventilation.

Progressive bulbar palsy

This accounts for about 20–25% of cases of MND, mostly occurring in people between the ages of 50 and 70 years, and it is slightly more common in women than men. Progressive bulbar palsy (PBP) affects the upper motor neurones and causes paralysis of the bulbar muscles that control speech, chewing and swallowing. Therefore, it tends to present in a different way from the above two forms of the disease. There is debate about whether PBP is a subtype of ALS or a separate disease; however, about 25% of patients with PBP will progress to ALS (Swash & Desai, 2000). Early symptoms are:

- Slurred or nasal type speech.
- Tongue atrophy with or without fasciculations.
- Pharyngeal weakness.
- Emotional lability.
- Choking on certain foods.

Progression is often rapid, with median survival time from diagnosis being 2–3 years; such rapid progression may have implications for nutritional support.

Primary lateral sclerosis

This is an extremely rare type of MND but with an unknown prevalence. It affects the corticospinal tracts that travel from the brain and are responsible for movement (upper motor neurones). Any part of the body can be affected in primary lateral sclerosis (PLS) and changes include brisk reflexes, increased muscle tone at rest and spasticity. Age of onset is typically in the 50s and is unrelated to the speed of progression of the disease. Unlike most forms of MND, the lifespan of the PLS patient is essentially normal. However, it may progress to MND ALS after a significant period of time, e.g. more than 25 years post PLS diagnosis.

Management

There is no cure for MND and management is targeted at changes in nutrition, respiration and physical functions, and includes supportive measures such as non-invasive positive pressure ventilation (NIPPV) and gastrostomy feeding. Riluzole, which acts by inhibiting the release of glutamate and protecting cells from glutamate mediated damage, is the only National Institute for Health and Care Excellence (NICE) approved drug for MND. It extends survival by about 3 months, primarily in the early stages of the disease. Unlike some neurodegenerative disorders, there is no remission in MND, although there may be temporary plateaus during which no further deterioration occurs.

Multidisciplinary care is crucial, with forward planning and good communication within the healthcare team being cornerstones of care. For dietitians working with patients with MND, a multidisciplinary team (MDT) approach will greatly assist in the assessment and planning of nutritional care and plays a key role in supporting the patient between the hospital and community (Table 7.6.2). Early dietetic referral is encouraged in guidelines produced by the Motor Neurone Disease Association (MNDA, 2000) and ensures that appropriate nutritional advice and monitoring are integrated into patient care (Rio *et al.*, 2005a). The benefits of integrated patient care provided by a multidisciplinary clinic are improved prognosis and enhanced survival compared with MND patients attending a general neurology clinic (Traynor *et al.*, 2003).

Nutritional management

Motor neurone disease affects each patient differently in terms of disease progression. Nutritional management will therefore depend on the nature of the individual

symptoms. Patients can experience periods of rapid weight loss leading to profound reduction in mobility, a weakened physical state, respiratory muscle weakness and susceptibility to opportunistic oral infections. Nutritional support has a central role in patient management and dietitians can influence decisions on nutritional care. The Royal College of Nursing's (RCN, 2001) identified three stages of the disease process; diagnostic, palliative and terminal. Patients will not remain in these stages for any set period of time and may progress so rapidly that they may move straight from diagnosis to the terminal stage. The dietitian needs to be empathetic and show a flexible and adaptable approach to patient care.

Nutritional assessment

Malnutrition in patients with MND increases the risk of death by 7.7 fold, with nutritional status acting as an independent prognostic indicator (Desport *et al.*, 1999); malnutrition in ALS resembles marasmus. Approximately 20% of patients with MND will develop malnutrition, even those without swallowing difficulties (Worwood & Leigh, 1998), as progression of the disease is associated with declining muscle and adipose tissue reserves. The incidence of malnutrition depends on the criteria used; a number of studies using a BMI of less than 18.5 kg/m² as an indicator of malnutrition found that 6–53% of patients were malnourished. Although frequently cited, this marker has a number of drawbacks, most notably lack of sensitivity in this patient group. If reduced energy intake is used, 70–100% are affected (Tandan *et al.*, 1999).

Percentage body weight loss is a useful tool. At the time of diagnosis, each 5% decrease in weight has been associated with a 30% increase in risk of death (Marin *et al.*, 2011). A loss of more than 10% from prediagnosis body weight in a short period of time is a clinical indicator for the introduction of nutritional supplements. The MDT should discuss the need for artificial nutrition and hydration.

Nutritional requirements

No disease specific energy or protein requirements have been set for patients with MND. The Schofield equation is commonly used as the starting point for calculating daily energy requirements. However, reliance on standard equations may lead to either under- or over-feeding (Sherman *et al.*, 2004). Resting metabolic rate (RMR) appears to change over the course of the disease and this should be factored into calculations. Despite a paradoxically low physical activity level, people with ALS are hypermetabolic by about 10% when compared to matched controls (Tandan *et al.*, 1999) and this increases as the disease progresses (Vaisman *et al.*, 2009). Patients may also have defective energy homeostasis, whereby the hypermetabolic state may accelerate the disease (Dupuis *et al.*, 2004). However, in end stage disease with mechanical ventilation, RMR is lower and approximates total calorie expenditure (Siirala *et al.*, 2010).

Nitrogen requirements are calculated using percentage body weight loss and malnourished state. Suggested nitrogen requirements are:

- 0.17 g/kg/day for patients in the early stages of disease.
- 0.2 g/kg/day for patients with body weight loss of 10%.
- 0.25 g/kg/day for malnourished patients and body weight loss of greater than 20%.

Fluid intake should be 30–35 mL/kg of body weight, depending on age. Requirements for vitamins and minerals are not affected by the disease state and, although patients may become severely malnourished, overt deficiencies are rare. Fibre intake should aim to meet the current recommended value (18 g/day).

Dietary guidance

Nutritional education should commence as soon as MND is suspected or diagnosed; dietitians are a vital source of consistent and evidence based dietary advice. The basic principles of nutritional support apply, with emphasis on nutrient dense food and drinks, a wide variety of foods, ease of food preparation, meal planning and adoption of a liberal and unrestricted diet. Initially, nutritional intake may be boosted by food fortification and by the consumption of frequent small meals and snacks. However, prescribable energy supplements may be necessary if dietary intake fails to meet requirements or if 10% of body weight is lost (see Chapter 6.3).

Constipation is a frequent digestive complaint with causes including decreased physical activity, fibre intake and fluid intake due to swallowing difficulties, or increased dependence for toileting, weakness in abdominal or pelvic muscles required to push, medications to control drooling or pain and slow bowel transit time. Management of constipation focuses on the underlying causes, which may include increasing fibre intake or fibre supplements, increasing fluid intake including thickened fluids, promoting good bowel habits and establishing a bowel routine, careful use of stool softeners or laxatives and control of medications (types, dosage, timing). Unresolved constipation can lead to faecal impaction due to poor dietary intake, dehydration or muscle weakness. Symptoms of faecal impaction include bloating, abdominal distension and, on abdominal X ray, stools and gas throughout the small bowel. Faecal impaction is resolved with macrogols, inert polymers of ethylene that sequester fluid in the bowels, at dosage of one to three sachets/day. If this is ineffective, eight sachets in 1L of water for a maximum of 3 days is recommended.

Dietitians should not forget that even in the most debilitated patient the ability to taste, smell and feel the texture of food remains intact, and eating should be made as pleasurable as possible. Patients may enquire about the use of alternative diets, vitamin supplements and plant extracts, and dietitians can help them make an informed choice based on open discussion of their likely efficacy and cost (Cameron & Rosenfeld, 2002; Rosenfeld & Ellis, 2009) (see Chapter 5.4).

Dysphagia

Approximately 70–80% of patients will develop dysphagia during the course of the disease. A speech and language therapist (SLT) can assess the presence, severity and nature of the dysphagia and advise on safe swallowing strategies, including chin tuck, head position, texture modification and use of food and fluid thickeners. Saliva drooling can be managed with medications such as sublingual atropine, amitriptyline, glycopyrronium, dermal hyoscine patches, botox or low dose radiation treatments.

Patients with severe dysphagia have an increased risk of aspiration pneumonia and may be advised to be nil by mouth (NBM). However, this measure denies terminally ill patients the pleasures associated with eating and drinking. A discussion with the patient and their carers regarding the risks of continuing oral intake is advisable. Some patients may choose to take small amounts of food or fluids of an appropriate texture or consistency for pleasure and quality of life.

Artificial nutrition and hydration

Artificial nutrition and hydration (ANH) is indicated in MND patients who have (Miller *et al.*, 2009):

- Severe dysphagia with risk of aspiration pneumonia or recurring chest infections.
- Malnutrition with weight loss of greater than 10% from the prediagnosis weight.
- Suboptimal energy intake.

The goals of ANH should be to (Heffernan *et al.*, 2004):

- Provide additional energy and protein.
- Stabilise body weight.
- Correct malnutrition.
- Act as a route for hydration and medications.
- While it will not completely eliminate the risk of aspiration, it will decrease the risk (there is still a risk of aspirating saliva and secretions).

The most common method of providing ANH is via gastrostomy, either percutaneous endoscopic gastrostomy (PEG) or percutaneous radiological gastrostomy (PRG). Respiratory status pregastrostomy will help define suitability for PEG or PRG insertion (Leigh *et al.*, 2003).

Current evidence demonstrates that PEG or PRG can be inserted any time during the disease, but that the nutritional benefits diminish as patients enter the terminal phase. Ideally, ANH should be for more than 4–6 weeks and careful patient selection is crucial to avoid early post procedure mortality. Pregastrostomy assessment should consider:

- *Respiratory function* – symptoms of poor respiratory function include morning headache, breathlessness, constant shallow breathing, raised PCO₂ levels and reduced forced vital capacity (FVC). Patients with respiratory failure require acclimatisation to NIPPV before gastrostomy. Single step intervention allows the patient

to adapt and their response to be fully evaluated whilst minimising complications.

- *Stage of the disease* – patients in the terminal phase are unlikely to benefit from gastrostomy.
- *Malnutrition* – patients presenting with severe malnutrition may benefit from nasogastric feeding, which should be evaluated before placement.
- *Quality of life* – gastrostomy may reduce quality of life by increasing the burden for both patient and carer, and increasing the number of hospital visits. Alternatively, gastrostomy feeding can increase quality of life by reducing the amount of time spent consuming food and the distressing symptoms associated with dysphagia.

When considering ANH in MND patients, the MDT should evaluate the risk–benefit ratio of the gastrostomy procedure. Gastrostomy insertion is a relatively routine procedure and can be performed any time during the course of the disease. However, PEG insertion in MND patients with respiratory failure or respiratory muscle weakness can be life threatening (Mathus-Vliegen *et al.*, 1994) and the 30-day mortality rate following gastrostomy in MND patients is between 2% and 25% (Forbes *et al.*, 2004). Another study showed a median survival of 185 days post PEG with worse outcomes in patients with weight loss of >10% of healthy body weight and FVC <65% (Chio *et al.*, 1999). The findings of a report into patient outcomes and death in the UK showed a less positive experience for patients having PEG; 43% of patients died within 1 week and 19% of advisers thought PEG a futile procedure (Cullinane *et al.*, 2004). However, it should be noted that the MND component in this study was quite small (7%).

This wide variation in mortality represents differing selection criteria and timing, varying respiratory function and nutritional status of the population and the expertise of the clinician involved. Thorough assessment by the MDT as to fitness for the procedure can help identify those MND patients likely to benefit. Dietitians should be aware that not all patients with MND progress to requiring a gastrostomy. When PEG or PRG appears to be indicated it should be offered early in the course of the disease when respiratory function is good and procedural complications are probably fewer. Early placement also has the advantage of greater nutritional benefit (Table 7.6.3). However, patients choose gastrostomy in their own time and for different reasons. Some patients may want to delay having a gastrostomy for as long as possible, which is understandable. Dietitians have a key educational role in helping patients reach this important decision by offering sensitive and timely information. An early referral allows the dietitian to get to know the patient and their family, enabling a relationship to be developed. Initiating education and discussion early allows for a non-crisis decision making process. Patients may have unfounded concepts of artificial feeding and a brief discussion with the patient can open avenues and opportunities to discuss the practical issues.

Table 7.6.3 Implications of early and late gastrostomy placement

	Early placement	Late placement
Clinical condition	Disease progression at an early stage	Disease state usually advanced
Respiratory status	Good respiratory function (FVC >50%)	Respiratory function often impaired Patients using NIPPV due to poor respiratory function or advanced disease state
Nutritional status	Minimal weight loss Meal times prolonged but dietary intake may be adequate	Weight loss >10% Dietary intake likely to be limited and the patient malnourished
Dysphagia	Swallow function mildly affected	Swallow function poor
Potential risks of gastrostomy insertion	Perceived to be fewer Procedure related	Respiratory (NIPPV) support needed for procedure Increased risk of mortality Stoma site infection
Benefits	Additional energy and protein intake Weight stabilisation (individual weight gain is variable)	Symptom control, including constipation management and reduced risk of aspiration Improved hydration Alleviates anxiety associated with eating and drinking (tube feeding likely to become the sole source of nutrition) Small weight gain/weight stabilisation May help stabilise respiratory function

FVC, forced ventilatory capacity; NIPPV, non-invasive positive pressure ventilation.

Percutaneous endoscopic gastrostomy

Percutaneous endoscopic gastrostomy is the standard nutritional intervention, although insertion of PEG poses a number of clinical challenges for the healthcare team. Risks associated with the procedure are serious, but relatively uncommon. They include infection at the insertion site, bleeding, temporary diarrhoea, cramping, nausea and vomiting (all major or minor), oesophageal perforation and injury to the bowel (Mitchell *et al.*, 2008). Decreased respiratory function and a high lying stomach may be contraindications.

The survival benefit to MND patients once associated with PEG is now unclear. Early evidence suggested improved survival (Mazzini *et al.*, 1995); however, this has not been demonstrated in other studies. It has been suggested that PEG be used for symptom control and improved quality of life rather than for survival (Chio *et al.*, 1999). On the other hand, a more recent study showed that PEG improves survival in dysphagic ALS patients with few side effects, and the procedure is safe and applicable even to patients with impaired respiratory function (Spataro *et al.*, 2011). This may be a reflection of increased experience of clinicians with this patient population. Whilst FVC is commonly used as a guide to respiratory function, it is not a wholly reliable indicator of survival post PEG. In a group of MND patients with a FVC of less than 50% (Gregory *et al.*, 2002), survival was similar to previously published data for a patient group with a FVC above the 50% threshold. In a small group of patients with advanced MND, PEG was successfully inserted without respiratory complications (Boitano *et al.*, 2001). Whilst a low FVC should not deprive patients of gastrostomy, thorough respiratory, nutritional and medical assessments are needed to reduce the 30-day mortality rate (Rio & Leigh, 2001).

Percutaneous radiological gastrostomy

This technique, often called radiologically inserted gastrostomy (RIG), is an alternative method of gastrostomy insertion done by an interventional radiologist. It is suitable for patients with MND as tube placement does not require oral access; instead tubes are placed directly into the stomach, a technique known as the push technique. This technique is therefore suitable for patients with bulbar symptoms, although this group is required to lie flat during the procedure. Preprocedural oximetry and history of desaturation whilst lying flat should be obtained to prevent unnecessary distress at the time of the procedure.

Preprocedural abdominal X rays should be performed to investigate if the patient has either chronic constipation, also known as faecal impaction, or gas in the abdomen. The presence of one of these factors can lead to problems post PRG insertion, which include pain, discomfort and bowel perforation. Serious complications, including bowel perforation, post PRG insertion occur in approximately 2–5%, which, importantly, are avoidable (Rio *et al.*, 2010). Patients who present with faecal impaction or gas in the bowel require these to be resolved prior to the procedure. The standard medications for treatment of chronic constipation are suitable for this patient group and should be prescribed for a minimum of 5–7 days. A repeat abdominal X ray is advised prior to tube placement to check if constipation has resolved; some patients may require a longer duration of laxative use.

Nutritional care of patients with a gastrostomy

Nutritional care of the MND patient with a gastrostomy is similar to the management of any patient receiving ANH. Some patients may receive all their nutrition or

they may choose (where appropriate) to supplement oral intake of food or fluids via the gastrostomy. Intake should provide adequate energy and adequate, but not excessive protein, and meet fluid requirements from the formula and addition water. Considerations in choosing a formula include energy density, protein content, fibre or non-fibre content and special requirements (diabetes and renal disease). Feeding schedules are individualised depending on full or supplemental feedings, lifestyle and method of administration (pump, gravity or syringe).

Nutritional care of patients assessed unsafe for gastrostomy

Patients with advanced disease presenting with respiratory failure and malnutrition will benefit from the input of the palliative care team. Patients may consider enteral feeding as symbolic of their fight against the disease. However, gastrostomy placement at this time may not be advisable due to the limited benefit of nutritional support in a patient close to death. Nutritional support should be carefully considered alongside anticipated goals (Ersek, 2003). Palliation of symptoms and comfort should take priority, whilst quality of life is paramount (see Chapter 7.16).

Nutritional support with nasogastric tube (NGT) feeding is advisable in this group of patients with advanced disease. Fine bore NGTs are the primary and most frequently used route of tube feeding in the acute hospital setting. However, patients may find a NGT cosmetically unappealing and socially intrusive. Treatment with a NGT has a number of advantages:

- Less invasive than PEG or PRG.
- Risk of aspiration is the same as with PEG or PRG.
- Allows immediate delivery of nutrition and hydration.

Feeding via a NGT can be a temporary route for ANH where expectations of extended survival and return to normal body weight are not sought. Importantly, NGT feeding also allows the response to enteral nutrition to be fully evaluated whilst the benefit–risk ratio of PEG or PRG is assessed.

Nutritional requirements should be calculated in the usual way (see Chapter 6.4), but feeds should be administered gradually over several days as per patient tolerance. Risk of aspiration can be reduced by:

- Effective saliva/secretion management.
- Limiting oral intake or placing patients nil by mouth.
- Using a daytime feeding regimen.
- Ensuring patients are sat upright during feeding.

Discharge into the community with a NGT requires the support of the local team, including the GP, district nurse, home enteral nutrition team and palliative care team. Community support of patients with a NGT may vary and information for tube replacement and tube care should be provided in advance of discharge. Dietitians have a key leadership role in the coordination and discharge of these patients.

Management of patients who refuse artificial nutrition and hydration therapy

Not all patients with MND will choose to have a feeding tube. Despite dysphagia, prolonged meal times, aspiration pneumonia and the presence of malnutrition, some patients will choose to maintain oral nutritional intake. Reasons why patients refuse ANH will vary and may include (Cawadias & Carroll-Thomas, 2001):

- Denial of the diagnosis.
- Reluctance to have an invasive procedure.
- Decision to let the disease take its course due to preference, age or comorbidities.
- Unwillingness to accept a milestone has been reached.
- Misperceptions about the procedure and how the gastrostomy can be used.
- Fear of the unknown.
- Dislike of change of lifestyle.
- Belief they will be connected to a feeding pump for lengthy periods.
- Inability to manage equipment due to decreased arm function.
- Lack of social support.

Support from the dietitian is vital for these patients and both the acute and community teams should be involved. The MNDA regional care advisor can also offer input and act as a valuable link with the different care services. Ongoing dietetic input and good communication between team members can help these patients maintain their quality of life and dignity. Some patients may initially refuse tube feeding and then suddenly decide they want to go ahead with a gastrostomy. As stated above, caution should be exercised and thorough assessment of medical fitness for the procedure and likely benefit should be evaluated before a hasty decision is made.

Multidisciplinary team in nutritional care

Working in a small team, dietitians may be challenged by the implications of MND and feel overwhelmed. Discussing quality of life issues and end of life decisions may be unfamiliar territory for many dietitians. Service provision differs greatly across the UK and this includes provision of dietetic and multidisciplinary care. Some areas may provide high standards of care, while in others dietitians may find themselves working in isolation with limited resources (Rio & Cawadias, 2009). Where services are limited, dietitians can encourage good practice by regular patient review, adoption of the MNDA nutrition guidelines, liaison with the speech and language therapist, communication with the patient's GP, consulting with a specialist MND centre dietitian and involving the patient in any decisions that affect their care. Confidence in working with this patient population comes with experience, both in terms of time and number of patients. Some patients may visit tertiary referral centres for review, clinical trials or respiratory management. Liaison with the team dietitian, centre coordinator, clinical nurse specialist or neurologist is highly recommended. Not only will

this help in terms of patient care, but it also provides a source of professional support and further information.

7.6.3 Rare neurological conditions

Suzu Yates and Angeline Brookes

Key points

- Patients with Guillain–Barré syndrome may require enteral tube feeding if ventilation is required. Nutritional intervention should concentrate on weight maintenance and meeting nutritional requirements.
- Patients with myasthenia gravis experience varying degrees of dysphagia due to muscle weakness and fatigue; they may require enteral nutrition support as a temporary measure.
- Autonomic dysfunction is a feature of pure autonomic failure, multiple system atrophy and postural orthostatic tachycardia syndrome. Appropriate education, lifestyle and dietary changes are key components of the management, aiming for improvement in or alleviation of symptoms.

Guillain–Barré syndrome

Guillain–Barré syndrome (GBS) is an autoimmune disease affecting the peripheral nervous system. It is characterised by weakness, pain and in some cases paralysis, which ascends up the body. In the majority of cases, symptoms are confined to the limbs; however, in 25% of cases weakness can spread to the trunk and respiratory muscles, leading to a requirement for artificial ventilation (Hughes & Cornblath, 2005). Some patients are also affected by bulbar (muscles of the mouth and throat responsible for chewing, swallowing and talking) muscle weakness, leading to difficulty with swallowing and speech.

It is caused by the body's immune system attacking either the myelin sheath or axons of the cells of the peripheral nervous system. The inflammation and damage to the peripheral cells leads to the characteristic pain and paralysis. A preceding unrelated virus or illness, such as gastroenteritis caused by *Campylobacter jejuni* or Epstein Barr virus often triggers the immune response (Hadden *et al.*, 2001).

Diagnostic classification

In Europe and North America, the most common (approximately 95%) subtype of GBS is acute inflammatory demyelinating polyradiculoneuropathy (AIDP). The other 5% of GBS patients present with axonal subtypes, where the axon of the nerve cell rather than the myelin sheath is damaged. In South East Asia and South America there is a higher prevalence of the axonal subtypes than in

Europe and North America (Hughes & Cornblath, 2005). Miller Fisher syndrome is a variant of GBS; this presents with descending rather than ascending paralysis, paralysis of muscles controlling eye movement and facial and bulbar weakness (Hahn, 1998). Electromyography (EMG) and lumbar puncture are used as diagnostic tests for GBS.

Disease consequences and epidemiology

The worldwide incidence of GBS is 2.3 in 100 000. It occurs in both sexes and at any age. The incidence increases with age and it is more common in men than women (van Doorn *et al.*, 2008). The acute deterioration generally lasts 2–4 weeks, after which the patient's function plateaus at the lowest level. After this, recovery begins and can take many months; 4–15% of patients will die, although mortality rates are lower at specialist centres (Hughes & Cornblath, 2005). Most patients will make a full functional recovery, but 20–30% of patients will have a permanent reduction in their level of function (Bersano *et al.*, 2006; Hughes *et al.*, 2005).

Clinical management

Patients should be monitored for deterioration in respiratory function. Intubation and artificial ventilation will be required if respiratory function is compromised secondary to paralysis of respiratory muscles and the diaphragm. These patients will invariably require alternative nutrition, with enteral feeding being the most preferred route via a nasogastric (NG) tube. Intensive care unit (ICU)

admission may also be required for patients whose autonomic function is severely affected (see Autonomic dysfunction section). Both intravenous immunoglobulin (IVIg) and plasma exchange have been shown to be equally effective treatments at accelerating recovery, and are most effective if the course of treatment is administered within the first 2 weeks of symptom onset (van Doorn *et al.*, 2008). Medical treatment will also be required for pain management, and potentially also for the management of autonomic failure or dysfunction (see Chapter 7.17.1).

Nutrition related symptoms and consequences

Weight and muscle loss

Weight and muscle loss can occur in both the acute and recovery stages of GBS, and the causes are multifactorial. In the acute phase, weight loss may be caused by muscle atrophy, secondary to reduced nerve conduction to the muscles, or by a prolonged intensive care unit (ICU) admission.

Hypermetabolism

One study has suggested that, due to the infective and inflammatory response, patients with GBS are hypermetabolic and hypercatabolic, leading to weight loss (Rubenoff *et al.*, 1992). However, no studies have measured energy expenditure using validated methods for a large enough sample of this patient group to establish the extent of the effect on metabolic rate.

Dysphagia

In the acute and recovery stages, dysphagia can be a cause of reduced oral intake, and therefore weight loss. One study showed that in the ICU, 57% of GBS patients present with bulbar weakness (Ng *et al.*, 1995), whilst another study assessing 20 years of GBS admissions to the ICU showed that 79% of patients had bulbar dysfunction (Dhar *et al.*, 2008) (see Chapter 7.3).

Limb weakness, pain and fatigue

In the recovery phase of GBS, the reduced ability to self feed may lead to a reduced intake, and therefore weight loss. Upper limb weakness is characteristic and patients may be unable to find it difficult to complete many activities of daily living, including feeding. Patients will only be able to self feed if function has returned to the upper limbs. Even with some function, neuropathic pain may limit the patient's ability to feed. Ruts *et al.* (2010) showed that even 1 year after the acute phase, 82% of GBS patients reported pain in their extremities. Fatigue, which is also common in GBS, may affect an individual's ability to engage in feeding activities for the length of time required, thereby limiting the amount of food taken at a meal.

Constipation

Constipation related to gastric dysmotility, or use of pain medications such as opioids or codeine phosphate, can cause a reduction in appetite, and therefore a reduction of food eaten, resulting in weight loss.

Gastric dysmotility

Two-thirds of GBS patients develop an element of autonomic dysfunction. One of the many symptoms related to autonomic dysfunction is gastric dysmotility, which affects 15% of severe GBS patients (Burns, 2008). Gastric dysmotility can affect tolerance of enteral feed, resulting in large aspirates and requiring the use of prokinetics. At worst, dysmotility can develop into an ileus.

Nutritional assessment

The following should be noted when completing a nutritional assessment.

Anthropometry

Anthropometric measurements should consider:

- Weight loss and, if possible, measurements of muscle loss – mid upper arm circumferences.
- In recovery/rehabilitation – reduced mobility may lead to abdominal weight gain; waist circumference measurement may be useful.

Clinical assessment

The clinical assessment should consider:

- Gastric aspirates if enterally fed.
- Monitoring of bowel function, paying particular attention to constipation.
- Bulbar weakness – an assessment from a speech and language therapist (SLT) will be required if there is any element of dysphagia with solids or fluids.
- Upper limb power in patients in the recovery stage. Limb power and strength may affect ability to self feed.
- Fine motor skills – can the patient hold cutlery and lift drinks to their mouth, or do they require assistance to do this?.
- Reports of fatigue from nurses or the patient themselves.
- Presence of pressure ulcers – long ICU admission/immobility can encourage their development.

Dietary assessment

Dietary assessment should consider:

- Is the food and drink of an appropriate texture and consistency in view of the patient's swallow function?
- During the recovery phase – is the patient following any diet that they feel may help symptoms? (see Balanced eating during recovery section)
- Is the patient meeting their nutritional requirements for energy and protein?
- Is the patient meeting their fluid requirements?

Economic and social assessment

For individuals in the recovery phase, is assistance at meal times and during meal preparation available if required?

Nutritional management

Weight loss and muscle loss

As weight loss is multifactorial in GBS, the individual causes should be considered when managing weight loss. It should be remembered that muscle wasting associated with reduced muscle use is unavoidable, and therefore it may be more appropriate to aim for weight stabilisation as a dietetic goal rather than weight gain.

Hypermetabolism

Few studies have investigated the nutritional requirements of patients with GBS. During the acute phase, when patients require intensive care input, Rubenoff *et al.* (1992) have suggested that patients should be fed 40–45 kcal and 2 g of protein/kg of body weight. These recommendations were based on a small sample, and the study did not consider the potential risks of overfeeding. Therefore, during the acute phase on an ICU, requirements should be calculated as for other critical care patients (see Chapter 7.17.1).

During the recovery phase, weekly weights and anthropometric measurements should be monitored. Provision of nutritional supplements may be required to reduce the rate of weight loss and to encourage weight gain; however, it should be remembered that if the patient is immobile, weight gain may occur as adipose tissue rather than lean body mass (see Chapter 6.3).

Dysphagia

A SLT, who will be able to recommend appropriate texture and consistency of food and drink, should assess patients with bulbar weaknesses. If patients are nil by mouth, NG feeding should be initiated unless there is a contraindication. Similarly, NG feeding will be required if patients are intubated. It can also be used to meet nutritional and fluid requirements in dysphagia (see Chapter 7.3 for further management advice on ensuring adequacy of nutritional intake).

Limb weakness, pain and fatigue

If upper limb weakness is present, assistance should be offered to the patient at meal times. Those providing assistance should be aware of the effect of fatigue, and therefore be aware that meal times can be prolonged and that food may go cold. Small regular meals may be more appropriate than three large meals per day. Pain relief should be appropriately provided for meal times so that the patient feels less pain at this time and can concentrate on achieving adequate intake. Assessment from an occupational therapist can determine whether the patient may benefit from modified cutlery for feeding.

Gastric dysmotility and constipation

If patients are suffering from large aspirates, prokinetics such as metaclopramide or erythromycin should be employed to increase absorption and decrease aspirate volume. Constipation can occur as a result of gastric dysmotility, so the use of enteral feeds containing fibre or higher fibre foods may be required alongside laxatives to

maintain adequate gut function (see Chapter 7.4.11). An ileus may occur with autonomic dysfunction: if an ileus persists, parenteral nutrition may be required until it resolves and the patient can tolerate enteral intake (see Chapter 6.5).

Balanced eating during recovery

Once the patient is eating and drinking, and a stable weight is maintained, a balanced diet should be recommended during recovery. There is no evidence to suggest that modified diets speed up recovery or improve function. Some support groups recommend the use of diets high in essential fatty acids (EFAs), postulating that this may improve the integrity of the myelin sheath of nerve cells; however, there is no evidence to suggest that taking large oral doses of EFAs can help regenerate damaged myelin sheaths. Similarly, avoidance of foods or food groups has not been shown to aid recovery, and may lead to an unbalanced diet, compromising nutritional status.

Myasthenia gravis

Myasthenia gravis (MG) is an autoimmune disease affecting the neuromuscular junction. It is caused by antibodies linking to neurotransmitter receptors on the muscle end plate, thus disrupting the flow of neurotransmitters from the neurone to the muscle. In the majority of cases, the antibodies link specifically to the acetylcholine receptors.

The disruption in the pathway leads to painless muscle weakness and fatigue. Approximately 85% of patients present with ocular muscle weakness; most patients with ptosis (drooping of the eyelids) and or diplopia (double vision). Only 17% of patients present with ocular muscle weakness without any further muscle weakness (Grob *et al.*, 2008). Bulbar weakness is also a common symptom in MG and presents as dysarthria (poor speech), dysphagia, dysphonia (problems with voice/pitch), nasal sounding speech and masticatory weakness (weakness in the muscles involved in chewing) (Meriggioli & Sanders, 2009). Half of all patients with MG will present with generalised weakness, affecting ocular, bulbar, limb, neck, facial and respiratory muscles.

Diagnostic classification

There are many classifications used in the diagnosis of MG, but the most widely accepted, internationally used is the Myasthenia Gravis Foundation of America Clinical Classification (Nicolle, 2002), which defines MG patients on the basis of the combination of weaknesses present and their severity.

In order to confirm the diagnosis of MG, blood tests should test for the presence of serum receptor antibodies (either antiacetylcholine receptor antibodies or anti-MuSK antibodies). Electromyogram and nerve conduction tests should also be completed. Cholinesterase inhibitor tests use medications such as edrophonium (Tensilon), which prevent the destruction of acetylcholine. The provision of these medications may temporarily

improve muscle weakness, thereby supporting the diagnosis of MG.

Disease consequences and epidemiology

The worldwide prevalence of MG ranges from 1.7 to 10.4 per million. It affects children and adults, with children accounting for 10–15% of cases. From puberty to the age of 40 years, MG is three times more prevalent in women than men. Above the age of 50 years, there are more male patients with MG than women (Meriggioli & Sanders, 2009). Mortality associated with MG is usually related to myasthenic crisis, where weakness affects respiratory muscles, leading to a requirement for intubation and ventilation. Alshekhlee *et al.* (2009) reported mortality rates of 4.5% in patients in myasthenic crisis.

Clinical management

Cholinesterase inhibitors are prescribed as they reduce the breakdown of acetylcholine, thereby increasing circulating levels. This has a beneficial effect on muscle weakness, as there is more acetylcholine available for binding to receptors. Pyridostigmine bromide (Mestinon) is a commonly used cholinesterase inhibitor and needs to be administered every 4–6 hours at varying doses. Side effects can include abdominal cramps, diarrhoea and nausea. An antispasmodic medication such as propantheline is frequently prescribed alongside pyridostigmine to reduce such side effects. Immunosuppressive medications such as prednisolone or azathioprine can be used in conjunction with cholinesterase inhibitors.

Plasma exchange and intravenous immunoglobulin treatment are immune therapies that are used when short term improvement is required, e.g. during myasthenic crisis (Wendell & Levine, 2011). Surgical removal of the thymus gland (a thymectomy) may be performed as it has been implicated in the production of receptor antibodies, although this treatment is only done in patients under the age of 60 years.

Nutrition related consequences

Dysphagia

Dysphagia occurs in 15–40% of MG patients (Llabrés *et al.*, 2005). On initial diagnosis, patients should be made aware of dysphagia as a consequence of the condition, as this can greatly impact on the self management of oral intake during future episodes of crisis or deterioration.

Fatigue

Fatigue can impact on oral intake and the ability to consume sufficient nutrition. It is therefore important to ensure optimal timing of the dose of pyridostigmine with respect to meal times in order to maximise oral intake and minimise effects of fatigue. Pyridostigmine should ideally be taken 30 minutes prior to meal times and at regular intervals throughout the day. Achieving this can

inevitably be problematic in the ward environment; however, educating the nursing staff and advising the medical team on appropriate timings should overcome most issues.

Blood glucose management

Blood glucose should be monitored with the commencement of prednisolone and patients should be advised regarding the potential for weight gain with steroid use.

Nutritional assessment

The following points should be noted when completing a nutritional assessment.

Anthropometry

Weight history (percentage weight loss) and body mass index (BMI) should be assessed, as patients presenting with a history of worsening dysphagia frequently experience weight loss.

Clinical assessment

The following points should be considered:

- Bowel function should be monitored closely due to the side effects of pyridostigmine. An antispasmodic medication such as propantheline should be prescribed if required.
- As already mentioned, pyridostigmine should ideally be administered 30 minutes before meals. Liaison with nursing staff and the medical team may be required.
- The patient's ability to manage medications orally should be reviewed. Does a liquid form of medication need to be considered or can the medications be crushed and added to a dessert of suitable consistency?
- Vital capacity (VC) readings will provide an indication of respiratory function, as decreasing VC indicates a worsening of the disease progress, with swallow function likely to be affected.
- The patient's sense of fatigue should be reviewed. Does the patient notice a difference in fatigue depending on the time of day?

Dietary assessment

The dietary assessment should consider:

- The latest recommendations from the SLT regarding the most appropriate choice of oral intake; close liaison is required throughout the disease progression.
- Current oral intake of food, taking into consideration the potential for variability throughout the day secondary to fatigue.
- Current fluid intake, taking into consideration whether thickened fluids are required, as well as the palatability of such drinks.

Consideration of artificial nutritional support if the patient is not meeting their nutritional requirements or fluid requirements, is unable to manage medications orally?

Economic and social assessment

It can be helpful to advise patients to limit talking and other distractions at meal times as this can impact further on fatigue and swallow function.

Nutritional management

Tailored nutritional management is required throughout the disease course as severity can vary from person to person, as well as on an individual basis during a myasthenic crisis. Close liaison with the SLT should be encouraged in order to best facilitate the patient's nutritional needs. A texture modified diet will be required if the patient is dysphagic. The nutritional adequacy of the diet should be assessed, especially in the case of progressive dysphagia (see Chapter 7.3). Patients often experience increasing fatigue towards the end of the day and it is not uncommon for the recommendation of a texture modified diet to vary according to individual meal times, e.g. patients may successfully manage a soft/moist diet at lunchtime, but benefit from a puréed meal in the evening.

Recommendations should be made for smaller, more frequent meals, rather than aiming to finish full portions at meal times. Additional snacks between meals should be encouraged, including oral sip feeds and dessert based supplements, to enable the patient to meet their nutritional requirements (see Chapter 6.3).

Nutrition support via a NG tube may be required if there are concerns regarding aspiration risk, dysphagia is severe or respiratory function is compromised, e.g. myasthenic crisis. During myasthenic crisis, patients may require intubation and ventilation, which may warrant an ICU admission. For these patients, requirements should be calculated as for other critical care patients (see Chapter 7.17.1).

Enteral feeding as a result of dysphagia is usually a short term measure, as the establishment of an effective medication regimen should assist in improving swallow function. Compared with other neurological conditions, gastrostomy insertion is typically considered too aggressive in MG, due to its variable course and crisis periods (Cereda *et al.*, 2009).

Autonomic failure (dysautonomias)

The autonomic nervous system (ANS) forms part of the central and peripheral nervous system and is responsible for the involuntary, unconscious function of the internal organs. It affects heart rate, digestion, respiration rate, salivation, perspiration, urination and sexual arousal. Although there are many conditions affected by the ANS, the conditions discussed here are pure autonomic failure (PAF), multiple system (MSA) and postural tachycardia orthostatic syndrome (POTS).

Pure autonomic failure

Diagnostic criteria

Pure autonomic failure is characterised by orthostatic (postural) hypotension. Orthostatic hypotension is de-

defined as a decrease in systolic pressure of at least 20 mmHg or in diastolic pressure of at least 10 mm Hg within 3 minutes of sitting or standing, or during a 60 degree° head up tilt (Kaufmann, 1996). In chronic autonomic failure, hypotension can also occur following the ingestion of food, which can aggravate postural hypotension. This is referred to as post prandial hypotension (Puvirajasingham & Mathias, 1996).

Disease consequences and factors affecting symptoms

Autonomic disease may present in any age group, but neurodegenerative disorders affecting the ANS often occur after the age of 50 years (Mathias, 2003a). Symptoms include feeling dizzy, changes in vision such as blurring and pain across the back of the shoulders or neck (often referred to as coat hanger pain) (Bleasdale-Barr & Mathias, 1998). Feeling muddled or vague and falls or loss of consciousness may also occur as a result of hypotension. The severity of symptoms can vary, with some patients eventually becoming unable to stand upright or sit for prolonged periods. Some patients may later be diagnosed with MSA. Autonomic disease can also cause reduced salivation and dry mouth, resulting in difficulty with dry foods. Dysphagia is unusual in PAF but often occurs in the later stages of MSA, leading to risk of aspiration.

Appropriate education, lifestyle and dietary changes with reconditioning are required to restore mobility and maintain quality of life. Factors that can influence orthostatic hypotension include (Mathias, 2003a):

- Time of day – blood pressure is lower in the mornings, especially on waking.
- Speed of positional change, e.g. standing quickly from a sitting or lying position can result in a drop in blood pressure.
- water ingestion – can raise blood pressure.
- Food ingestion – large meals can result in post prandial hypotension.
- Warm conditions, e.g. hot weather and hot baths can lead to hypotension.
- Straining – constipation should be avoided as straining lowers blood pressure further.

Nutritional assessment

The following should be considered as part of the nutritional assessment.

Anthropometry

The anthropometric assessment should review weight, BMI and any history of weight loss.

Clinical assessment

The clinical assessment should consider:

- Bowel function, aiming to avoid constipation.
- Results of autonomic function tests, e.g. presence of post prandial hypotension.
- Level of mobility (severe deconditioning will result in reduced/minimal mobility).

Dietary assessment

Dietary assessment should:

- Obtain an accurate diet history, with a focus on portion sizes, salt, fluid and sugar intake.
- Assess the current oral fluid intake.
- Assess for recent changes to diet or food avoidance.

Economic and social assessment

The impact on meal preparation should be assessed, e.g. other family members may be following a low sodium diet for hypertension.

Clinical investigation and management

Measurement of lying, sitting and standing blood pressure is essential to determine if orthostatic hypotension is present (pulse rate should also be measured to consider POTS). Autonomic investigations should be undertaken to evaluate the cardiovascular system, including measurements of blood pressure during head up tilt at a 60 degree angle, a liquid meal challenge and modified exercise testing. In addition, a 24-hour blood pressure recording should be completed. Post prandial hypotension is assessed by recording blood pressure whilst the patient is lying flat and on head up tilt prior to the ingestion of a liquid meal consisting of carbohydrate, protein and fat, and again 45 minutes after the meal (Mathias, 2003a).

Management is often focused on the alleviation of symptoms and requires a combination of pharmacological and non-pharmacological approaches. Pharmacological interventions can have a significant effect on blood pressure management. Frequently used medications include fludrocortisone, ephedrine, midodrine, desmopressin (DDAVP) and octreotide. Octreotide is given as an injection before meals, which can reduce post-prandial hypotension (Mathias, 2003b).

Nutritional management

The aim of nutritional management is to encourage the improvement or alleviation of symptoms. The advice can appear unconventional; however, due to the severity of symptoms, individuals may benefit from making dietary modifications. There are four main areas where dietary adjustments can assist with symptom control, although the supporting evidence for these is limited.

Avoid large meals

Puvi-Rajasingham & Mathias (1996) have shown that consuming three larger meals per day, rather than six smaller meals per day, resulted in significantly lower blood pressure both after and between meals. Therefore, patients should be encouraged to aim for five to six smaller snacks throughout the day, rather than three large meals.

Increase fluid intake

Although the precise mechanisms are unclear, oral fluids increase seated blood pressure in chronic autonomic failure. Studies have shown that the oral ingestion of 480 mL of water increases seated blood pressure in patients with PAF and MSA (Young & Mathias, 2004a). This effect continues to be consistent on a daily basis

(Deguchi *et al.*, 2007). Studies have also shown that the provision of water via a gastrostomy tube has similar haemodynamic effects to the oral ingestion of water (Young & Mathias, 2004b).

As blood pressure is lower on waking, patients are advised to drink 480–500 mL of (non-sugar containing) fluids before getting out of bed. Patients should be advised to have fluid by the bedside before going to bed. Patients should also aim to avoid fluids 1 hour prior to going to bed to avoid the need to get up during the night, which will increase the risk of falls or hypotension.

Increase salt intake

It is speculated that an increased salt intake may help increase blood pressure in patients with orthostatic hypotension; however, there is no evidence to support this and no guidance to suggest recommended quantities. Advice should be aimed at increasing high salt containing foods in the diet and adding additional salt to food at the table rather than using salt tablets. Salt in water solution should not be recommended.

Reduce intake of sugars and carbohydrates

Studies have shown that restriction of carbohydrates and glucose can reduce the effects of postural hypotension (Jansen & Lipsitz, 1995; Mathias *et al.*, 1991). Symptoms of post prandial hypotension have also been found to be less frequent and severe, and significantly shorter with a low carbohydrate intake (25 g) (Vloet *et al.*, 2001). Advice should be aimed at avoiding food and drinks high in sugar, although there may be improved tolerance towards the end of the day when blood pressure is higher.

Weight loss can occur due to food restriction or dysphagia. Due to the high sugar content of most supplement drinks, it can be difficult to recommend an oral sip feed without worsening symptoms. These should be tried on an individual basis as clinical experience suggests that some patients can successfully tolerate 1.5–2 kcal/mL of oral sip feeds if sipped slowly. Alternatively, a lipid-based supplement such as Calogen (Nutricia) or Fresubin 5 kcal Shot (Fresenius) can be beneficial as an additional source of calories. Food fortification advice concentrating on increasing additional fat sources within the diet can also help to prevent weight loss (see Chapter 6.3). Occasionally, enteral feeding may need to be considered, especially if there are concerns regarding dysphagia.

Multiple system atrophy

Multiple system atrophy (MSA) is a progressive neurodegenerative condition characterised by autonomic failure, parkinsonism (see Chapter 7.6.1) and cerebellar ataxia (poor balance and coordination) (Gilman *et al.*, 2008).

Diagnostic criteria and classification

It can be difficult to distinguish between Parkinson's disease and MSA as features that would be atypical of the former, such as rapid progression and poor response to anti-parkinsonism medication, only become evident over

time. Early autonomic involvement of the bladder and cardiovascular system can be indicators of MSA. There is no single clinical feature or investigation that confirms MSA. However, recent diagnostic criteria have been agreed to improve the recognition of patients with early or possible MSA (Wenning & Stefanova, 2009).

The diagnostic criteria for probable MSA, according to the second consensus statement on the diagnosis of MSA (Gilman *et al.*, 2008), are:

- A sporadic, progressive, adult (over 30 years) onset disease characterised by:
 - Autonomic failure involving urinary incontinence (with erectile dysfunction in males) or an orthostatic decrease of blood pressure within 3 minutes of standing by at least 30 mmHg systolic or 15 mmHg diastolic; *and*
 - Poorly levodopa responsive parkinsonism; *or*
 - A cerebellar syndrome (gait ataxia with cerebellar dysarthria, limb ataxia, or cerebellar oculomotor dysfunction).

The incidence is approximately 5 per 100 000 population; however, due to under recognition and misdiagnosis, it is calculated that approximately 10% of patients with parkinsonism have MSA (Bhidayasiri & Ling, 2008).

Disease consequences

The disease affects both men and women, usually in their 50s and 60s, with a disease progression that ultimately leads to death within 8 years from symptom onset. However, some individuals have survived for 15 years or more. There is no specific drug therapy available and treatment is aimed primarily at symptom relief (Swinn, 2005).

Nutritional management

As previously discussed, dietary measures can help with the symptomatic relief of orthostatic hypotension. Constipation should be avoided in these patients, as previously discussed. Patients with MSA can experience speech and swallowing difficulties. Speech can become quieter, monotonous and/or slurred. Texture modified diets and oral sip feeds may need to be considered if fatigue impacts on oral intake or if weight loss occurs (see Chapters 7.3 Chapter 6.3). Enteral tube feeding should be considered if there are concerns regarding risk of aspiration. Approximately 30% of patients will develop a degree of stridor (Wenning & Stefanova, 2009); therefore, a radiologically inserted gastrostomy (RIG) may be considered (see Chapter 6.4).

Postural orthostatic tachycardia syndrome

In addition to MSA and PAF, there is a subgroup of patients who present with a disorder termed orthostatic intolerance/tachycardia. This has been defined as the development of symptoms on standing that are relieved when sitting.

Diagnostic criteria

Postural orthostatic tachycardia syndrome has been defined as *'the presence of orthostatic intolerance symptoms associated with a heart rate increase of 30 beats/minute (or a rate that exceeds 120 beats/minute) within the first 10 minutes of standing or upright tilt'* (Grubb *et al.*, 2006). Reported symptoms can include tachycardia, palpitations, fatigue, headache, nausea and light headedness, and can have a limiting impact on everyday activities. It is important to note that many patients with orthostatic intolerance will not have orthostatic hypotension, or indeed a change in blood pressure. Orthostatic intolerance can be incorrectly classified as chronic anxiety or a panic disorder (Grubb *et al.*, 2006).

Disease consequences

The prevalence of POTS is unknown; however, it is estimated to be 5–10 times as common as orthostatic hypotension, and that 40% of patients with chronic fatigue syndrome have POTS. Low *et al.* (2009) noted a consistent female to male ratio of 5:1, with an average age of onset of 30 years. Patients with POTS present with poor exercise tolerance and physical reconditioning can be severe, especially in patients with prominent fatigue.

The most recognised cause of POTS is associated with the connective tissue disorder joint hypermobility syndrome (JHS). In these patients, blood vessels have abnormally elastic connective tissue, resulting in a reduced ability to constrict that in turn results in compensatory tachycardia. One example is Ehlers–Danlos syndrome, an inherited connective tissue disorder.

Nutritional management

Patients are encouraged to maintain a high salt and fluid intake as previously discussed, aiming for 2 L of fluid/day. Occasionally, gastric dysmotility can occur and should be managed on an individual basis according to symptoms.

7.6.4 Multiple sclerosis

Catherine Dunn and Maryanne Harrison

Key points

- Multiple sclerosis (MS) is a disease of the central nervous system affecting the brain and spinal cord. Damage to the myelin and axons of nerves can lead to significant neurological disability.
- Multiple sclerosis is the most common neurological disease among young adults with an incidence of approximately 1 in 1000; onset is usually between 20 and 40 years.
- It is an incurable, long term condition. Medications can manage symptoms, e.g. fatigue, bladder dysfunction, pain, spasticity and weakness.
- Nutritional management depends on the symptoms and their severity, and varies from a healthy, balanced diet to nutritional support, including enteral tube feeding and dysphagia management.
- There is no conclusive evidence that dietary modification influences the course of MS; however, n-3 and n-6 polyunsaturated fatty acids may play a role in relapsing–remitting MS. There is mounting evidence that vitamin D is implicated in both development and progression of MS.

Multiple sclerosis (MS) is an immune mediated progressive disease of the central nervous system (CNS). The myelin sheaths around the brain and spinal cord are damaged, affecting the ability of the nerve cells to communicate with each other. It is the most common neurological disease among young adults, with an incidence of approximately 1 in 1000 and an onset usually between the ages of 20 and 40 years. Women are about twice as likely to develop MS as men. Multiple sclerosis is characterised by inflammation, demyelination of the protective myelin coating and nerve axon damage throughout the CNS. Diagnosis can be confirmed using magnetic resonance imaging (MRI). It is a long term condition and can have a wide range of clinical presentations that are dependent on the severity and location of CNS damage. Some people become significantly disabled in a very short time, while others live their entire lives with minimal or no disability.

Diagnostic criteria and classification

There are four recognised clinical courses of MS, identified on the basis of the rate of progression (Chiaravalotti & DeLuca, 2008).

- *Relapsing–remitting* – following diagnosis 80% of patients follow this course. It is characterised by periods of acute attacks followed by full or near full recovery. Relapses may last days or months and vary from mild to very severe; the latter may require hospital admission. During relapses, symptoms are exacerbated and new symptoms may develop.
- *Secondary progressive* – approximately 80% of individuals with relapsing–remitting MS later develop secondary progressive MS (Herndon, 2003). Symptoms gradually worsen with or without occasional relapses or minor remissions. As a result, symptoms and disability become steadily worse.
- *Progressive relapsing* – this has a progressive decline after the onset of the disease with some acute periods of symptom relapse. There may or may not be recovery from these acute periods.
- *Primary progressive* – this affects 10–15% of patients; there is continuous and gradual worsening of the symptoms with no distinct periods of relapse or remission of symptoms.

Disease processes

Very little is known about the mechanism and causes of MS, although immunological, environmental and genetic factors have been implicated. Environmental factors include Epstein–Barr virus infection, smoking and low serum concentrations of vitamin D (Ascherio & Munger, 2007). Although vitamin B₁₂ plays a role in myelin formation, no definitive relationship has been identified with vitamin B₁₂, although low or decreased levels have been reported in MS (Farinotti *et al.*, 2009). There is a correlation between sunlight exposure and lack of vitamin D both for occurrence and progression of MS. These are

now considered predisposing factors for MS (Esparza *et al.*, 1995; Llorca *et al.*, 2005; Freedman *et al.*, 2000; Ponsonby *et al.*, 2005).

The incidence of MS increases with geographical latitude. There is a strong inverse correlation between distance from the equator and duration and intensity of ultraviolet B (UVB) light from sunlight. In turn, serum vitamin D concentration is closely correlated with exposure to UVB (Viglietta *et al.*, 2004). Populations at high latitudes with a high consumption of vitamin D rich fatty fish have a lower than expected prevalence of MS (Goldberg, 1974; Swank *et al.*, 1952; Westlund, 1970). Risk decreases with migration from high to low latitudes (Gale & Martyn, 1995). Less than optimal blood levels of vitamin D have been linked to an increased incidence of MS (Embry *et al.*, 2000; Munger *et al.*, 2006) and there is also a positive association between low blood vitamin D levels and relapse in MS (Soilu-Hanninen *et al.*, 2005; Mowry *et al.*, 2010).

Diet is a poor source of vitamin D compared with sun exposure. A food serving can provide 40–400 IU (1–40 µg) (Yetley, 2008), whereas whole body exposure to sunlight for 20 minutes for a Caucasian during the summer months will produce at least 10 000 IU (Holick, 1995; 2004; Engelsen *et al.*, 2005). However, under circumstances when the strength of the UVB reaching the earth's surface is reduced, e.g. in winter or at high latitude, or where the effectiveness of UVB in catalysing the synthesis of vitamin D is reduced, e.g. increased skin pigmentation, age, use of sunscreen and living in a built up environment diet can become the primary source of vitamin D. Evidence suggests that although 25 hydroxyvitamin D concentrations in blood above 50 nmol/L have been deemed adequate, a minimum of 75 nmol/L and perhaps more than 90 nmol/L is optimum for many health outcomes. This could be achieved by judicious sun exposure or daily supplementation with 1000–4000 IU of colecalciferol, which would increase 25 hydroxyvitamin D to over 75 nmol/L in most individuals. However, as yet there have been no agreed or recommended levels for patients with MS. Further large randomised controlled trials are needed (Bishoff-Ferrari, 2009; Bishoff-Ferrari *et al.*, 2006; Looker *et al.*, 2008).

Disease consequences

Mortality is only slightly higher in MS patients than in the general population. In itself MS is not fatal; causes of death in those with MS are most commonly associated with respiratory and cardiovascular diseases and infections (Ragonese *et al.*, 2008). However, MS is associated with considerable morbidity and many symptoms that include:

- Difficulties with balance and dizziness.
- Fatigue – an overwhelming sense of tiredness.
- Visual problems such as blurred or double vision.
- Numbness, tingling or pins and needles that can be painful.
- Bladder problems.

- Bowel problems.
- Cognitive problems, including memory and thinking.
- Stiffness or spasms in muscles – sometimes called spasticity.
- Emotional and mood changes.
- Tremor.
- Sexual problems.
- Speech difficulties.
- Swallowing difficulties (dysphagia).

People with MS can present with diverse and multiple symptoms of varying severity related to the location of nervous system damage. There is also consistent evidence that health related quality of life is compromised (Ruddick & Miller, 2008).

Nutritional assessment

Using the ABCDE model, there are some key aspects of the nutritional assessment to consider in MS.

Anthropometry

Specialised weighing scales (wheelchair, sitting scales or hoist scales) will be required for patients unable to stand unsupported.

Biochemistry

Measurement of vitamin D levels is helpful before advising on vitamin D supplementation.

Clinical assessment

Identification of MS subtype, presenting symptoms or disability will inform likely nutritional priorities:

- If positioning in bed or a chair is difficult, pressure areas may be present and these may affect nutritional requirements (see Chapter 7.17.6).
- Bladder dysfunction may make people self limit fluid intake, potentially leading to dehydration.
- Constipation is fairly common in MS, although the neurological basis for this is unclear; however, reduced mobility, reduced fluid intake and other dietary changes may play a part (Chia *et al.*, 1995).

Dietary assessment

The dietary assessment should consider:

- Dysphagia may affect food choices; certain food types and textures may need to be avoided.
- Ability to self feed may be affected by weakness or lack of coordination of arm or hand muscles (ataxia); varying degrees of assistance may be needed to eat and drink.
- Fatigue can be debilitating, leaving the person without energy to shop or prepare food and even to eat a meal.
- Alternative diets, e.g. Swank and Best Bet, may be followed; some of these are extremely restrictive.

- There are no specific guidelines on energy and protein requirements in MS; however, energy requirements are likely to be increased with tremor or spasticity.

Economic and social assessment

Many people with MS require the support of carers to eat and drink; daily routine (such as the timing of visits from carers and their duration) may help or hinder oral intake.

Clinical investigation and management

There is no known cure for MS, although stem cells trials are currently being conducted. Non-curative treatment with medications is common in MS. Drug therapy is aimed at either management of symptoms or treatment of MS itself.

Symptom management

Symptoms such as spasticity, ataxia and tremor, fatigue, pain and bladder, bowel and sexual dysfunction can be treated with medication. For example, spasticity may be managed by medications such as baclofen, botulinum toxin or tizanidine. Where fatigue is impacting on daily life, modafinil and amantadine may be prescribed to increase alertness. As with all medications, side effects may impact on nutritional intake and/or nutritional status. For example, baclofen (which acts as a skeletal muscle relaxant) can induce nausea with possible consequent reduction in food intake. A review by Thompson *et al.* (2010) provides a comprehensive overview of drugs prescribed for symptoms management in MS, their efficacy and associated side effects.

Disease modifying therapies

Since the early 1990s, an increasing number of drugs have been licensed for the treatment of MS, including beta interferon (Avonex and Rebif), natalizumab (Tysabri) and fingolimod (Gilenya), although the latter has not been approved for use in the UK by the National Institute for Health and Care Excellence (NICE). Fingolimod is taken orally, whereas the others are given via injection or intravenous infusion. All these drugs affect the immune system and are known as disease modifying therapies (DMTs). The evidence for efficacy of DMTs in relapsing–remitting MS is far greater than for primary or secondary progressive MS. Nonetheless, there are ongoing trials to evaluate whether the course of progressive forms of MS can be influenced by DMTs.

Rehabilitation

Multidisciplinary rehabilitation is also an important aspect of MS management. Whilst there is no evidence that multidisciplinary rehabilitation programmes influence level of functional impairment, they can improve the experience of people with MS in relation to activity and participation (Khan *et al.*, 2008).

Nutritional management

As with any long term condition, healthy eating should be an integral part of daily life. The eatwell plate should be used as a tool for empowering individuals to achieve optimum nutrition, especially at the beginning of the pathway following diagnosis (see Chapter 4.2). A low saturated fat intake is strongly recommended and ways to ensure this include the use of low fat dairy products and lean meat. Inclusion of oily fish –two to three times a week to provide n-3 polyunsaturated fatty acids (PUFAs) and frequent use of vegetable oils such as sunflower, corn, safflower, nuts seeds and soya to provide n-6 PUFAs (linoleic acid) is recommended. Emphasis is given to eating at least five portions of fruit and vegetables a day and to the inclusion of dark green leafy vegetables. Wholegrain bread and cereals are encouraged, as is enough fluids to produce pale urine. Caffeine intake should be kept to a minimum. As the disease progresses, other priorities may take precedence, e.g. weight loss or weight gain.

Constipation is common in MS and advice on its prevention by dietary means can be very helpful. Individualised high fibre advice, including the use of golden linseeds and prune juice can lead to reduction or cessation of laxative use.

Obesity

Obesity in MS can occur for a variety of reasons, including reduced activity as a consequence of disability, treatment with steroids, depression leading to comfort eating and excessive intake of high fat and/or high sugar foods. Successful treatment depends on an empathetic approach, facilitating behaviour change. A detailed dietary assessment should be completed and agreed realistic targets set that reduce energy intake (Stuifbergen *et al.*, 2003). Appropriate follow-up, ideally in conjunction with the rest of the multidisciplinary team, can be very successful. Obesity may not be successfully treated in all patients and weight loss may not be a realistic goal for some. It may be that prevention of further weight gain is a better approach in some cases.

Alternative diets

In a study by Schwarz *et al.* (2008), 41% of participants with MS reported having used diet modification at some point. In addition to relatively minor dietary modifications, people with MS may choose to follow a variety of alternative or extreme diets with a view to influencing the course of their disease. Diets that offer hope of improvement of symptoms or a cure are very attractive to many people with MS and therefore will have followers. The Swank and Best Bet diets are two of the best known alternative diets for MS; however, gluten free or low allergen diets may also be followed. There is no substantiated evidence that following an alternative diet will affect the MS disease process. Whilst being mindful that restrictive diets can increase risk of certain nutritional deficiencies, health beliefs of individuals must be respected.

Swank diet

Swank *et al.* (1952) demonstrated a correlation between MS and diet, and devised this diet. A low fat diet was advised because of an apparent association between fat intake and MS. A group of 144 people on the Swank diet were followed for up to 34 years, with good results reported in long term disability. Those who adhered strictly to the diet and who were experiencing mild symptoms had slower disability progression than those who had not adhered strictly to the diet. However, there was no control group in this study and therefore there is a likelihood of a self selection bias arising from the probability that only patients who perceived a benefit from the treatment would continue with it. It is therefore impossible to know whether the good results represent a genuine improvement over the entire population of MS patients.

The principles of the diet are:

- Saturated fat kept to 15 g or less/day.
- No red meat for the first year, then 75 g/week.
- Unsaturated fat kept to 20–50 g/day.
- No processed foods containing saturated fat.
- Dairy products must contain 1% or less butter fat.
- Three eggs per week and no more than one per serving.
- Suggested daily cod liver oil and a multivitamin and mineral supplement.

Best Bet diet

The Best Bet diet is a strict exclusion diet based on the premise that undigested food proteins with a similar structure to the protein in myelin pass across a leaky gut and cross the blood–brain barrier. This triggers an autoimmune attack on myelin, so causing, or worsening, MS. A wide range of food types is restricted, including red meat, dairy products, legumes and grains; therefore, achieving a balanced diet will be a challenge. Over 24 dietary supplements are recommended; thus following the Best Bet diet will also be expensive. At the time of writing, no clinical trials or results in relation to the Best Bet diet have been published in any peer reviewed journal. More information can be found at www.ms-diet.org.

Polyunsaturated fatty acids

Both n-3 and n-6 PUFAs have anti-inflammatory properties and have been considered as potential treatments for MS (Harbige *et al.*, 2007; Mehta *et al.*, 2009). Supplementation with n-3 and n-6 PUFAs has been shown to reduce immune cell activation through a variety of complex pathways. However, clinical trials in humans have not demonstrated definitively that PUFA supplementation can influence disability and rate or severity of relapses in MS, which may be due to limitations in trial design and outcome measure selection (Mehta *et al.*, 2009; Farinotti *et al.*, 2009). The evidence supporting the use of PUFAs in the treatment of relapsing–remitting MS is far stronger than for primary or secondary progressive MS.

The NICE (2003) guidelines advise that a daily intake of 17–23 g of linoleic acid (n-3 PUFA) may reduce the

accumulation of disability over time, especially early in the disease process. This recommendation was based on a systematic review of three double blind trials undertaken in the early 1980s (Dworkin *et al.*, 1984). However, since publication of the NICE guidelines there has been debate as to the quality of these trials and whether 17–23 g/day is the optimum dose of linoleic acid is uncertain. Rich sources of linoleic acid include:

- Food oils such as corn, sunflower, safflower, peanut, rapeseed.
- Evening primrose oil (available as a supplement).
- Sunflower spread (full fat).
- Nuts such as walnuts, brazil nuts, peanuts.
- Mayonnaise (full fat).
- Taramasalata.

In two double blind, parallel group studies of n-3 PUFA supplementation [fish oil; combination of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)] versus placebo supplementation, no significant differences were found between the groups in terms of progression of disability (Bates *et al.*, 1989) or relapse rates (Weinstock-Guttman *et al.*, 2005), although there was a non-significant trend toward less disability progression in the former study. In both studies there were methodological problems that may have masked any meaningful treatment effect of n-3 PUFA supplementation, such as both groups being instructed to restrict saturated fat intake. However, given that n-3 and n-6 PUFAs are accepted as being beneficial to overall health, their intake should be encouraged in those with relapsing–remitting MS as part of a varied and balanced diet.

A low intake of saturated fat should also be promoted, as there is significant epidemiological evidence that high intakes of saturated fatty acids are detrimentally associated with MS (Harbig & Sharief, 2007). Naturally, this advice must be implemented using clinical judgement, as the nutritional priorities of people with MS differ. Early in the disease process, when disability may be relatively mild, more attention should be paid to promoting PUFA intake, particularly where people are motivated to make positive lifestyle changes. However, it would not be appropriate to focus on PUFA if disease and disability have progressed, or where malnutrition is the primary concern.

Dysphagia

The prevalence of swallowing disorders in MS is high (30–40%) (Restivo *et al.*, 2011). Dysphagia is significantly more prevalent in those with greater neurological disability (Poojavad *et al.*, 2010). Consequences of dysphagia can be severe, such as the development of pneumonia from aspiration of food or fluid into the lungs. Dysphagia can lead to significant weight loss and dehydration as a result of the inability to meet nutritional and fluid requirements. With progressive forms of MS and where dysphagia exists, swallowing function may deteriorate over time. Where dysphagia is a feature of MS, nutritional management should ideally be undertaken with input from a speech and language therapist, who can advise on

modification of food and fluid textures, positioning for eating and drinking, and swallowing strategies to reduce the risk of aspiration with oral intake. Nutritional support (oral or artificial) will be required where dysphagia is associated with an inability to meet nutritional requirements (see Chapter 7.3).

Malnutrition and nutritional support

The incidence of malnutrition in MS has not been determined. However, it is well recognised that unintentional weight loss and cachexia can occur in MS (Payne, 2001; Habek *et al.*, 2010). Contributory factors include (but are not limited to):

- Dysphagia.
- Fatigue.
- Difficulties in self feeding.
- Cognitive impairment.
- Restrictive alternative diet.

Where malnutrition or a high risk of malnutrition has been identified in someone with MS, nutritional support strategies should be implemented.

Oral nutritional support

A food first approach should be recommended with progression to using prescribed nutritional supplements as required (see Chapter 6.3). Prethickened sip feeds are available should dysphagia mean that thickened fluids are required.

Artificial nutritional support

Use of artificial nutritional support (such as nasogastric or gastrostomy feeding) in people with MS has not been studied extensively. It will only be relevant in a small minority of cases, but can be successful in promoting weight gain. It is acknowledged that enteral tube feeding impacts on people's quality of life (Brotherton & Judd, 2007); therefore, quality of life considerations should always guide decision making around gastrostomy feeding.

7.6.5 Chronic fatigue syndrome/myalgic encephalomyelitis

Jennifer McIntosh

Key points

- The World Health Organization classifies chronic fatigue syndrome/myalgic encephalomyelitis as a neurological illness.
- It is a poorly understood, chronic disabling condition affecting both adults and children with 60–70% reporting irritable bowel syndrome symptoms.
- Dietary advice recommending small, frequent meals as part of a balanced diet may improve patients' energy levels.

The Chief Medical Officer (Department of Health, 2002) and the Medical Research Council (2003) recommend the use of the term chronic fatigue syndrome/myalgic encephalomyelitis (CFS/ME) rather than chronic fatigue syndrome (CFS), myalgic encephalomyelitis (ME) or post viral fatigue syndrome (PVFS). These were often considered to be separate conditions (Whiting *et al.*, (2001), however, they are now considered to be the same condition. The World Health Organization classifies CFS/ME as a neurological illness, although its aetiology is unknown. Several factors have been suggested, including neurological, endocrine, immunological, genetic, psychiatric and infectious (NICE, 2007).

It is a relatively common clinical condition affecting 0.2–0.4% of the population. It causes profound, often prolonged, illness and disability, and can have a substantial impact on the family and individual. The physical symptoms are as disabling as other chronic condition such as multiple sclerosis, rheumatoid arthritis and congestive heart failure (NICE, 2007; Department of Health, 2002) The symptoms vary and often fluctuate in intensity and severity between individuals but also within the individual. This can make it difficult for family, friends and health professionals to understand the condition.

Diagnostic criteria and classification

There is no diagnostic test for CFS/ME and diagnosis is made on the basis of a recognisable pattern of characteristic symptoms and the exclusion of other known causes. There are several sets of diagnostic criteria but in the UK, NICE (2007) diagnostic criteria are used (Box 7.6.1). Diagnosis is considered if symptoms have persisted for 4 months in an adult or 3 months in a child or young person. In a young child or young person the diagnosis should be made or confirmed by a paediatrician. If the following features are present they should be investigated before a diagnosis of CFS/ME is made:

- Localising or focal neurological signs.
- Significant weight loss.
- Sleep apnoea.
- Clinically significant lymphadenopathy.

Box 7.6.1 Criteria for diagnosis of chronic fatigue syndrome/myalgic encephalomyelitis [from NICE (2007, p. 14)]

Fatigue with all of the following features:

- New or a specific onset, i.e. not lifelong
- Persistent and/or recurrent
- Unexplained by other conditions
- Has resulted in a substantial reduction in activity level
- Characterised by post exertional malaise and/or fatigue (typically delayed, e.g. by at least 24 hours, with slow recovery over several days)

And one or more of the following symptoms:

- Difficulty with sleeping, such as insomnia, hypersomnia, unrefreshing sleep, a disturbed sleep–wake cycle
- Muscle and or joint pain that is multisite and without evidence of inflammation
- Headaches.
- Painful lymph nodes without pathological enlargement
- Sore throat
- Cognitive dysfunction, such as difficulty thinking, inability to concentrate, impairment of short term memory, and difficulties with word finding, planning or organising thoughts and information processing

- Signs and symptoms of inflammatory arthritis or connective tissue disease.
- Signs and symptoms of cardiorespiratory disease.

Classification of symptom severity

The severity of CFS/ME can vary enormously and is classified as mild, moderate or severe (NICE, 2007):

- *Mild* – patients are mobile, can care for themselves and do light domestic tasks, but with difficulty. Most are still working or in education, but to do this they

have probably stopped all leisure and social pursuits. They often take days off work or school, or rest at the weekend in order to cope with the rest of the week.

- *Moderate* – patients have reduced mobility and are restricted in all activities of daily living, although they may have peaks and troughs in the level of symptoms and ability to do activities. They have usually stopped work, school or college and need rest periods, often sleeping in the afternoon for 1–2 hours. Sleep at night is generally poor of quality and disturbed.
- *Severe* – patients are unable to do any activity for themselves or can carry out minimal daily tasks only (such as face washing and cleaning teeth). They have severe cognitive difficulties and depend on a wheelchair for mobility. They are often unable to leave the house., or, if they do, this has a severe and prolonged after effect. They may also spend most of their time in bed, and are often extremely sensitive to light and noise.

Prevalence

Chronic fatigue syndrome/myalgic encephalomyelitis affects people of every age, gender, ethnicity and socio-economic group, although it is four times more common in women than in men. The most common age at onset is 40–50 years. It is less common in children than in adults, but children can develop CFS/ME, particularly during adolescence (14–15 years). As already mentioned, the prevalence is estimated to be approximately 0.2–0.4% of the population (Department of Health, 2002; White *et al.*, 2007).

Prognosis

Most patients will show some degree of improvement over time, especially with treatment. A substantial number of patients will pursue a fluctuating course with periods of relative remission and relapse, and a significant minority become severely and perhaps permanently disabled (Cairns & Hotopf, 2005; Department of Health, 2002).

Nutrition problems

Chronic fatigue syndrome/myalgic encephalomyelitis is a chronic condition that impacts on nutritional health in a variety of ways. This can be challenging for the individual, their family and /or carers, and healthcare professionals. Simple tasks such as shopping, and preparing and cooking a meal can prove challenging when energy levels are impaired. Patients often report fluctuating energy levels and therefore may need meals that require minimal preparation and effort to eat. Those who are severely affected may require nutritional support, ranging from nutritional supplements to enteral feeding. The following nutritional problems may occur.

Weight gain

It is generally recognised that a large percentage of patients gain weight, averaging 12–18 kg, due to reduced

activity levels, increased eating to boost energy levels, comfort eating, medication and less energy to buy or prepare fresh foods. Weight gain can impact on fatigue and pain, and increase other health risks such as diabetes and heart disease (see Chapter 7.13.1).

Weight loss

This tends to be more common in children and young people, and those with symptoms of nausea. Some patients can be severely underweight, which impacts on fatigue levels. Weight loss is particularly common during the initial onset of CFS/ME (see Chapter 6.2).

Irritable bowel syndrome

Approximately 60–70% of CFS/ME patients (Rao *et al.*, 2009) report irritable bowel syndrome (IBS) symptoms that range from mild to severe in severity (see Chapter 7.4.10).

Nausea

Nausea is more common in children and young people, and can affect the ability to eat. There is some evidence for the presence of delayed gastric emptying (Burnet & Chatterton, 2004). Antiemetics may be useful in some patients (see Chapter 7.4.3).

Food intolerances

Food intolerances are frequently self reported and alternative diets, e.g. the anti-Candida and Stone Age diets, are frequently adopted. Currently, there is no evidence to support the use of these diets and they may also lead to nutritional deficiencies, which further impact on energy levels.

Osteoporosis

Osteoporosis can occur due to lack of exposure to sunlight, especially in those severely affected with CFS/ME. Lack of weight bearing exercise and dietary self restriction can increase the likelihood of osteoporosis (see Chapter 7.9.1).

Fluid

Patients can report either over or under drinking, due to increased thirst as part of the symptoms or forgetting to drink due to change in lifestyle, respectively.

Reactive hypoglycaemia

Patients may report a craving for sweet foods when tired, followed by symptoms similar to reactive hypoglycaemia, although there is no evidence to support this.

Other symptoms that may lead to a restrictive diet include difficult or painful swallowing or sore throat, sensitivity to smell or taste of food and disturbed sleep patterns.

Nutritional assessment

Anthropometry

Weight and height should be monitored to calculate and assess body mass index (BMI).

Biochemistry

The following routine blood tests are used to exclude other possible diagnoses (NICE, 2007):

- Full blood count.
- Creatinine, urea and electrolytes.
- Thyroid and liver function tests.
- Erythrocyte sedimentation rate and C-reactive protein.
- Glucose.
- Urinalysis.
- Serum calcium.
- Creatine phosphokinase.
- Coeliac screen.

Clinical assessment

A detailed weight history prior to CFS/ME and currently is important. Depending on the reason for referral, potential food allergies and intolerance beliefs should be investigated. If symptoms of IBS or nausea are present, further information should be gathered to aid dietary advice. There should be an awareness of the impact of CFS/ME on concentration and short term memory, and it can be helpful if a carer is present in terms of remembering dietary advice given. It helps to provide written information or summary notes.

Dietary assessment

A detailed diet history should be taken, particularly noting use of nutritional supplements and alcohol and caffeine intake. Good and bad days with regard to food intake should be enquired about.

Economic and social assessment

Patients may be unable to work or work only part time, which impacts on their financial situation. There may be less money for food, which limits dietary choices. It is important to assess support available at home for shopping, food preparation and cooking.

Management

There is no single management approach that has been found to be universally beneficial and currently there is no known cure for CFS/ME. Most patients are managed in primary care, ideally with access, if required, to a specialised team that may include a specialist, physiotherapist, occupational therapist, dietitian and psychologist or cognitive behaviour therapist.

Pharmacological interventions

There is no known pharmacological treatment for CFS/ME and also limited evidence on the overall benefits of pharmacological treatments for CFS/ME. The focus is on symptom control for sleep, mood disturbance, IBS and menstrual problems. Some patients report sensitivity to medications and although there is no evidence for this, lower doses than normal given. The most commonly prescribed drugs include antidepressants and melatonin. Tricyclic antidepressants (amitriptyline or trimipramine) are used at a low dose and may be prescribed for poor sleep or pain. Selective serotonin reuptake inhibitors (SSRIs), (fluoxetine, citalopram and paroxetine) may be used for symptoms of anxiety and are less sedating than tricyclics. Side effects of both can include weight gain, cravings for carbohydrate foods, constipation or diarrhoea (see Chapter 7.10.3). Melatonin is responsible for regulating the body's biological clock and is produced naturally in the pineal gland; deficiency can lead to insomnia. Melatonin may be considered for children and young people with CFS/ME who have sleep difficulties, but only under specialist supervision as it is unlicensed in the UK.

Non-pharmacological interventions

The main interventions recognised as beneficial are cognitive behavioural therapy (CBT), graded exercise therapy (GET) and pacing.

Cognitive behaviour therapy

In CFS/ME CBT aims to reduce the level of symptoms, disability and distress as part of the overall management. A number of randomised controlled trials (Deale *et al.*, 1997; Sharpe *et al.*, 1996; Prins *et al.*, 2001; Rao *et al.*, 2001; Taylor *et al.*, 2004; Cox, 1999; Stulemeijer *et al.*, 2005) have reported beneficial effects with CBT on physical functioning, fatigue and global improvement. Two studies (Cox, 2002; Friedberg & Krupp, 1994) have shown no significant difference. It is recommended that CBT should be offered to people with mild or moderate CFS/ME (NICE, 2007; White *et al.*, 2011).

Graded exercise therapy

Graded exercise therapy relies on negotiations between the healthcare professional and the patient, and involves appropriate physical assessment, mutually agreed and meaningful goal setting and education. Initially, an achievable level of physical activity is agreed, followed by gradual and planned increases that are individually tailored to the patient. A number of randomised controlled trials (Fulcher & White 1997; Wearden *et al.*, 1998; Moss-Morris *et al.*, 2005; Wallman *et al.*, 2004; Powell *et al.*, 2001) have shown significant improvements in fatigue and physical function. Again, NICE (2007) recommends that people with mild or moderate CFS/ME should be offered GET.

Pacing

Pacing is managed by the patient and is defined as '*energy management, with the aim of maximising cognitive and*

physical activity, while avoiding setbacks/relapses due to overexertion' (NICE, 2007). The evidence to date to support pacing is equivocal.

Other interventions that patients report are beneficial include activity management, sleep management, rest periods, relaxation, relapse and set back advice, and mindfulness based cognitive therapy (Surawy *et al.*, 2005; Sampalli *et al.*, 2009).

Nutritional management

The evidence base for the use of nutrition in CFS/ME is small and conflicting. Current management programmes are based on the available evidence and clinical experience. Patients have access to a large amount of nutritional information, often via the Internet, which can be conflicting. The National Institute for Health and Care Excellence and others (Baumer, 2005; Morris & Stare, 1993) recommend advising a healthy dietary approach. Although one study has shown that CFS/ME patients tend to lead a healthier lifestyle compared with the general population (Goedendorp *et al.*, 2009), explaining the psychological and physical benefits of dietary advice is important in terms of compliance and understanding. Currently, the following is recommended:

- Eating a balanced diet according to the eatwell plate (see Chapter 4.2).
- Incorporating low glycaemic index foods to improve energy levels, particularly in relation to hypoglycaemic type symptoms.
- Aiming to eat every 3–4 hours, e.g. three meals with the addition of three snacks in between to improve energy levels.
- Reducing caffeine intake if sleep is affected or if it impacts adversely on energy levels or bowel symptoms.
- Encouraging adequate fluid intake.
- Possibly reducing or avoiding alcohol, depending on reported impact on symptoms.
- Practical dietary advice regarding problem solving for reduced energy levels, e.g. ready meals or Internet food shopping.

Weight reduction

Initially, it is helpful to assess the reasons for weight gain, which may include reduced activity, cravings, medication or energy levels. In view of reduced activity levels, weight loss may be slower, e.g. 1–2 kg/month. Dietary advice can then be tailored to the individual situation (see Chapter 7.13.2).

Weight gain

It is important that patients understand that weight gain may be a slow process in view of symptoms of nausea. Dietary advice should be tailored to the individual, e.g. food fortification or frequent, small meals and snacks (see Chapter 6.3).

Nausea

Little and often should be encouraged and standard dietary advice for nausea given. If nausea is severe, antiemetic drugs may be considered (NICE, 2007).

Food allergies and intolerances

There is no evidence that CFS/ME sufferers have a greater incidence of immunoglobulin (IgG) mediated food allergy than the general population. However, some patient perceptions are that food allergies or food intolerances may be the cause. Explaining the difference between food allergy and food intolerance and how they are diagnosed can be helpful. Exclusion diets are not generally recommended for managing CFS/ME; however, they can be helpful for symptom management, especially IBS symptoms. Exclusion diets should only be undertaken under the supervision of a dietitian (see Chapter 7.11.2).

Bowel symptom management

Patients often benefit from strategies employed in the management of IBS, particularly modified dietary fibre. There have been some studies recommending use of probiotics (Lakhan & Kirchgessner, 2010; Rao *et al.*, 2009; Sullivan *et al.*, 2009). Low sugar and low yeast diets are popular; however, Hobday *et al.* (2008) and Morris & Stare (1993) found no benefit when compared with healthy eating.

Nutritional supplements

There is insufficient evidence for the use of nutritional supplements; however, patients still report a high usage. If the diet is inadequate or supplementation is advised, a multivitamin and mineral supplement within the recommended daily amount with an essential fatty acid supplement such as evening primrose oil (up to 1 g/day) and fish oils (1 g/day) is recommended. In those with moderate to severe CFS/ME, especially those who are housebound, it is important to assess dietary intake of vitamin D and if necessary to supplement (5–10 µg/day) this to prevent osteoporosis (NICE, 2007; Berkovitz *et al.*, 2009).

Evidence for the use of supplements is conflicting. Cox *et al.* (1991) showed an improvement in energy, pain, emotional reactions and general health with magnesium. However, all other studies have found no conclusive evidence. Nicotinamide adenine dinucleotide (NADH) is involved in ATP metabolism and was shown by Forsyth *et al.* (1999) to improve quality of life and general health, but Santaella *et al.* (2004) reported no significant difference. Following limited reports of benefit (Werbach, 2000), there is a trend to give 1 g/week of vitamin B₁₂ intramuscularly for 12 weeks, then monthly for 1 year or more. This appears to have beneficial effects in some patients, but is not accepted medical practice. Essential fatty acid supplementation studies are also conflicting. One randomised controlled trial reported no improvements, while another slightly larger controlled trial reported an overall beneficial affect (Warren *et al.*, 1999;

Behan *et al.*, 1990); Puri *et al.*, 2004). A recent study (Maes & Leunis, 2008) demonstrated some positive results with essential fatty acids; however, more research is needed in this area. There is no evidence to support the use of coenzyme Q10, vitamin C and B complex supplementation.

Complementary and alternative therapies

There is insufficient evidence that complementary therapies are effective treatments for CFS/ME (NICE, 2007). However, people with CFS/ME may choose these therapies due to the frustration of no conventional cure for CFS/ME being helpful. More evidence is required in this area (see Chapter 5.4).

7.6.6 Neurorehabilitation

Emma Dresner, Jennie Dunwoody, Katie Richards and Samantha Parry

Key points

- Neurorehabilitation is dependent upon collaboration, goal setting, outcome measures, communication, coordination and effective leadership.
- The neurological effects of brain injury can have significant implications in terms of nutritional status and intake.
- It is essential that dietitians are aware of the extent and nature of these effects.

It is imperative that nutritional assessment is carried out within the confines of a specialist team so that expert opinion on other parameters that impact on food intake can be taken into account.

Rehabilitation is a process of assessment, treatment and management by which the individual (and their family and carers) are supported to achieve their maximum potential for physical, cognitive, social and psychological function, participation in society and quality of living. Patient goals for rehabilitation vary according to the trajectory and stage of their condition. Specialist rehabilitation is the total active care of patients (and their families and/or carers) with a disabling condition by a multidisciplinary team (MDT) that has undergone recognised specialist training in rehabilitation and led or supported by a consultant trained and accredited in rehabilitation medicine. Generally, patients requiring specialist rehabilitation are those with complex disabilities.

Such patients typically present with a diverse mixture of medical, physical, sensory, cognitive, communicative, behavioural and social problems. These patients are likely to require specialist input from a wide range of rehabilita-

tion disciplines as well as specialist medical input. A subgroup of patients will have profound disability; these require help for all aspects of their basic care, as well as specialist interventions, e.g. spasticity management, postural support programmes and highly specialist equipment (Turner-Stokes *et al.*, 1998). The principles of neurorehabilitation are that it should be goal orientated and individual specific. The emphasis should always be on the individual's lifestyle and background.

This chapter concentrates on neurorehabilitation of individuals who have an acquired brain injury (ABI), which can be divided into traumatic, e.g. road traffic accidents, assaults and falls, and non-traumatic brain injury, e.g. infection, HIV, stroke and, hypoxic brain damage.

General principles

Phases of rehabilitation

Rehabilitation does not occur solely in a specialist centre or unit. It begins from the minute an individual is admitted to hospital and continues long after their return to

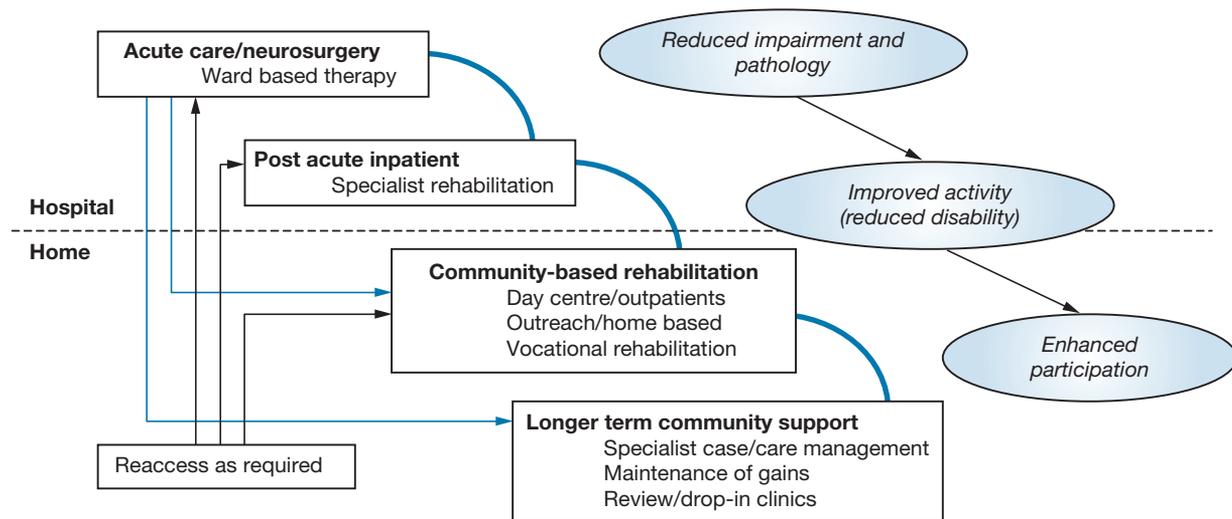

Figure 7.6.1 Phases of rehabilitation (source: National Clinical Guidelines 2013. Reproduced with permission of The Royal College of Physicians)

their community, as shown in Figure 7.6.1. The key to its success is continuity across the phases, leading to seamless care. In an acute hospital or ward, while a patient is waiting to move to a rehabilitation ward or unit, some maintenance interventions are still likely to be needed, such as managing positioning, preventing loss of range of movement, preventing contractures, establishing alternative forms of communication and many others. These interventions are primarily focussed on preventing complications that could magnify later disability.

Guidelines

In 2003, the British Society of Rehabilitation Medicine (BSRM) in collaboration with the Royal College of Physicians (RCP) produced the clinical guidelines for rehabilitation following acquired brain injury (BSRM/RCP, 2003). These guidelines promote interdisciplinary team working towards individual centred goals, with timely interventions to best facilitate cost effective integrated rehabilitation.

More recent guidelines are the BSRM Standards for Rehabilitation Services Mapped to the National Service Framework for Long-Term Conditions (2008) and in 2010 the BSRM, in collaboration with the RCP, joint working party document, Medical Rehabilitation in 2011 and Beyond. This latter report outlined the benefits that rapidly available, ongoing access to high quality rehabilitation services offers patients with disabilities arising from injury or long term conditions. The report is the work of an expert group comprising medical specialists, patients and allied professionals. Following a wide ranging review of the evidence, the group has provided specifications for designing cost effective services that maximise opportunities for recovery.

The neurological rehabilitation team

Following brain injury, rehabilitation from a specialised team should be established as soon as possible. An effective

team works collaboratively to provide integrated care and towards achieving a single set of individual centred goals. The key to the success of neurorehabilitation is collaboration, communication, coordination and leadership. The team comprises a number of healthcare professionals who work closely together in conjunction with the individual and/or carers to assess the individual's needs, devise an individual plan of care and monitor its implementation and progress. The team may include a:

- Dietitian.
- Rehabilitation nurse.
- Physiotherapist.
- Consultant in rehabilitation medicine.
- Speech and language therapist.
- Occupational therapist.
- Music therapist.
- Neuropsychologist.
- Social worker.
- Recreation and leisure facilitator.
- Rehabilitation assistant.

Goal planning

Neurorehabilitation should be goal driven with regular multidisciplinary meetings to discuss, review and set specific, measureable, attainable, relevant and timely (SMART) goals. A standardised set of outcome measures, e.g. the Extended Rehabilitation Complexity Scale, Northwick Park Therapy Dependency Score and Function Assessment Measure, should be used as a marker of outcome within neurorehabilitation (BSRM, 2008).

Consequences of brain injury

Damage to the brain as a result of acquired brain injury can have profound effects on an individual's physical and mental capabilities. The effects depend on the location, nature and extent of the damage. Brain injury can be classified as mild, moderate or severe. In mild cases,

patients may be able to return home and even commence paid employment. In more severe cases however, they will be dependent on other people for many aspects of care for the rest of their lives.

Damage to the left hemisphere of the brain is most likely to affect:

- Language.
- Speech.
- Reading and writing ability.

Damage to the right hemisphere is most likely to affect:

- Processing of visual and spatial information.
- Recognition.
- Coordination.

Although damage to brain tissue is irreversible since the body has no ability to regenerate brain cells, in some types of brain injury, particularly stroke, the body does seem able to adapt to some types of damage by rerouting the way in which information is processed, hence enabling the individual in time to recover some or all of an ability, e.g. speech or swallowing. This is termed neuroplasticity.

Nutritional implications of brain injury

The neurological effects of brain injury can have significant implications in terms of nutritional status and intake, and it is essential that dietitians are aware of the extent and nature of these effects in a particular individual before attempting to make nutritional assessment or provide dietary guidance. Dietetic expertise has a vital role in the neurorehabilitation process and a dietitian should be an active member of the specialised team.

Acquired brain injury can significantly alter an individual's nutritional status and mitigating its effects can help an individual cope with the demands of the rehabilitation process. Another key role of the dietitian is to educate other team members about the nutritional implications and management of ABI. To achieve this, it is vital that the dietitian understands the role of other team members.

Effects on the ability to communicate

Aphasia (damage to the language centre in the left hemisphere of the brain) may result in loss of or difficulties with speech (expressive aphasia). The ability to read or even interpret pictures may also be impaired (receptive aphasia). As a result of dysphasia, individuals may be unable to communicate their wishes, e.g. that they are hungry or thirsty, or express their likes and dislikes. Aphasic individuals may also have difficulty in completing a hospital menu card or making sense of dietary information provided in a written or even pictorial form.

Effects on eating behaviour

Behavioural alteration

Behavioural alteration, often resulting from frontal damage, may include:

- Antisocial behaviour, e.g. poor table manners, spitting or throwing food.
- Aggression.
- Physical and/or verbal abuse.
- Disinhibition, e.g. hyperphagia may not be kept in check to the extent it would normally be (Henson *et al.*, 1993).
- Disinterest or apathy.

Mood alteration

Alteration in brain function or sometimes drugs used to treat brain injury may have a direct effect on neurotransmitters and result in short or long term alteration in mood, e.g. depression or withdrawal.

Effects on appetite

Damage to the hypothalamus may result in loss of appetite control, resulting in hyperphagia (Henson *et al.*, 1993) or hyperphagia to particular foods such as a craving for sweet carbohydrate foods. Drug therapy, particularly the use of mood altering drugs, may also affect appetite.

Effects on the physical ability to eat

Ataxia

Ataxia describes tremor or shakiness, usually as a result of damage to the cerebellum, brainstem or pyramidal tracts causing poor motor control. It can result in considerable difficulties in getting food to the mouth, possibly to such an extent that the individual has to be fed. Equipment has been devised that enables the ataxic individual to self feed (by creating a resistance against tremor and therefore allowing a smooth transit from plate to mouth), but some individuals find the equipment too large and difficult to use; others feel that it draws attention to their disability and prefer to be discreetly fed by a carer.

Apraxia

Apraxia is the term used to describe disordered purposeful movement. Apraxia is often associated with left hemisphere damage and may appear in a number of forms:

- People with *ideomotor apraxia* may be unable to perform a specific task on request despite understanding the concept and having the physical ability to do so. However, the individual may be able to carry out the task automatically.
- Individuals with *ideational apraxia* may be unable to select the appropriate tool to carry out a particular task, e.g. may try to use a fork as a straw.

Hemiplegia

This results in paralysis of limbs on the side of the body that is opposite to the site of the brain lesion. Other physical consequences may be muscle wasting, limb oedema and slowing of nail growth on the affected side. Hemiplegia is particularly likely to compromise nutritional status

because energy requirements may be increased as a result of the reduced efficiency of movement and the presence of spasticity (Potempa *et al.*, 1995), and food intake is often limited in both type and amount because of the difficulties of manipulating food with just one hand. Measures such as the use of anti-slip mats and adapted cutlery may be helpful.

Effects on the ability to swallow

Dysphagia is a common consequence of many types of brain injury. Not only may damage to cranial nerves affect the swallowing reflex, but other aspects necessary for the normal swallow, such as the ability to visualise and recognise the food, achieve and maintain an appropriate posture of the head, neck and body and have good lip and tongue movement, may also be affected by brain injury. Abnormal oral reflexes, e.g. tongue thrust and bite reflex, inability to concentrate, fatigue and fear of choking, may further compound a problem. Any loss in swallowing ability is likely to compromise nutritional intake as a result of:

- Insufficient consumption of food (intake of energy and nutrients may be inadequate).
- Limited choice of food (dietary intake may be imbalanced).
- Losses as a result of drooling and leakage of food from the mouth.

Measures that are likely to be needed in dysphagic brain injured individuals are:

- Assessment by the specialist team and appropriate assistance provided, e.g. helping individuals convey food to the back of the mouth to trigger the swallowing reflex.
- Changes in food consistency and texture, which may necessitate either a uniform soft consistency, e.g. puréed foods, or appropriately thickened fluids, depending on the nature of the dysphagia. As altered texture diets are nutritionally dilute, nutritional supplements may be required to meet energy needs.
- Maximisation of sensory input. Foods may become more palatable and easier to swallow if they are served either 'hot' or 'cold', rather than just 'warm' or at room temperature. Chilled foods and drinks are often particularly well accepted. Main meals initially served as hot as possible are more likely to remain at an acceptable temperature throughout what may be a long meal time. Flavoursings should be used to make food as appetising as possible.

The management of dysphagia is discussed in detail in Chapter 7.3.

Psychological effects of the injury or disease

As well as physical effects, the psychological consequences of having suffered ABI or having been diagnosed with a serious neurological disorder can affect nutritional intake.

Emotional reactions

Awareness of the nature of the injury or disease and the prospect of permanent or progressive disability is likely to be followed by an emotional reaction similar to that of bereavement and including:

- Shock.
- Emotional lability and depression.
- Realisation (which can result in further depression).
- Adjustment.

Relatives may go through a similar process so both individual and family need support.

Depression may also result from, or be compounded by, chemical changes following the brain injury. Depression can have a profound effect on food intake; individuals may, for a while, simply not want to get better. Physical difficulties with eating or swallowing may be compounded by fatigue and poor concentration. The consequent problems may make people feel frustrated or resentful and consequently irritable, even angry, with carers and health professionals. Alternatively, the inability to cope with what can be a stressful situation can make people withdrawn or tearful.

Social isolation

Embarrassment because eating is accompanied by spillage as a result of tremor, drooling or dribbling, or simply as a result of having to be fed, may make people reluctant to eat with others or in public. As a result, both individuals and their relatives or carers can be very isolated (Osborn & Marshall, 1993). Every effort should be made to help people overcome the problems that cause them most distress and to retain as much independence as possible.

Nutritional management

Table 7.6.4 lists the variety of patients from a nutritional perspective who may present on a neurorehabilitation ward.

Many individuals who have suffered ABI will commence the phase of rehabilitation in a state of undernutrition as a result of the hypercatabolic effects of acute trauma and the likelihood of energy and nitrogen needs not having been met (see Chapter 7.17.2 and Chapter 7.14.5). Undernutrition is particularly likely if the injury was severe (which will result in a greater and more prolonged catabolic response) or the individual was malnourished prior to the injury (as may be the case in some elderly people who have suffered a stroke).

The initial nutritional priority in such individuals is thus to restore nutritional status and maximise ability to participate in therapy sessions. As rehabilitation progresses, this objective gradually changes to helping individuals overcome, or mitigate, their neurological difficulties affecting food intake and ensuring that nutrient intake is adequate. With further recovery but persisting disabilities, the aim may be to prevent weight gain and overnutrition. The ultimate aim is to optimise nutritional

Table 7.6.4 Feeding methods that patients may require on a neurorehabilitation ward

Nil by mouth	All nutrition provided via nasogastric, gastrostomy or jejunal feeding tube
Feeding tube with tastes	Assessed by speech and language therapist as safe to commence trials of oral intake Usually teaspoons with therapist initially, then handed over to nursing staff Majority of nutrition, all fluid and medication via tube
Feeding tube, oral meal and some fluids	Oral intake increasing and commence taking meals during the day Start to reduce volume of nutrition via feeding tube and monitor weight May still need significant amounts of fluid via percutaneous gastrostomy
Feeding tube, oral food and fluid	Managing increased oral intake of food and fluid May start to manage medication orally Continue to reduce nutritional provision via feeding tube Dietitian requests oral intake record charts
Feeding tube water only	Reached a stage where weight can be maintained by oral diet; this may be inclusive of oral nutritional supplements but unable to drink enough to maintain hydration It is not uncommon for patients to be discharged from a rehabilitation setting with a feeding tube for fluids and medication only
Full oral diet	Managing enough food and fluid orally to maintain weight and nutritional status
Healthy eating diet for weight management	Oral intake may reach a stage where unwanted weight increases occur Healthy eating dietary advice will be needed; in extreme cases patients might become hyperphagic as a result of their brain injury

intake in a way that maximises the individual's rehabilitation potential.

Nutritional assessment

Many factors impact upon nutritional intake in the brain injured individual; therefore, it is essential that nutritional assessment is carried out within the confines of a specialist team so that expert opinion on other parameters that impact on food intake (as outlined earlier) can be taken into account.

Factors that need to be considered as part of a nutritional assessment are:

- The cause of the brain injury, its management and likely prognosis.
- The physical and psychological consequences of the injury on:
 - The desire to eat.
 - The ability to eat.
 - The ability to swallow.
 - Bowel function.
 - The ability to carry out everyday tasks.
- The individual's nutritional intake.
- The individual's hydration status.
- The individual's nutritional status and whether this is likely to improve, worsen or remain stable.

The aim is to identify individuals who are:

- Malnourished and in need of nutritional support.
- At risk of malnutrition and whose nutritional status needs to be monitored.
- At risk of dehydration and whose fluid intake and hydration status need to be monitored.
- In need of remedial measures to help alleviate diet related problems.

Multidisciplinary team involvement

Liaison with the other members of the MDT helps to provide a full picture of the individual's overall presenting condition. Each professional will carry out their initial assessment and then come together to discuss the situation and devise achievable interdisciplinary goals that the individual can work towards.

Liaison with other healthcare professionals is key to ensuring all aspects of nutritional care are covered. Dietetic interactions with other members of the MDT may include:

- Close working with the speech and language therapist is essential to be fully aware of the patient's swallow ability.
- Liaising with the occupational therapists to be aware of the patient's physical ability to get food to their own mouth, with or without specialist equipment, or to clarify if they need full assistance.
- Obtaining recommendations from the physiotherapist on posture and positioning to best enable a patient to feed themselves, if able, as well as reducing risk of aspiration.
- Doctors and pharmacists can advise on relevant drug-nutrient interactions. As well as the patient's presenting condition, some of the drugs used may impact on their ability to meet nutritional requirements. They may be on medications that reduce their level of arousal and so they are too tired to eat at meal times or medications may make them feel unwell.

Target weight setting

The use of target weights with this type of patient is a way of ensuring appropriate and timely responses to weight fluctuations. The dietitian should agree on a target weight

range with a patient and/or their family or carers on admission to a rehabilitation setting. If this is not possible to do, the target weight should be set in the patient's best interest. Patients in the early stages of rehabilitation and for whom it may still be relatively early post injury may have energy requirements far greater than expected. This may be due to a number of reasons, including autonomic storming, high tone and spasticity or repeated infection.

As time progress, patients may require far less energy as they receive appropriate postural management, medication to manage tone and spasticity, and are sat out in a wheelchair daily. Setting and maintaining target weights are also of great importance when considering a patient's 24-hour postural management. Large fluctuations in weight can cause issues with custom made wheelchairs and splints no longer fitting.

Assessing the extent of nutritional depletion

Weight loss

This is usually the best way of assessing the degree of nutritional depletion in brain injured individuals. Comparison of the individual's weight at the start of rehabilitation with the individual's usual premorbid weight provides a good indication of the extent of energy depletion. This can be calculated as:

$$\% \text{ Usual body weight} = \frac{\text{Current weight (kg)}}{\text{Usual weight (kg)}} \times 100$$

However, measurement of weight is often difficult in severely disabled ABI individuals as appropriate scales may not be available. Hoist or weighbridge type scales can be used to weigh an immobile individual, but such specialist equipment is not always available. When wheelchair or hoist scales are available, then a structured weighing programme can be set up to ensure regular monitoring (see Chapter 7.17.3 for details on alternative weighing scales).

Ascertaining accurate weight trends is invaluable over the period of rehabilitation. It can ensure that nutritional intervention is tailored to the individual. This can often lead to different nutrient provision than first suggested by solely using estimated energy requirements. The weighing programme can enable target weight ranges to be set as the dietitian can be confident that they are working with up to date information. A dietetic or rehabilitation assistant can play a key role in helping to manage the weighing programme and be the liaison between the ward and dietetic department to ensure the patient is weighed in a timely fashion.

Adiposity measurements

These indicate the level of body fat stores, but can be either difficult to measure or inappropriate, in some types of brain injured individuals. Body mass index can only be calculated if measurements of body weight and height are available. As well as practical problems in measuring weight, measurement of height is particularly difficult in brain injured individuals because, even if standing is pos-

sible, they may not be able to stand erect or immobile for long enough. Alternative body measurements such as demispan and knee height, from which height can be derived (see Chapter 2.2), are not always appropriate alternatives since brain injured individuals may be unable to stretch their arms sufficiently for the former measurement or achieve the correct position for the latter. However, it is often possible to obtain an estimate of height directly from the individual or relative.

Skinfold thickness measurements, particularly triceps skinfold thickness, are fraught with problems in many brain injured individuals. In those with hemiplegia, the arm on the affected side may be oedematous, have abnormal muscle wasting and be flaccid or spastic, all of which may distort skinfold measurements. Skinfold measurements at other sites may be affected by poor posture or immobility.

Estimates of muscle mass

Measurements of, for example, mid arm muscle circumference can be useful, but are inappropriate for individuals with limb paralysis (in addition to the likelihood of muscle wasting in the affected arm, there is usually a compensatory increase in muscle mass in the unaffected arm). Immobility will also result in muscle wasting.

Biochemical and haematological indices

Measurements of blood glucose, electrolytes, serum urea and urinary nitrogen are used to monitor the degree of catabolism in the acute post injury phase, but in the rehabilitation phase provide limited information about an individual's nutritional status other than the state of hydration (Labbe, 1986). Haematological indicators may be relevant if anaemia is suspected, and biochemical markers in the rehabilitation setting are likely to be useful in a patient who is undergoing autonomic storming or who has an infection.

Assessing dietary intake

It can be difficult to obtain accurate dietary information from brain injured individuals. Many individuals will have memory and cognitive impairments, and dysphasia (receptive and expressive), which limit their ability to understand or communicate. Behavioural and mood changes may result in hostility or aggression towards the questioner, or alternatively withdrawal and lack of response. It is essential to understand the individual's capabilities as well as limitations and to draw on the expertise and advice from other members of the care team.

The amount and degree of reliability of dietary information that the individual is able to provide will vary considerably and the dietitian will need to be adaptable and innovative to make best use of the relevant circumstances. A skilled dietitian may be able to build up a useful diet history from no more than single word responses to the display of food photographs or food models. The use of specialised computer based packages and technology

can be useful for patients with limited communication ability.

One of the most valuable ways of obtaining additional dietary information is by observing meal times. Not only does this give an estimate of the quantity of food and fluid consumed, but it also reveals any physical difficulties associated with eating or swallowing, together with any behavioural problems.

Assessment tools designed to evaluate problems such as food refusal, antisocial behaviour or assistance needed with feeding have been devised for individuals with dementia (Watson 1994a,b; Watson & Deary 1994; VOICES, 1998), but as yet no such assessment tool has been devised for brain injured individuals whose behaviour and care needs are very different. Food and fluid intake charts that are accurately completed can be useful in assessing dietary intake.

Autonomic storming and fluid requirements

Abnormal autonomic function is well recognised after brain injury. This has been variously termed autonomic dysfunction syndrome, or autonomic or sympathetic storming. Features of the syndrome include increases in heart rate, respiratory rate, temperature and blood pressure, with decerebrate or decorticate posturing, increased muscle tone, and profuse sweating. This autonomic storming can greatly increase the nutritional requirements of these patients and also lead to vastly increased fluid requirements due to increased losses from sweating. In order to maintain biochemical markers of dehydration within normal limits, patients often require significantly more than 30–35 mL/kg of fluid/day.

Managing dietary problems

Inadequate food intake is most likely to result from:

- Physical difficulties with eating or swallowing.
- Anorexia (often as a result of depression, anxiety or medication).
- Cognitive issues.
- Frustration or fatigue over the effort involved in eating.
- Intensive therapy.
- Food refusal as a result of behavioural change or because the patient finds it degrading to have to be fed.
- Drug induced side effects such as nausea and vomiting.

Some of these problems may be remedied by quite simple measures, e.g. smaller, more frequent, energy dense meals for those suffering from anorexia or nausea, the use of various aids to help overcome the physical difficulties of getting food to the mouth, assistance with feeding, involvement of patients in meal or menu planning groups, creating a pleasant meal atmosphere or changing the timing of the administration of drugs to lessen their effects on food intake.

Individuals with evidence of malnutrition, or at high risk of malnutrition, will require a greater level of nutritional support via:

- Food enrichment (see Chapter 6.3).
- Use of energy and protein supplements (see Chapter 6.3).
- Enteral feeding (either overnight supplementary or total support, and via the nasogastric or gastrostomy route) (see Chapter 6.4).

The extent, means and route of support will depend on the level of nutritional depletion, the physical and psychological effects of the neurological lesions, whether the condition is relapsing–remitting or chronically progressive, and the preferences of the individual and carers. Specific problems that may have to be addressed are outlined below.

Dehydration

Hydration status is particularly likely to be inadequate in those with poor oral or swallowing abilities. The problem often results from individuals not being encouraged to consume fluids (either in liquid or semi solid form) at regular intervals throughout the day, either because of lack of time by care staff or lack of awareness of the importance of this. In addition to this, the use of medication within this patient group can be a risk factor for dehydration. The potential for increased susceptibility to infection means antibiotics can increase the risk of diarrhoea, as can sorbitol containing supplements. Furthermore, medications used to correct tone, e.g. baclofen, can also have a laxative effect.

Constipation

This is extremely common in neurorehabilitation patients and may result from:

- Inadequate fluid intake.
- Low fibre intake (especially on a modified consistency diet).
- Reduced gut motility (as a result of reduced neurological signals from the brain or muscle wasting in the gastrointestinal tract).
- Reduced mobility of the individual.
- Side effect of medication (such as opiates for pain relief).

Symptoms may be alleviated by increasing consumption of:

- *Fluid* – ideally to about 2 L/day, although some patients may require more, particularly in the early stages following a traumatic brain injury.
- *Fibre rich foods* that are compatible with the individual's eating or swallowing difficulties. Foods such as porridge, wholegrain breakfast cereals, bananas, peeled oranges or satsumas, vegetables with skins, beans, lentils and peas, and prunes and dried fruit may be suitable possibilities. Speech and language therapists should be involved to advise on the suitability of such foods.

All individuals with, or identified as potentially being at risk of, nutritional problems should be regularly monitored and reviewed by the dietitian and other members of the care team.

Involvement of carers

Some relatives or carers might be very involved in the care and management of the patient and may take an interest in the nutritional management. Regular updates on a patient's weight, progress and nutritional intake may be an important part of dietetic input. Providing day in, day out care for someone with serious physical or psychological difficulties is exhausting and emotionally demanding, and people who have this responsibility require considerable support if they are to maintain their own physical and mental health. The needs of carers have been increasingly recognised in recent years and strategies are being put in place to provide better support measures (Department of Health, 1999).

Most units provide support groups or education sessions for carers and direct them to relevant long term support groups, e.g. Headway. Addressing the carer's needs ensures a more holistic approach to neurorehabilitation. The team can play an important part in ensuring that carers know about, and make use of, any available local support services, which could make life easier or help them feel less isolated.

7.7

Refsum's disease

Eleanor Baldwin

Key points

- Adult Refsum's disease is a rare autosomal recessive disorder of lipid metabolism.
- The primary management of adult Refsum's disease is through dietary modification.
- Foods rich in phytanic acid must be avoided. Phytanic acid is a fatty acid found in ruminant animal products, fish and shellfish.
- Fasting and rapid weight loss must be avoided in order to prevent a rapid increase in plasma phytanic acid and deterioration in symptoms.

A Norwegian neurologist, Sigvald Refsum, first described adult Refsum's disease in 1946. He documented four cases from two families, who had been treated between 1937 and 1943. They initially presented with disturbed visual fields and subsequently developed abnormal gait, muscle wasting and paralysis (Refsum, 1946). He first chose the name heredoataxia hemeralopica polyneuritiformis, but later changed the name to heredopathia atactica polyneuritiformis. Fortunately, most of the scientific literature now uses the term adult Refsum's disease (ARD).

It is important when reviewing the literature on Refsum's disease to distinguish between ARD and infantile Refsum's disease (IRD), because they are completely different disorders, with different management strategies and prognosis. Infantile Refsum's disease is the mildest in the spectrum of a group of global disorders of the peroxisomal assembly. As a result, the peroxisome is deficient in multiple enzymes responsible for different metabolic functions. It presents in infancy with severe mental and physical retardation. Adult Refsum's disease is a disorder affecting one metabolic function of the peroxisome and presentation does not usually occur until the second to fifth decade of life with night blindness associated with retinitis pigmentosa and polyneuropathy or other signs.

Diagnostic criteria and classification

Adult Refsum's disease is a rare autosomal recessive disorder of lipid metabolism. Straight chain fatty acids are normally degraded by beta oxidation in the mitochondria. However, fatty acids with a complicated structure including a methyl or other functional group on carbon 3 can only be broken down by alpha or omega oxidation

in the peroxisomes. The fatty acid phytanic acid (3, 7, 11, 15 tetra methyl hexadecanoic acid) is a common branched chain fatty acid in the diet that is derived from the microbial degradation of the chlorophyll side chain. Normally, this fatty acid is rapidly degraded by alpha oxidation so that plasma levels are usually less than 10 µmol/L (normal range 0–30 µmol/L). The alternative omega oxidation pathway for phytanic acid has a much lower capacity. Patients with ARD have a mutation in an enzyme in the alpha oxidation pathway that degrades phytanic acid. As a result, patients present with plasma phytanic acid levels ranging from 100 to 6000 µmol/L.

The clinical symptoms of ARD evolve slowly and visual symptoms are usually noticed first. Typically, night blindness occurs in the teens, followed by a reduction in the visual fields associated with retinitis pigmentosa. On questioning, patients describe anosmia (lack of sense of smell). Some will have bony abnormalities such as short third or fourth toes or fingers. Deafness, peripheral neuropathy and cerebellar ataxia develop later. Nerve conduction studies are abnormal, with slowing of conduction velocities, and cataracts are common. When the phytanic acid levels are very high (>1000 µmol/L), ichthyosis (rough, hard, scaly, skin), paralysis and cardiac involvement (conduction abnormalities and cardiomyopathy) can occur.

A diagnosis of retinitis pigmentosa in association with any of the above symptoms should arouse suspicion of ARD. Suspected cases of Guillain-Barré syndrome, particularly when they present with acute demyelinating polyneuropathy that appears to be familial and recurrent, should be tested for Refsum's disease as Refsum's can mimic Guillain-Barré (Verny *et al.*, 2006). Measurement of plasma phytanic acid and genetic testing will confirm the diagnosis of ARD.

Genetics

Refsum's disease is genetically heterogeneous; two Refsum's disease genes, phytanoyl CoA hydroxylase (PAHX) and peroxin 7 (PEX7, the PTS2 receptor), have been identified (Jansen *et al.*, 2004). Peroxin 7 is responsible for importing PAHX into the peroxisome along with a small number of other proteins. A severe deficiency in peroxin 7 function is associated with rhizomelic chondrodysplasia. A further enzyme defect in the alpha oxidation pathway involving alpha methyl acyl CoA racemase (AMACR) can mimic ARD, but levels of pristanic acid are more elevated than those of phytanic acid. Another Refsum like disorder has also recently been identified, called PHARC (polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, cataract) (Fiskerstrand *et al.*, 2010), which involves deficiency in aldehyde. It is caused by mutations in alpha/beta hydrolase 12 (ABDH 12), which is involved in the metabolism of the endocannabinoid 2 arachidonyl glycerol. This disorder presents with similar symptoms to ARD, but patients do not have anosmia and both plasma phytanic acid level and peroxisomal function are normal.

Metabolism and disease processes

The clinical manifestations of ARD usually begin in adolescence with night blindness and then progressive loss of visual field and diagnosis of retinitis pigmentosa (Reuther *et al.*, 2010). The other clinical manifestations described earlier develop later. Phytanic acid accumulates in the plasma and all fat containing tissues, liver, brain, adipose tissue, etc. The mechanisms that cause these symptoms remain obscure; however, molecular distortion and antimetabolite hypotheses have been put forward (Young *et al.*, 2001; Wierzbicki *et al.*, 2002); modern evidence favours a mechanism based on mitochondrial toxicity. Anecdotally, lifespan appears normal (personal communication). Provided phytanic acid levels are well controlled, the acute complications (cardiac), ichthyosis and acute neuropathy do not develop. Retinitis pigmentosa seems to progress as people age and within siblings with the condition there can be significant differences in the clinical severity of symptoms (personal communication).

Management

Treatment of people with ARD follows three approaches:

- **Dietary restriction of phytanic acid** to a level (<10 mg) at which the omega oxidation pathway has the capacity to manage and gradually reduce the phytanic acid present in the plasma. Case study reports and audits of groups of Refsum's disease patients attending a Refsum's clinic for more than 10 years have demonstrated that Refsum's patients can be successfully managed by diet, without the development of cardiomyopathy or high plasma phytanic acid levels requiring plasmapheresis (Baldwin *et al.*, 2010).

- **Supportive management of symptoms.** Cochlear implants have successfully treated deafness in at least three Refsum's patients (personal communication). Physiotherapy can induce symptomatic improvement in physical strength and emollients can soothe itchy, scaly skin. Appropriate use of social services for sensory assessments and agencies such as the Royal National Institute for the Blind for advice on living with visual impairment and blindness can help patients to improve their quality of life.
- **Plasmapheresis** should be offered when the plasma phytanic acid levels are very high (1000 µmol/L and above) and acute symptoms such as cardiac abnormalities or acute polyneuropathy are evident, or the clinical condition of the patient is rapidly deteriorating. More than half of phytanic acid in the plasma is localised within very low density (VLDL), low density (LDL) and high density (HDL) lipoprotein particles. Low density lipoprotein and VLDL bound phytanic acid can be effectively eliminated from plasma with extracorporeal LDL apheresis using membrane differential filtration (Straube *et al.*, 2003).

Nutritional assessment

At diagnosis a full dietetic assessment should be made.

Anthropometry

Anthropometric assessment should include:

- Weight.
- Height.
- Body mass index (BMI).
- Weight history.

Dietary assessment

The dietary history should assess intake of foods rich in phytanic acid (Table 7.7.1). Phytanic acid is a type of fat made by some animals (ruminants) when they digest grass. It is also found in fish because they eat algae, or have eaten fish that have eaten algae. The higher the fat content of the food that contains phytanic acid, the higher the phytanic acid content will be, e.g. cheddar cheese will contain more phytanic acid than reduced fat cheddar cheese.

Caffeine intake and recreational drug use should be assessed. Adrenergic substances theoretically increase the plasma phytanic acid levels by increasing lipolysis.

Dietary management

Advice should be given on complete avoidance of foods containing phytanic acid (Table 7.7.1) and appropriate substitutes suggested. The Westminster Diet for ARD is based on the analysis of the phytanic acid component of common foods listed by Brown *et al.* (1993). The absolute level of phytanic acid in, for example, beef and dairy products will depend on the feed the cattle have been

Table 7.7.1 Foods rich in phytanic acid and suitable alternatives that are low in or contain virtually no phytanic acid

Foods	Foods containing phytanic acid – to be avoided	Foods low in phytanic acid
Meat, meat products and meat substitutes	Beef Beef burgers Calves liver and kidneys Cottage pie Duck Goose Lamb Mutton Meat lasagne Rabbit Shepherd's pie	Bacon Bean curd Chicken Chicken liver Turkey Eggs Ham Pork Pork liver and kidneys Pork sausages Quorn Soya meat substitutes, e.g. soya mince, soya sausages, etc. Tofu
Dairy products	Cheese made from cow's, sheep's or goat's milk Milk Cream Cow's milk (full cream or semi skimmed) Goat's milk Sheep's milk Ice cream Yoghurt (full cream or Greek) Butter Ghee	Cheese substitutes made from soya, e.g. Pure soya cheese spread, redwood soya cheeses, Bute island foods soya cheeses Cream substitute (Alpro soya single cream, soya too dairy free spray cream, soya too cooking cream and soya too topping cream) Cow's milk (skimmed only) Soya milk Swedish glace ice cream substitute Yoghurt (fat free or virtually fat free only) Soya yoghurt style puddings Low fat spreads made only from vegetable oil, e.g. Pure range Vegetable ghee
Other fats and oils	Suet	Vegetable suet, lard
Fish	Fish, especially oily fish such as herring, salmon and sardines Shellfish – clams, mussels, octopus, prawns, shrimps. Fish oil	Soya or pulse based fish substitutes such as Redwood foods fish style fingers, fish style steaks, scampi style pieces and Thai style fish cakes
Nuts	Walnuts and peanuts	Very few nuts have been analysed
Alcoholic drinks	Any drinks containing cream, e.g. Bailey's Irish Cream	Any alcoholic drink that does not contain cream
Bread and baked goods	Brioche, croissants, shortcrust pastry Biscuits and cakes made with butter, suet or fish oil	Puff pastry Filo pastry,* e.g. Jus-Rol All bread, biscuits and cakes that do not contain butter, suet or fish oil
Breakfast cereals	Tesco choco snaps	Breakfast cereals that do not contain milk powder (skimmed milk powder is appropriate) Small portions only of cereals containing nuts, e.g. muesli
Confectionery	Milk chocolate	Dark chocolate, carob, chocolate that does not contain milk fat or butter Fat free sweets, e.g. boiled sweets

*Check ingredients label as filo pastry is occasionally made with butter.

given (Lough, 1977). Therefore, the values in Brown *et al.*'s article should be taken as a representation only. The phytanic acid content of a food product will also relate to the overall fat content because phytanic acid is a fatty acid. Therefore, products such as semi skimmed milk will inevitably have a lower phytanic acid content than full cream milk.

Foods known to contain virtually no phytanic acid include:

- Most breakfast cereals (for exceptions see list).
- Safflower oil, corn oil, olive oil, sunflower seed oil.
- Bread, rice, pearl barley, pasta.
- Jelly.
- Honey.
- Tea, coffee.
- Cooked green vegetables, carrots, mushrooms, onions, potatoes and swede.
- Salad vegetables.
- Fruit.

A moderate caffeine intake (200–350 mg/day for adult women and 300–450 mg/day for adult men) should be advised.

A suitable n-3 fatty acid supplement should be encouraged as status in peroxisomal disorders is known to be low (Martinez *et al.*, 2000) and oily fish is excluded in ARD due to its high phytanic acid content (Omacor™ is the only supplement known to have a low phytanic acid content).

Anecdotal reports (Perera *et al.*, 2011) suggest that Orlistat therapy may be beneficial in some patients by reducing absorption of fat and fatty acids, including phytanic acid. However, weight loss must be monitored and rapid weight loss avoided.

Regular dietetic review is recommended to maximise dietary compliance and support people with ARD. The symptoms of ARD can be controlled by diet (Baldwin *et al.*, 2010), but deterioration in vision occurs over time. This can result in practical difficulties in following the diet (cooking, shopping and reading food labels), depression and social isolation, which can also affect body weight. It is also essential to ensure rapid access to advice on nutritional support to avoid deterioration during episodes of intercurrent illness or fasting for unrelated surgery.

During weight loss or fasting

During weight loss or extended periods of fasting, the plasma phytanic acid levels increase exponentially, doubling approximately every 29 hours (Wierzbicki *et al.*, 2003). This is because of the liberation of phytanic acid stored in the liver and adipose tissue. Patients often have a low BMI at diagnosis. Nutritional supplementation to promote weight gain may be required at diagnosis, during periods of intercurrent illness or pre or post surgery. Most nutritional supplements are suitable for use, with the exception of those containing fish oil, full fat milk or full fat dairy products, because these ingredients are rich in phytanic acid. Weight gain can cause a reduction in plasma phytanic acid as some of the phytanic acid will be shunted into adipose tissue deposits. Patients should be advised against weight loss unless the plasma phytanic acid levels are well controlled and their symptoms are stable. Where weight loss is advised, rates should be slow (0.25 kg or less/week) and the plasma phytanic acid levels should be closely monitored in order to detect and avoid deterioration.

Drug-nutrient interactions

The role of the peroxisome in drug metabolism in man is unclear, especially in patients with deficient or abnormal peroxisomal function. However, some lipid lowering drugs (e.g. fibrates) and hypoglycaemic drugs (thiazolidinediones; glitazones) rely on mechanisms associated with increased peroxisomal activity in animals and should be used with caution in people with peroxisomal disorders. The only common drug known to be metabolised through the peroxisome is ibuprofen, which is metabolised through a pathway involving AMACR. Therefore,

alternative non-steroidal anti-inflammatory drugs are preferred in people with ARD.

Inherited metabolic disorders in adults

Sarah Boocock, Louise Robertson, Avril Micciche, Sarah Adam, Heidi Chan, Charlé Maritz, Sarah Ripley, Hazel Rogozinski, Pat Portnoi and Sarah Donald

Key points

- Most inherited metabolic disorders (IMDs) require dietetic input as part of their treatment. This may include dietary modification of the amount or type of protein, fat and/or carbohydrate.
- Many IMDs need an emergency regimen as part of treatment during a metabolic decompensation.

Inherited metabolic disorders (IMDs) are a rare group of genetic diseases where a mutation in a single gene affects the production or degradation of protein, carbohydrate or fat (see Chapter 5.1). There is often an enzyme or transport protein defect that can cause serious illness due to toxin accumulation if not treated. Inherited metabolic disorders can develop at any time, including during adulthood, but usually the later they present, the less severe they are. As medical science improves, more patients with IMDs are now surviving into adulthood, resulting in a need for adult services and a smooth transition from paediatric services. In the UK, the incidence is 1 in 800, but this varies between countries and ethnicity (Sanderson *et al.*, 2006). This chapter outlines the dietetic treatment for adults with the most common IMDs and practical strategies to aid a successful outcome. Chapter 3.8.16 introduces the topic in children.

Phenylketonuria

Phenylketonuria (PKU) is an autosomal, recessive IMD caused by a deficiency of the enzyme phenylalanine hydroxylase (PAH), which catalyses the conversion of phenylalanine into tyrosine. High phenylalanine blood concentrations are neurotoxic during infancy and childhood, leading to irreversible brain damage if not treated from birth. The severity of PKU depends on the amount of residual activity of PAH.

Nutritional management

Dietary treatment is a restricted phenylalanine diet and involves:

- Protein substitute, which contains all the indispensable (essential) amino acids except phenylalanine – 60–80 g

of protein equivalent taken in three to four doses throughout the day.

- Low protein diet and exchanges (one exchange = 1 g of protein = 50 mg of phenylalanine).
- Prescribed low protein foods – bread, pasta, rice, flour, cereals and milk.
- Naturally low protein foods – fruit, vegetables, fats and sugars.

Patients on this PKU diet should be reviewed 6 monthly and those off diet annually (National Society for Phenylketonuria, 2004). Blood phenylalanine concentrations in adults should be monitored at least monthly using dried blood spot analysis [Medical Research Council (MRC), 1993]. Annual biochemical monitoring, including nutritional bloods and particularly vitamin B₁₂, is recommended (Hvas *et al.*, 2006).

For those returning to the PKU diet, a step wise introduction should be used. A baseline measurement of blood phenylalanine should be taken before any dietary changes are made. It is important to identify the patient's or care team's reasons for recommencing the diet, as these can be later used as outcome measures to help ascertain the success of the diet.

Protein substitute should initially be given once a day and slowly increased to the full requirement. Once the full dose of protein substitute is reached, high protein foods can be safely excluded. Cow's milk should be swapped for a lower protein alternative and prescribed low protein foods should be introduced to help lower phenylalanine intake, ensure sufficient energy intake and provide variety. If the desired phenylalanine levels are not achieved, protein exchanges should be considered. A dietary review 3–6 months after restarting the diet can ascertain the benefits of the diet and whether it should be continued in late treated patients (see Late treated PKU section).

Table 7.8.1 Evidence for diet for life in phenylketonuria

Study findings when off diet	Reference
Negative mood reported by both patient and family member	Ten Hoedt <i>et al.</i> (2010)
Reduced quality of life	Bik-Multanowski <i>et al.</i> (2008)
Tremors, brisk tendon reflexes, and impaired coordination	Cerone <i>et al.</i> (1999)
Lower scores on accuracy and performance speed when off diet for 5 years	Channon <i>et al.</i> (2007)
Phobias, low self esteem, social isolation and lack of autonomy	Brumm <i>et al.</i> (2010)

Diet for life

There is a growing body of evidence to suggest that patients with PKU should stay on diet for life. Table 7.8.1 summarises some of this evidence. Acceptable blood phenylalanine levels in adults vary worldwide with no general consensus. Levels range from <600 µmol/L in the USA and Germany, and <1200–1500 µmol/L in France. In the UK, a blood phenylalanine concentration of between 120 and 700 µmol/L is recommended, aiming for <480 µmol/L for good control (MRC, 1993). The restrictive nature of the PKU diet can make adherence challenging. It is vital to educate patients on the benefits of adhering to the diet, but also to support their decision if they choose not to follow the diet. For women of child bearing age the risks of conceiving off diet must be emphasised (see Maternal phenylketonuria section).

Adult patients can be classified into four groups, each with specific problems and nutritional issues requiring different strategies for care and monitoring (Figure 7.8.1).

Maternal phenylketonuria

Women with PKU must return to a strict diet when planning a pregnancy. High phenylalanine levels are teratogenic for the foetus and raised levels during pregnancy can cause microcephaly, mental retardation, congenital heart disease, spontaneous abortion and low birth weight (<2500g) (Lenke & Levy, 1980).

Metabolic control must be closely monitored during pregnancy and the target range for phenylalanine should be maintained between 60 and 250 µmol/L (MRC, 1993); however, this range may differ at different centres. Tighter control is necessary as there is a positive amino acid gradient across the placenta, thereby exposing the foetus to higher phenylalanine concentrations than the mother (Cleary & Walter, 2001). Evidence suggests that optimal birth outcomes occur when the phenylalanine level is between 120 and 360 µmol/L by 8–10 weeks of gestation and this is then maintained throughout pregnancy (Koch *et al.*, 2003). Ideally, patients should commence the diet before conception.

Preconception

Patients should have phenylalanine levels within the recommended range for a couple of weeks and feel confi-

dent about the diet before stopping contraception. A baseline blood test should be done before patients start the diet to give an indication of phenylalanine levels while off diet. The appropriate number of protein exchanges to start the diet can be estimated from the off diet level. Patients will be required to monitor this one to two times a week. Folic acid is provided in the amino acid supplements. However, if levels are low before going back on diet, patients may be advised to take a standard 400 µg preparation. Once the diet has been commenced, this can be discontinued provided the amino acid supplement has adequate amounts of folic acid and the serum folate level is within range.

Arachidonic acid (AA) levels appear adequate in PKU patients due to the abundance of linoleic acid in the diet from vegetable oils and spreads (Cleary *et al.*, 2006). However, the conventional dietary sources of docosahexaenoic acid (DHA) such as fish are prohibited in the PKU diet. Evidence suggests that preformed DHA is needed in the diet (Cleary *et al.*, 2006) and that DHA can have beneficial effects on foetal development (SACN & Committee on Toxicity, 2004). It has recently been recommended that pregnant and lactating women should have an intake of at least 200 mg of preformed DHA (Koletzko *et al.*, 2008). Some amino acid supplements may already have added DHA or it can be given separately. Care should be taken to recommend DHA supplements without additional vitamins A and D.

First trimester

A frequent problem during the first trimester is morning sickness. Patients may find it difficult to tolerate the amino acid supplement and energy intake may be compromised due to nausea and vomiting. It may be useful to advise eating little and often, encouraging patients to have plenty of energy dense foods such as sugary, non-caffeinated drinks and to snack on low protein foods every 2–3 hours. This advice will help to prevent the phenylalanine level from increasing. Reducing the volume of supplement at each dose, spreading it out over the day or changing the supplement to tablet form may be useful. Increasing the dose of amino acid supplement to drive the phenylalanine level down is also advisable. Supplementing the diet with products such as glucose polymers will provide important extra energy (see Appendix A10). The phenylalanine level will increase if the patient becomes catabolic, which is detrimental to the foetus.

Second and third trimesters

During the second trimester (16–20 weeks), the phenylalanine tolerance increases as the baby grows rapidly and it may be necessary to increase the exchanges by two to three at a time to keep up with the baby's growth. It is also important to consider whether or not to supplement tyrosine during the pregnancy. Little evidence is available to support this, but it has been speculated that low tyrosine could be a factor in foetal damage in maternal PKU (Rohr *et al.*, 1998). Practice varies but many centres supplement from 16 weeks of gestation onwards or when tyrosine levels are below 40 µmol/L. Tyrosine can

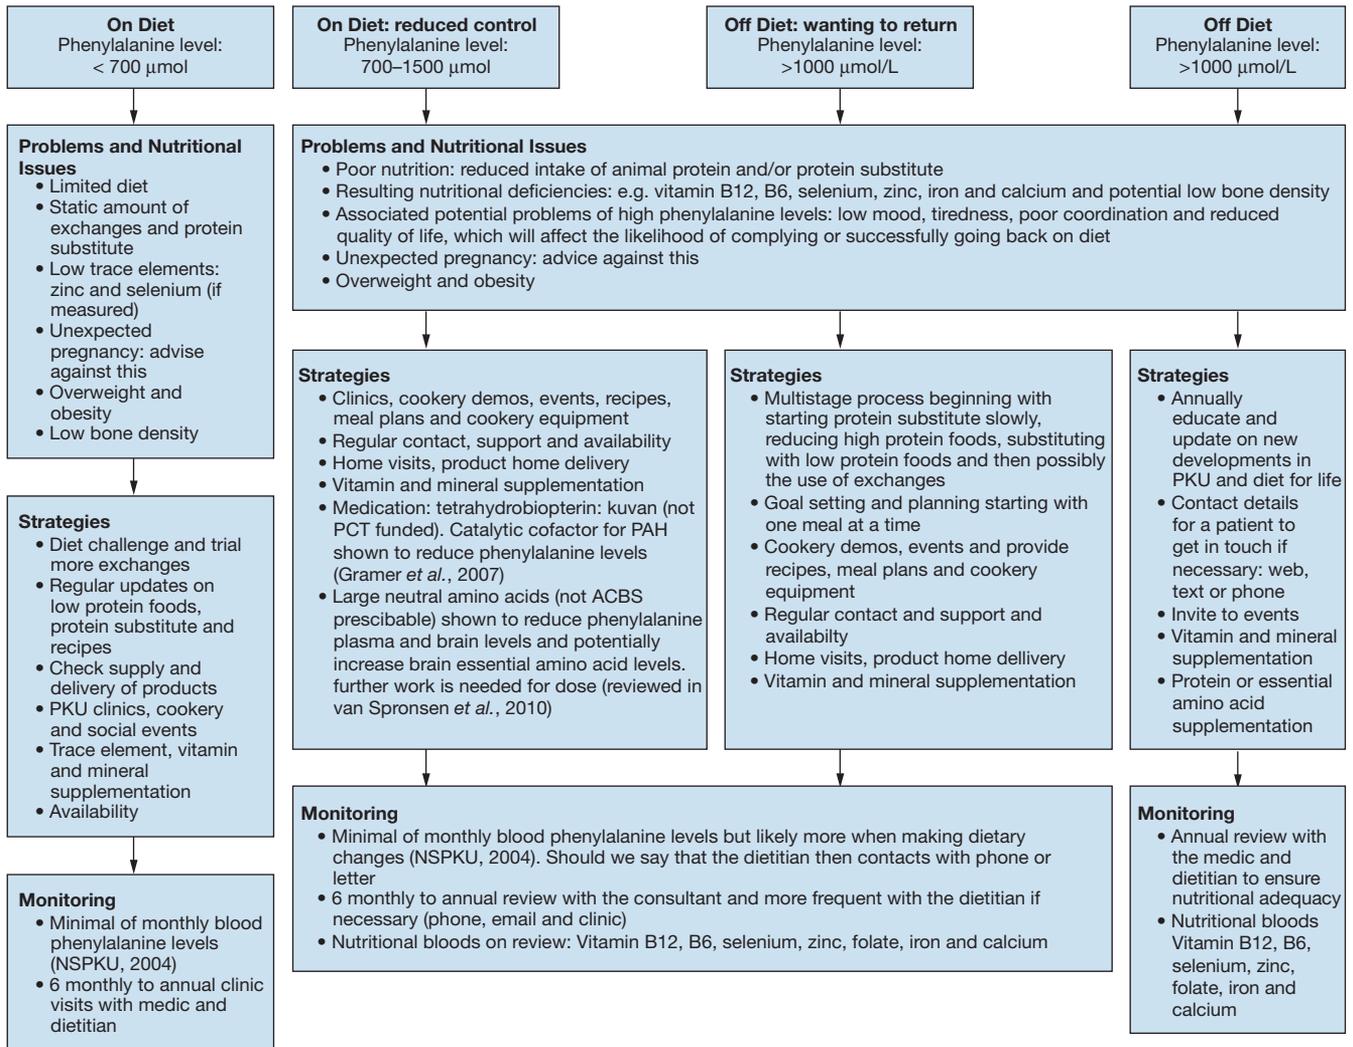

Figure 7.8.1 Challenges and strategies in adult phenylketonuria (PKU)

be supplemented using powder formulations. Aim to provide a total of 8g of tyrosine/day from the supplement and additional tyrosine powder combined.

Late treated phenylketonuria

Adults with PKU born prior to the late 1960s typically have severe intellectual disabilities and challenging behaviour, as it was not until then that newborn screening for PKU was introduced. Patients were not commenced on diet early in life. These individuals should be considered for dietary treatment, because metabolic control has been shown to progressively improve behaviour in such patients (National Institute of Health, 2000). Phenylalanine concentrations in people with classical PKU are typically $>1500 \mu\text{mol/L}$ pre diet. The desired blood phenylalanine concentration in treated adult PKU patients is $120\text{--}480 \mu\text{mol/L}$ but values up to $700 \mu\text{mol/L}$ still show benefits (MRC, 1993).

Anecdotal evidence suggests that lowering blood phenylalanine with a phenylalanine restricted diet can improve communication, relationships with carers and social skills, although not all show benefit. A randomised

placebo controlled double blind trial of a phenylalanine restricted diet in adults with late diagnosed PKU concluded that there are potential benefits to quality of life for the individuals and their carers (Lee *et al.*, 2009); while the overall benefit was not high, a positive effect in about three-quarters of the individuals was demonstrated. About 70% of the carers continued with the diet even after the trial had ended. Another study demonstrated that giving a phenylalanine restricted diet to adults with previously untreated PKU led to economic benefits to the UK's NHS and society in general (Brown & Guest, 1999).

Urea cycle disorders

The urea cycle metabolises the hepatic pool of nitrogen and a fault in an enzyme in the pathway results in a urea cycle disorder (UCD) causing hyperammonaemia (Leonard, 2006). Accumulation of ammonia in the brain may lead to damage that can result in coma and death if left untreated (Singh, 2010). Protein aversion is common, leading to disordered eating and a poor quality diet.

Some adults may rely on artificial feeding. There is limited evidence on the long term outcome in adults.

The UCDs are:

- Carbamoyl phosphate synthase deficiency (CPS).
- Ornithine transcarbamoylase deficiency (OTC).
- Citrullinaemia.
- Argininosuccinic aciduria (ASA).
- Arginase deficiency.
- N-acetyl glutamate synthase deficiency (NAGS).
- Ornithine amino transferase deficiency (OAT).

The most prevalent UCD results from OTC deficiency, which is an X linked disorder, while the other disorders are inherited in an autosomal recessive manner. Clinical presentation in adults varies due to residual enzyme activity, genotype and exogenous nitrogen load (Singh, 2007). By restricting nitrogen consumption from protein, ammonia production is limited. Ammonia scavenging drugs such as sodium benzoate and/or sodium phenylbutyrate are used to treat these disorders pharmacologically as they provide an alternative pathway for excretion of excess nitrogen (Scaglia, 2010).

Nutritional management

Long term management is to restrict protein intake whilst maintaining optimal nutritional status with supplementation. The WHO/FAO/UNU (2007) recommends safe protein levels based on actual body weight. Within that daily requirement, part of the protein intake should comprise natural protein, with the remainder from essential amino acid supplement. Protein tolerance is greater in those with higher levels of residual enzyme and when pharmacological doses are high (Singh, 2010). Protein should be evenly distributed throughout the day along with medication.

Energy provision should be sufficient to prevent fluctuations in weight. Sources include naturally low protein foods that are high in energy, specialist low protein prescribable items and high energy, non-protein nutritional supplements. Restricting protein also restricts the intake of certain vitamins and minerals and can therefore lead to significant deficiencies in the long term. Determination of micronutrient levels from diet diary analysis and plasma biochemistry is useful in influencing whether supplementation is required. Often, depletion in vitamin B₁₂ and calcium levels is observed and regular monitoring of such nutrients after supplementation is a requisite.

Lean body mass will be broken down to produce arginine if the urea cycle does not produce sufficient quantities. Therefore, arginine becomes an essential nutrient and oral supplementation is necessary (Singh, 2007). L-Arginine can be administered in all the UCDs except in arginase deficiency where it does not become essential.

Treatment when unwell

Metabolic decompensation occurs when the body is in a catabolic state. This is exacerbated by infections, fever, trauma, surgery, intense physical activity and prolonged

labour. During such periods, the body requires additional non-protein energy to prevent the breakdown of lean body mass. Withdrawal of protein should be initiated immediately and the oral emergency regimen commenced (see Emergency regimens section). Ammonia scavengers need to be administered orally or intravenously depending on the function of the gastrointestinal tract.

Organic acidaemias

Propionic acidaemia (PA) and methyl malonic acidaemia (MMA) are autosomal recessive disorders whereby isoleucine, valine, methionine, threonine and odd chain fatty acids are not metabolised fully. The deficient enzyme is propionyl-CoA carboxylase in PA, and methyl-malonyl-CoA mutase, which is vitamin B₁₂ dependent, in MMA (Yannicelli, 2010). Some MMA patients respond well to vitamin B₁₂ supplementation. Isovaleric acidaemia (IVA) affects leucine metabolism, whereas glutaric aciduria type 1 (GA1) affects lysine and tryptophan metabolism.

Nutritional management

This entails a high energy, low protein diet with supplementation of amino acids, except for the propiogenic acids in MMA and PA (Ogier de Baulny *et al.*, 2005). Supplementation of glycine is indicated in IVA and lysine in GA1. L-Carnitine supplementation counteracts urinary losses of acylcarnitine (Ogier de Baulny *et al.*, 2005). Vitamin and mineral replacement are advised to prevent deficiencies. Additional aims of the long term management include prevention of fasting and immediate medical and dietary treatment during illness (see Emergency regimens section).

Disorders of fatty acid oxidation

Fatty acid oxidation disorders (FAODs) are autosomal recessive genetic disorders in the mitochondrial fatty acid oxidation pathway. During increased energy demand, mitochondrial fatty acid oxidation plays an important role in energy homeostasis as it competes with glucose as the primary oxidative substrate (Spiekerkoetter *et al.*, 2010). Fatty acid oxidation disorders vary in severity and can present in infancy or during adolescence and adulthood. During infancy patients typically present with encephalopathy and hypoglycaemia as a result of the accumulation of toxic metabolites or during periods of increased energy demand. Cardiomyopathy is a life threatening complication of acute metabolic decompensation in many patients with FAOD. Patients with a milder phenotype may not present until adulthood and typically present with exercise intolerance and recurrent episodes of rhabdomyolysis (the breakdown of muscle, which leads to the release of muscle fibre contents, myoglobin) and myoglobinuria (Gillingham, 2010).

Fatty acid oxidation consists of four components; the carnitine cycle, beta oxidation cycle, electron transfer path and ketone bodies synthesis (Stanley *et al.*, 2006):

- *Carnitine cycle defects* – carnitine transport defect (OCTN2), carnitine palmitoyltransferase 1 (CPT-1) deficiency, carnitine/acylcarnitine translocase (TRANS) deficiency and carnitine palmitoyltransferase 2 (CPT-2) deficiency.
- *Beta oxidation defects* – very long chain acyl-CoA dehydrogenase (VLCAD) deficiency, medium chain acyl-CoA dehydrogenase (MCAD) deficiency, short chain acyl-CoA dehydrogenase (SCAD) deficiency, long chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, short chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) deficiency, medium chain 3 ketoacyl-CoA thiolase (MCKT) deficiency and 2, 4-dienoyl-CoA reductase (DER) deficiency.
- *Electron transport defects* – ETF/ETF DH deficiencies.
- *Ketone synthesis* – HMG-CoA synthase and HMG-CoA lyase.

Nutritional management

Fatty acid oxidation disorders are treated mainly by diet. The primary aim is to reduce fatty acid oxidation by avoiding fasting, limiting dietary fat intake in severe disorders and using the emergency regimen during illness.

Fasting

There are few published data on fasting duration in MCADD, the most common of the FAODs. It is important that prolonged fasting is avoided as fatty acid oxidation rates increase with fasting (Gillingham, 2010). The British Inherited Metabolic Disease Group (BIMDG) set a safe fasting time for older children and teenagers with MCADD as 12 hours (Dixon, 2007a). Generally, fasting for >12 hours should be avoided (Gillingham 2010).

Fats and essential fatty acids

Fat restriction in patients with SCADD and MCADD does not appear to be of any benefit and patients can follow a normal diet. In MCADD this is due to near normal oxidation of medium chain fatty acids (MCFAs) (Dixon, 2007a). Medium chain fatty acids enter the mitochondria without being bound to carnitine, therefore bypassing the step at which fatty acid oxidation is normally regulated (CPT1). Therefore, patients with SCADD or MCADD should never be given medium chain triglycerides (MCTs) as ingestion could lead to a more severe metabolic disturbance than with long chain fats (Gillingham, 2010; Dixon, 2007a).

For long chain fatty acid oxidation defects, dietary long chain fats (LCTs) should be restricted (calculated as a percentage of total energy derived from fat) to minimise fatty acid oxidation (Spiekerkoetter *et al.*, 2010). The safe upper limit for LCT intake has not been established, as this will depend on the severity of the disorder (Dixon, 2007a). Patients on a low fat diet are at an increased risk for essential fatty acid (EFA) deficiency and supplementation with EFAs should be provided. In patients developing exercise induced rhabdomyolysis, enrichment of the diet with MCTs, with or without carbohydrates, prior to exercise may be beneficial (Dixon, 2007b; Spiekerkoetter *et al.*, 2010).

Carnitine therapy

There is clear evidence that treatment with carnitine in patients with primary carnitine transport defect improves cardiac and skeletal muscle function (Spiekerkoetter *et al.*, 2010). Supplementation with L-carnitine in long chain FAODs remains controversial (Gillingham, 2010; Stanley *et al.*, 2006).

Emergency regimen

Intervention with increased fluid and carbohydrates during acute illness is crucial (see the Emergency regimens section).

Homocystinuria

Homocystinuria (HCU) results from a deficiency of the enzyme cystathionine β synthase (C β S), which is involved in the metabolism of the amino acid methionine. C β S is dependent on a cofactor derived from pyridoxine (vitamin B₆) and the biochemical response to pyridoxine distinguishes the two phenotypes of homocystinuria. In the pyridoxine responsive phenotype, pharmacological doses of pyridoxine partially or completely control the biochemical abnormalities, and in the non-pyridoxine responsive phenotype pyridoxine has no effect. The disorder is characterised by the accumulation of homocysteine and methionine in blood. Untreated homocystinuria can lead to developmental delay, ectopia lentis and severe myopia, skeletal abnormalities and thromboembolism (Levy *et al.*, 2002). Newborn screening has led to early diagnosis and effective treatment, and fertility does not appear to be affected.

The biochemical aim of treatment is to control, and if possible normalise, the severe hyperhomocysteinaemia. The clinical aims are to prevent abnormalities in the four organ systems and optimise intelligence in patients diagnosed by newborn screening. In late diagnosed patients, the aim is to prevent life endangering vascular events and manage existing complications (Yap, 2003). Routine measurement of total homocysteine (tHcy) enables treatment effectiveness to be monitored. The aim is to maintain levels at 80–120 μ mol/L; in the normal population tHcy levels are 5–15 μ mol/L.

Nutritional management

Treatment of non-pyridoxine responsive homocystinuria is through dietary methionine restriction with methionine/protein exchanges (20 mg of methionine = 1 g of protein) and a methionine free amino acid preparation, e.g. XMet Homidon and HCU Cooler. Manufactured low methionine foods are available on prescription, provide variety in an otherwise very limited diet and are a valuable energy source. The protein substitute used should contain cysteine as this amino acid is usually formed from methionine but becomes deficient in HCU due to the metabolic block. The protein substitute should be given in divided doses together with the methionine exchanges at main meals. This prevents excessive rises in plasma homocysteine, ensures a complete range of amino acids and

allows protein synthesis. If vitamins and minerals are not contained in the protein substitute, these must be provided separately. Folic acid (5 mg/day) is prescribed to ensure adequate intake for use in the remethylation pathway (Walter *et al.*, 1998). The principal pathway for the metabolism of dietary methionine is through conversion of homocysteine to cysteine.

Betaine

Betaine is a methyl donor that stimulates the methylation of homocysteine and reduces homocysteine levels, but usually results in significantly increased plasma methionine levels. Oral betaine can improve biochemical control in individuals where dietary compliance is poor. However, compliance with betaine can also be an issue. The safety of betaine therapy in pregnancy has not been established, but there have been reports that suggest no adverse maternal or foetal effects (Pierre *et al.*, 2006).

Maternal homocystinuria

Newborn screening has led to early diagnosis and effective treatment. Unlike maternal PKU, no strong evidence of teratogenic effects has been found. Fertility does not appear to be affected; however, the incidence of spontaneous abortion is high and there is evidence of increased risk for thromboembolic complications, especially postpartum. Anticoagulant therapy during pregnancy and 6 weeks postpartum will minimise these risks (Levy *et al.*, 2002).

Maple syrup urine disease

Maple syrup urine disease (MSUD) is characterised by the accumulation of the branched chain amino acids (BCAAs), leucine, isoleucine and valine, and their metabolites, which are neurotoxic and life threatening. Leucine is thought to be one of the main toxic metabolites and is restricted in the diet using leucine exchanges (50 mg of leucine = 0.5 g of protein = one exchange). Essential dietary components also include BCAA free protein substitute, vitamin and mineral supplements and low protein prescribed and natural foods similar to those for PKU. Dietary treatment is life long and aims to maintain plasma BCAAs within safe ranges; leucine 200–400 µmol/L, isoleucine 100–200 µmol/L and valine 100–300 µmol/L. Illness is treated by an emergency regimen that should include the usual protein substitute.

Tyrosinaemia

Type 1 tyrosinaemia results in an increased plasma tyrosine and its metabolites, including succinylacetone, which damage the liver. Treatment is a combination of 2-(2-nitro 4-trifluoromethylbenzoyl)-1, 3-cyclohexanedione (NTBC) and a low tyrosine, low phenylalanine diet, aiming to maintain plasma tyrosine at 200–400/500 µmol/L. A tyro-

sine and phenylalanine free protein substitute is given, plus low protein foods (as in PKU). Tyrosine is given as 1-g protein exchanges.

Galactosaemia

Galactosaemia is an autosomal recessive, rare, inherited metabolic condition in which there is an inability to metabolise galactose. It is caused primarily by the deficiency of the enzyme galactose 1 phosphate uridyl transferase (GALT). Patients present initially in the neonatal period with a life threatening liver disease, and after the initial crisis, are managed with a low galactose, lactose free diet. Presentation at an adult clinic usually follows transfer from a paediatric clinic. Occasionally, patients present having been discharged from a clinic earlier in their lives and may not be on diet. As a result of the enzyme deficiency, galactitol and galactonate accumulate in abnormal quantities. Increased galactitol causes cataracts and galactonate is believed to play a role in hepatic and renal toxicity.

Ovarian dysfunction, central nervous system problems, language and speech defects, cataracts and reduced bone mineral density have been reported (Berry & Elsas, 2011). Complications are independent of diet and occur even if the diet is started immediately after birth (Waggoner *et al.*, 1990, Schweizer *et al.*, 1993). The cause of these problems is unknown, but may result from endogenous galactose synthesis. Endogenous production is a constant in patients and is not influenced by diet. Adults have been shown to have slower rates of release of endogenous galactose than newborns (Schadewaldt *et al.*, 2004). Most centres measure red blood cell galactose 1 phosphate annually, and aim for levels of <0.60 µmol/g of haemoglobin (<150 µmol/L), but the measurement varies in and between individuals and is probably most useful as a compliance monitor, detecting severe non-compliance (Bosch, 2006).

Nutritional management

Life long dietary restriction of galactose is the only effective treatment for galactosaemia, i.e. following a low galactose diet. Table 7.8.2 summarises the issues associated with this diet. The main source of galactose is lactose; so all lactose is excluded from the diet. There are other sources of galactose, but in the UK these are not restricted and there is no evidence for making the diet stricter. Other countries may have different policies. The following are allowed in the UK:

- *Galactosides* – found in legumes, soya and cocoa. Although galactosides are the main subunit of these oligosaccharides, they are not hydrolysed by the intestinal mucosa.
- *Free and bound galactose* – occurs in small amounts in many fruits and vegetables, but is probably insignificant.
- *Galactose* – can also be found in offal in galactocerebrosides.

Table 7.8.2 Dietary issues in adult galactosaemia

Dietary and monitoring issues	Evidence	References
Need for strict life long dietary restriction	No randomised controlled trials in adults comparing patients on and off diet therefore consensus to maintain a low galactose diet for life. However, an individual with Q188R mutation stopped a strict diet at 3 years, and developed normally.	Lee <i>et al.</i> (2003)
Alcohol	No evidence that alcohol intake should be limited	Walter <i>et al.</i> (1999)
Bone mineral density (BMD)	Low BMD due to primary ovarian insufficiency	Rubio-Gozalbo <i>et al.</i> (2002)
Calcium and vitamin D supplementation	Supplement calcium, vitamin D and other nutrients to ensure long term bone health	MacDonald (2013)
Biochemical monitoring of control	Galactose-1-phosphate measurement varies in and between individuals and is better regarded as a compliance indicator Annual monitoring suggested	Bosch (2006) Walter <i>et al.</i> (1999)
Restriction of galactosides, free and bound galactose, galactocerebrosides	Foods containing these are allowed in the UK, but not in some other countries. There is no evidence to suggest that restriction of these foods is harmful	MacDonald <i>et al.</i> (2001); Bosch (2011)

Figure 7.8.2 Protected designation of origin (PDO) seal (source: European Commission, Agricultural and Rural Development 2013. Reproduced with permission of the European Commission, Agriculture and Rural Development)

Practicalities of a lactose free diet

Milk, all milk products and derivatives are excluded. This includes all milk (cow's, sheep's, goat's, etc.), yoghurt, most cheese, dairy desserts, butter and cream. Milk derivatives such as whey and casein must also be avoided. Low lactose milk and products are not suitable. All manufactured foods such as biscuits and cakes must be carefully checked. However, as milk is a potential allergen, and all allergens must be clearly labelled, all packaging should carry information on the presence of milk.

In the UK a number of hard mature cheeses are now allowed following extensive analysis. This includes Emmental, Gruyere, Jarlsberg, Italian Parmesan and Grano Padano. Only mature cheddar cheese from the West Country farmhouse Cheesemakers Association is allowed, and can be identified by the red and yellow PDO seal (Protected Designation of Origin), which is shown in Figure 7.8.2.

Calcium requirements for teenagers are particularly high and it is important for both adults and teenagers to have a good intake of calcium, as decreased bone mineralisation in both females and males has been reported

(Panis *et al.*, 2004). A calcium supplemented milk replacement is recommended (such as soya) and a calcium supplement is often necessary. The intake of other nutrients such as vitamin K and vitamin D must be adequate for good bone health. Alcohol is allowed in moderation; there is little information on its adverse effects in galactosaemia.

Diet for life

It is unclear how much tolerance to galactose changes with age. One adult woman with classical galactosaemia who discontinued her diet at 3 years has shown good progress (Lee *et al.*, 2003). However, relaxation of the diet in adults is not recommended.

Maternal galactosaemia

Pregnancy is not common in galactosaemia due to female fertility issues. However, if pregnancy occurs the diet should be followed strictly; outcome appears to be good.

Glycogen storage disorder types I and III

Glycogen storage disorder (GSD) type I is divided into two major subtypes, type Ia and type Ib. Type Ia is characterised by a deficiency in the enzyme glucose 6 phosphatase. Type Ib is characterised by a deficiency in glucose 6 phosphate translocase enzyme. These enzymes function together and are responsible for the breakdown of glycogen stores in order to maintain blood glucose levels within normal range during periods of fasting. Both subtypes phenotypically display glucose 6 phosphatase deficiency, characterised most usually by growth retardation, hypoglycaemia, hepatomegaly and a deranged biochemical profile (Goldberg & Slonim, 1993). Type Ib patients also suffer from chronic neutropenia and functional deficiencies of neutrophils and monocytes (Chou *et al.*, 2002).

Glycogen storage disorder type III is characterised by a deficiency in the glycogen debrancher enzyme (amylase

1,6 glucosidase). This is a key enzyme in the degradation of glycogen, and its deficiency leads to hypoglycaemia and an accumulation of short chain glycogen. Type IIIb is characterised by a deficiency of the debrancher enzyme in the liver only, whereas the majority of patients have type IIIa which is characterised by a more widespread deficiency of the enzyme in both skeletal and cardiac muscle.

Poor metabolic control comprising high plasma concentrations of uric acid, cholesterol, lactate and triglycerides consequently occur when patients are hypoglycaemic, which is frequently. It has been demonstrated that secondary metabolic control is better when the tendency toward hypoglycaemic episodes is decreased (Weinstein & Wolfsdorf, 2002). Long term consequences of GSD type I and III can include hepatic adenomas, hepatocellular carcinoma, progressive renal insufficiency, short stature and hypoglycemic brain damage (Roth, 2009).

The current treatment is dietary therapy to prevent and manage hypoglycaemia, and emergency regimens during periods of illness. In addition, patients with type Ib are also treated with granulocyte colony stimulating factor to restore myeloid function (Chou *et al.*, 2002). Biochemical markers of poor control, such as lactate, cholesterol, uric acid and triglycerides, should be monitored in addition to liver ultrasound. These patients will also need to be monitored for any micronutrient deficiencies. Bone density may also be monitored. It is advisable for this group of patients to have a facility to test blood glucose while adjusting their diet, and cornstarch therapy or an overnight feeding regimen.

Nutritional management

The aim of dietary treatment is to maintain normoglycaemia. The following aspects of the patient's diet need to be taken into consideration.

Percentage of total daily energy from carbohydrate

It is recommended that 65% of total energy comes from carbohydrate sources, 10–15% from protein and 25% from fat (Goldberg & Slonim, 1993).

Meal and snack pattern

Most centres recommend small, frequent carbohydrate containing meals throughout the day with either continuous tube feeding overnight or the use of uncooked cornstarch (Glycosade®) to prevent hypoglycaemia (Mayatepek *et al.*, 2010), with a guideline dose of 0.2–0.25 g of glucose/kg/hour (Dixon, 2007c). Some adult patients remain reliant on continuous overnight feeding

Supplementation with uncooked cornstarch (Glycosade®)

Uncooked cornstarch is digested slowly, providing a steady release of glucose in between meal times and overnight. The amount and timing of administration depends on the patient's weight and tendency towards hypoglycaemia during fasting periods. In most cases it is given every 4–6 hours. A weight based dose is given at bedtime to cover the fasting period overnight. Cornstarch should

not be mixed with drinks high in ascorbic or citric acid, nor should it be heated.

Weight maintenance

Importantly, a balance between energy from cornstarch and normal food needs to be achieved in order to maintain weight and prevent micronutrient deficiencies. Patients should be encouraged to engage in physical activities up to individual limits, but to avoid contact sports due to the high risk of bleeding, infection and liver damage (Roth, 2009).

Fructose and galactose restriction

Some centres recommend a restriction in fructose and galactose containing foods, although the degree of restriction of these foods is still debated.

Emergency regimens

These patients should be provided with an emergency regimen during periods of fasting or illness (see Emergency regimens section).

Pregnancy in inherited metabolic disorders

An increasing number of children with IMDs are now surviving into adulthood due to expanding newborn screening programmes and improvements in diagnostic tests and therapeutic interventions (Lee, 2002). Many of these patients are able to integrate into the community, form relationships and have children (Lee, 2006). The main aim of managing a pregnancy in a woman with an IMD is to optimise maternal health by regularly monitoring metabolic markers and evaluating nutritional status at regular intervals.

Preconception

Fertility can be a problem in women with classical galactosaemia (Walter, 2000) due to primary ovarian failure, usually manifesting as secondary amenorrhoea (de Jongh *et al.*, 1999). However, spontaneous pregnancies have been reported (de Jongh *et al.*, 1999; Briones *et al.*, 2001). In women with GSDI, subfertility may be due to oligomenorrhoea secondary to polycystic ovaries (Lee, 2006) and maternal HCU may be associated with a risk of early miscarriage, especially with poor metabolic control (Walter, 2000).

It is essential that all IMD patients are offered genetic counselling at the early stages of planning a pregnancy. The risk of having a child with MCAD is 1 in 10 000, but for adults with the condition the risk is 1 in 100 (Lee, 2006). Preimplantation genetic diagnosis is widely available for X linked IMDs such as OTC and antenatal diagnosis is also available.

Pregnancy

Although there are clear guidelines about managing pregnancy in PKU, little has been published regarding pregnancy in other IMDs, apart from case reports or small

patient series (Walter, 2000; Langendonk *et al.*, 2012). A major risk for women with IMDs of energy metabolism (MSUD, UCD, FAOD, GA1 and GSD), especially during the first trimester, is metabolic decompensation due to morning sickness and weight loss. This can cause reduced intake of medication or dietary supplements, resulting in poor metabolic control (Lee, 2006). It is essential that women and their local obstetric services have an up to date copy of their oral and intravenous emergency protocol. Nutritional status and metabolic control should be optimised in all women on a restricted diet before conception to improve the outcome of the pregnancy (Lee, 2006).

The teratogenic effects of hyperphenylalaninaemia in maternal PKU have been well documented, yet little is known in pregnancies associated with other IMDs, although normal foetal outcome has been reported (Pierre *et al.*, 2006; Walter, 2000). Some IMDs worsen during pregnancy, such as dyslipidaemia, particularly hypertriglyceridaemia, in lipoprotein lipase deficiency leading to pancreatitis. The risk of thromboembolic complications during pregnancy appears to be increased in women with HCU. Anticoagulation therapy should be included in the management (Pierre *et al.*, 2006).

Labour

Labour and delivery is a period of increased metabolic stress and it is important that a clear delivery protocol is devised beforehand. Women may require additional energy supplementation, usually in the form of intravenous dextrose. Additional complications in labour may include bleeding tendencies due to platelet dysfunction in GSDI, deterioration of underlying organ damage, i.e. cardiomyopathy, in GSDIII and women with mitochondrial respiratory chain disorders may tire more easily during labour and need earlier intervention to shorten labour.

Post partum

The post partum period is a time of considerable risk for metabolic decompensation, especially in IMD of protein metabolism, such as MSUD and OTC deficiency. This could be due to an increased protein load following the involution of the uterus and can typically last up to 6–8 weeks. Women should continue oral or intravenous emergency regimens until they are able to have a normal oral intake post delivery. Women with HCU are at increased risk of venous thrombosis post delivery and aspirin and low dose subcutaneous heparin should be continued throughout. In addition, women who wish to breastfeed should be encouraged to have extra fluids and an increased energy intake.

Emergency regimens

Many inherited metabolic disorders are complicated by episodes of decompensation and potentially encephalo-

lopathy, and require an emergency regimen. During episodes of illness, catabolism and a fasting state secondary to poor oral intake can cause the production of metabolites that, in specific disorders, have the potential to be toxic.

Metabolic disorders requiring an emergency regimen during periods of illness are:

- Urea cycle disorders.
- Organic acidaemias.
- Maple syrup urine disease.
- Fatty acid oxidation disorders.
- Glycogen storage disorders.
- Fructose-1, 6-bisphosphatase deficiency.
- Disorders of ketogenesis.

To prevent periods of decompensation, an emergency regimen should be administered. The emergency regimen is a glucose polymer solution (25% carbohydrate) that is given regularly while the usual diet is stopped for 24 hours. Glucose polymers used may include Maxijul, Polycal, Caloreen, Vitajoule and S.O.S 25.

The emergency regimen should be commenced immediately if the patient becomes unwell, e.g. nausea, vomiting, diarrhoea, high temperature or any illness resulting in loss of appetite and inability to take the normal diet. It is important to check regularly that the patient has an up to date emergency regimen, a supply of glucose polymer and knows how to make up the emergency regimen drink.

The aim of an emergency regimen is to provide an exogenous energy source to prevent catabolism, prevent or reduce production of toxic metabolites and prevent hypoglycaemia. The emergency regimen is the same for all disorders; however for some, it may be used in addition to medications and amino acid supplements (such as in MSUD). The emergency regimen is not nutritionally complete, so ideally should not be followed for >24–48 hours and it is advisable that the patient contacts their metabolic team to inform them that the emergency regimen is in use.

The emergency regimen formulation is a 200 mL drink (25% carbohydrate solution) given every 2–3 hours, day and night. It should aim to provide a total fluid volume of 2–2.4 L/24 hours. For patients who are vomiting, taking small sips frequently throughout the day may be easier. If the patient is tube fed, then a 24-hour feeding regimen can be devised that provides 25% carbohydrate. Alternatively, fruit juices and commercial drinks such as Lucozade original (17% carbohydrate) and Ribena (not light) (10% carbohydrate) can be used and extra glucose polymer added to make it up to a 25% carbohydrate solution.

Fat is not routinely used as part of the emergency regimen as it delays gastric emptying, may reduce palatability, is less easy to mix and may be difficult to take if the patient is vomiting. However, fat should never be added to the emergency regimen in fatty acid oxidation disorders. Dioralyte may be used to treat diarrhoea or vomiting; however, it contains very little glucose and is not a replacement for glucose polymer drinks and must

be used in conjunction with glucose polymer drinks to provide an adequate concentration of carbohydrate. It may be advisable to provide a lower concentration of carbohydrate solution when the patient has diarrhoea to prevent exacerbating both the diarrhoea and the illness.

The emergency regimen should be started at home upon the first signs of illness. However, if the emergency regimen is not tolerated and the patient continues to vomit, they should attend an accident and emergency (A&E) department immediately as they will need 10% intravenous dextrose and medical management. Over the following 24–48 hours as the patient improves, intravenous fluids can be reduced as oral feeding is increased.

Reintroduction of normal diet

If the emergency regimen is well tolerated, the patient's normal diet or feeds can be reintroduced over 1–2 days. However, for patients usually on low protein diets, their normal diet should be gradually regraded over a period of 1–2 days. It is always beneficial to use their clinical condition as a guide. It is advisable to continue with the emergency regimen drinks until the patient is back to eating normally, clinically improving and receiving their full energy requirements.

A three stage approach to using the emergency regimen (Dixon & Leonard, 1992) is:

- If in doubt that the patient is unwell, give an emergency regimen drink and review their condition every 1–2 hours.
- If there is an improvement after this time, the normal diet can be resumed.
- If the patient's condition has deteriorated, the full emergency regimen should be commenced for 24–48 hours.
- If the emergency regimen is not tolerated, i.e. vomiting or refusing drinks, then the patient should go to A&E for intravenous fluids.

7.9

Musculoskeletal disorders

7.9.1 Osteoporosis

Jean Redmond and Inez Schoenmakers

Key points

- Osteoporosis is the most common clinical disorder of bone metabolism; it is a major and increasing public health problem.
- To maximise peak bone mass attainment and to minimise age related bone loss, a balanced diet sufficient in calcium, good vitamin D status and regular weight bearing physical activity are essential.
- Low bone mineral density, a high propensity to fall, a low body weight and other comorbidities are risks for osteoporotic fracture.
- A high percentage of hip fracture patients are malnourished on admission to hospital and their nutritional status may decline in the postoperative period.

Osteoporosis is the most common clinical disorder of bone metabolism and primarily affects the elderly population. It is characterised by low bone mass and micro-architectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fractures (World Health Organization, 1994). Osteoporotic fractures are a significant cause of morbidity and mortality, particularly in developed countries (Johnell & Kanis, 2006). Most commonly, these are fractures of the hip, vertebrae and wrist. The incidence of osteoporotic fractures increases with advancing age, and the lifetime risk of any osteoporotic fracture lies within the range of 40–50% in women and 13–22% for men (Johnell & Kanis, 2005). As people live longer and the world's population grows, osteoporosis and fracture incidence will increase. The estimated 1.7 million hip fractures occurring worldwide in 1990 may rise to 6.3 million by 2050 (Cooper *et al.*, 1992), with Asia expecting to see the greatest increases (Cooper *et al.*, 1992; Prentice, 2004).

Fractures are associated with a substantial decline in an individual's functional status, a loss of independence, difficulty with normal daily activities and chronic pain. In particular, hip fractures are associated with significant increases in morbidity and mortality in the elderly (Bentler *et al.*, 2009). These fractures can also cause psychological symptoms (most notably depression and loss of self

esteem), associated morbidity and consequent dependency that may influence social roles for patients and their families (National Osteoporosis Foundation, 2010).

The pathogenesis of osteoporosis reflects the complex interaction between genetic, metabolic and environmental factors that determine bone growth, peak bone mass, calcium homeostasis and bone loss. Ageing, physical activity, sex hormone levels and nutritional status influence these factors. The increasing burden of osteoporosis means that modifiable factors such as nutrition have become of public health importance.

Functions and structure of bone and disease process

Bone is a specialised connective tissue, serving three major functions:

- Metabolic – a reserve and buffer of minerals.
- Mechanical – providing structure and muscular attachment for movement.
- Protective – enclosing bone marrow and vital organs.

Metabolic control of calcium

The metabolic function of bone is crucial for calcium homeostasis. The plasma concentration of ionised calcium

is strictly maintained, which is essential for the functioning of all body cells (Department of Health, 1998). When ionised calcium concentration falls, the parathyroid hormone (PTH) concentration increases, which inhibits renal calcium excretion and stimulates liberation of calcium from bone. Parathyroid hormone also stimulates the renal synthesis of the active form of vitamin D (calcitriol, $1,25(\text{OH})_2\text{D}$) which, in turn, enhances intestinal calcium absorption.

Structure of bone

Macroscopically bone has two components that differ in structure and function; cortical (compact) bone with a dense structure and trabecular (cancellous) bone, consisting of a latticework of bony tissue (trabeculae) (Department of Health, 1998). The adult human skeleton is composed of 80% cortical bone and 20% trabecular bone; different bones have different ratios of cortical to trabecular bone (Clarke, 2008). Cortical bone has mainly mechanical and protective functions, whereas trabecular bone also has a metabolic function in mineral regulation (Department of Health and Human Services, 2004). Bone consists of an extracellular mineralised matrix and a number of cell types, including osteoblasts, osteocytes and osteoclasts, and the cells of its vascular and nervous supply. The matrix consists of mineral salts [mainly hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) crystals] bound to proteins, largely collagen (Department of Health and Human Services, 2004). The osteoblast is the primary bone forming cell which creates the osteoid (prebone tissue), and facilitates calcification. Osteoclasts remove bone tissue and provide for the release of calcium and phosphate ions. The osteocytes respond to changes in strain on bone, thereby driving and regulating the action of osteoblasts and osteoclasts (Ward, 2011).

Bone development, metabolism and the development of osteoporosis

Two processes, modelling and remodelling, mediate change in size and shape of bone during bone growth and in response to mechanical stress (Department of Health and Human Services, 2004). During childhood and adolescence, the process of modelling allows for skeletal growth. Increases in length, i.e. longitudinal growth, occur at the growth plates (Clarke, 2008), while increases in diameter, i.e. radial growth, result from the deposition of new bone on the external surfaces and resorption on the internal surfaces. An increase in the amount of bone tissue occurs until peak bone mass (PBM) is achieved. The majority of bone mass is achieved by the end of longitudinal growth (~18 years) and an additional 5–10% of bone mass is accrued during the third decade of life. Gender and ethnic differences determine PBM, as well as a variation determined by lifestyle factors (Rizzoli & Bonjour, 1999). Achieving a high PBM within an individual's genetic potential is crucial for the prevention of osteoporosis in later life.

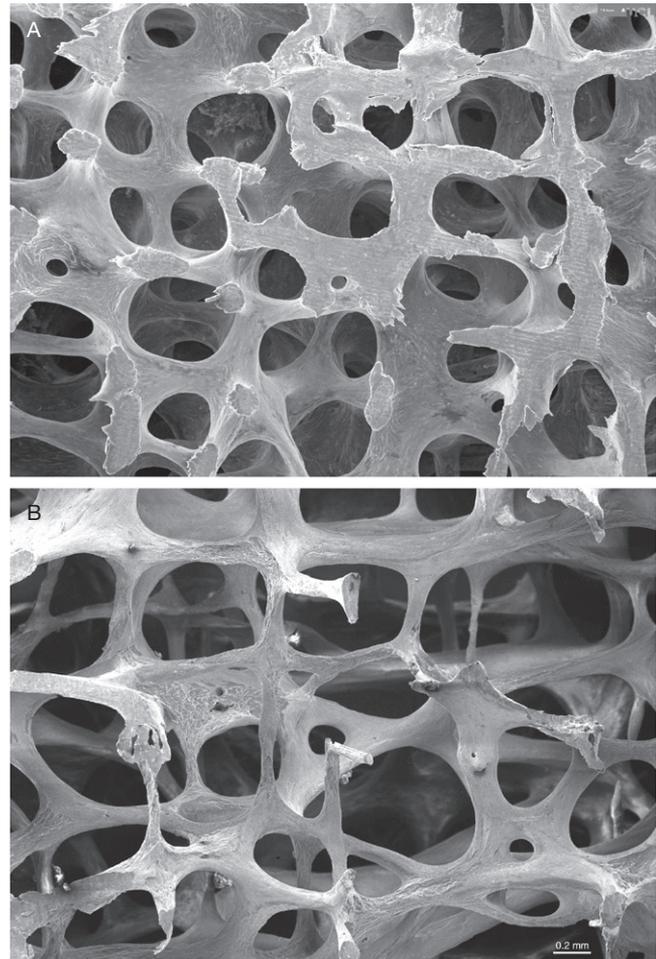

Figure 7.9.1 Comparison of (A) normal and (B) osteoporotic vertebrae, with thinning of the trabeculae (source: T. Arnett, University College London, 2013. Reproduced with permission of T. Arnett)

After skeletal growth is complete, remodelling of bone continues throughout adulthood. In health, remodelling is a coupled process; the amount of bone removed by resorption is replaced by new bone formation. Bone loss occurs when the rate of bone resorption exceeds that of bone formation (Figure 7.9.1), and occurs during menopause and with advancing age (National Osteoporosis Foundation, 2010) (Figure 7.9.2). The lifetime risk of developing osteoporosis is therefore determined by a combination of:

- Attainment of maximal PBM through optimal growth in childhood, adolescence and young adulthood.
- Maintenance of bone mass in middle age.
- Rate of age related bone loss.

Diagnostic criteria and classification

The diagnosis of osteoporosis relies on the quantitative assessment of bone mineral density (BMD) or bone mineral content (BMC), usually by dual energy X ray absorptiometry (DXA) of the axial skeleton (skull, spine, ribs and sternum), with the femoral neck providing the reference site (National Osteoporosis Guideline Group,

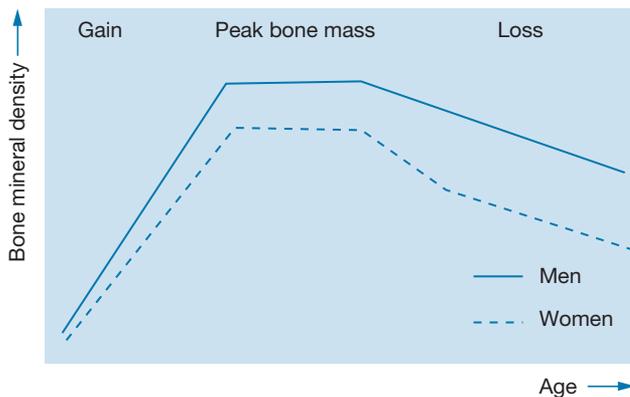

Figure 7.9.2 Age related changes in bone mass throughout life (source: Poole & Compston 2006, figure 5, p. 1252. Reproduced with permission of the *British Medical Journal*)

Table 7.9.1 Classification of bone mass and osteoporosis in adults (WHO, 1994)

Normal	BMD or BMC ≤ 1 SD below the average value of young adults
Low bone mass or osteopenia	BMD or BMC > 1 SD below the young adult average but ≤ -2.5 SD
Osteoporosis	BMD or BMC > 2.5 SD below the young adult average value
Severe osteoporosis (established osteoporosis)	BMD or BMC > 2.5 SD below the young adult average value and presence of one or more fragility fractures

NB: These cut-offs do not apply to children
BMD, bone mineral density; BMC, bone mineral content.

2010). Categories of the disease are defined in terms of bone mineral mass, as shown in Table 7.9.1 (World Health Organization, 1994). These diagnostic criteria apply to post menopausal women and men aged 50 years and older, but may not apply to premenopausal women and younger men (Lewiecki *et al.*, 2008).

Osteoporosis is associated with an increased risk of fragility fracture, i.e. fractures caused by minimal trauma, such as a fall from a standing position (Prentice *et al.*, 2006). These fractures are most common at the hip, vertebrae and wrist, but osteoporotic fractures can occur elsewhere in the skeleton (Prentice *et al.*, 2006). At present there is no universally accepted policy for population screening in the UK and most other countries to identify individuals with osteoporosis or those at high risk of fracture. Patients are identified opportunistically on the finding of a previous fragility fracture or the presence of significant clinical risk factors, as shown in Table 7.9.2. These factors may act through their association with low BMD or through a BMD independent mechanism (Poole & Compston, 2006; National Osteoporosis Guideline Group, 2010).

The differential diagnosis of osteoporosis is based on the assessment of risk factors and a range of tests. The choice of test depends on the severity of the disease, age at presentation and the presence or absence of fractures

Table 7.9.2 Clinical risk factors used for the assessment of fracture probability [adapted from National Osteoporosis Guideline Group (2010)]

Age
Sex
Low body mass index (≤ 19 kg/m ²)
Previous fragility fracture, particularly of the hip, wrist and spine, including morphometric vertebral fracture
Parental history of hip fracture
Current glucocorticoid treatment (any oral dose for 3 months or longer)
Current smoking
Alcohol intake of ≥ 3 units/day
Propensity to fall

Specific patient groups at increased risk of osteoporosis

Rheumatoid arthritis
Inflammatory bowel disease (Crohn's disease/ulcerative colitis)
Coeliac disease
Anorexia nervosa
Athletic amenorrhea
Malabsorption syndromes
Untreated hypogonadism in men and women
Prolonged immobility
Organ transplantation
Type I diabetes
Hyperthyroidism and hyperparathyroidism
Chronic liver disease
Chronic obstructive pulmonary disease

Drugs that may influence bone metabolism

Corticosteroids
Thyroxine
Heparin
Loop diuretics, e.g. furosemide, increase urinary excretion of calcium (unlike thiazides which decrease calcium loss)
Proton pump inhibitors (PPIs) interfere with calcium absorption

(National Osteoporosis Guideline Group, 2010). Routine investigations to exclude secondary causes of osteoporosis include full blood count and erythrocyte sedimentation rate, liver and renal function tests, bone function tests (calcium, phosphate, vitamin D status, PTH and alkaline phosphatase) and thyroid function tests (Poole & Compston, 2006), and may include assessment of nutrient deficiencies.

The National Institute for Health and Care Excellence (2012) recommends the assessment of the risk of fragility fracture using either FRAX® (FRAX (www.shef.ac.uk/FRAX) or QFracture (www.qfracture.org). FRAX®, the WHO fracture risk assessment tool, can be used for people aged 40–90 years with or without BMD values, and can be applied to men and women from several European countries (National Osteoporosis Guideline Group, 2010). QFracture can be used for people aged between 30 and 84 years without the requirement of BMD values and is validated in UK primary care populations to include ethnic origin and many comorbidities.

Dietary assessment

Dietary assessment through a 24-hour diet history and food frequency questionnaire or through the use

of food diaries will indicate if a patient's dietary calcium intake and other nutrients are adequate to meet recommendations.

Nutritional aspects of bone development and osteoporosis

A range of nutrients are involved in bone development and maintenance. Bone formation requires adequate supplies of energy, amino acids, the main bone forming minerals (calcium, phosphorus, magnesium and zinc) and other ions including copper, manganese, carbonate and citrate, and vitamins (C, D, K) that are involved in crystal and collagen formation, cartilage and bone metabolism and/or calcium and phosphate homeostasis (Prentice *et al.*, 2006). Of these, calcium and vitamin D are the most commonly associated with bone health (Shea *et al.*, 2002; Greer & Krebs; 2006; Huncharek *et al.*, 2008).

General recommendations are to consume a calcium intake close to the reference nutrient intake (RNI), optimise vitamin D status through adequate summer sunshine exposure (and dietary supplementation where appropriate), be physically active, have a body weight in the healthy range, restrict salt intake and consume plenty of fruit and vegetables (Department of Health, 1998).

Calcium

The evidence base for the long term effects of dietary calcium intake on bone health through randomised controlled trials is limited and there are knowledge gaps, particularly in children and young adults. In addition, a paradox exists between populations; while a low calcium intake is associated with an increased risk of osteoporosis in older Caucasian subjects, this may not be the case universally (Prentice, 2004). In the UK, the RNI for calcium is derived factorially and is calculated on the basis of the needs for growth and the maintenance of bone mineralisation, and takes into account factors influencing bioavailability of calcium to the skeleton (Department of Health, 1998). The RNI represents a value that is likely to provide for the nutrient needs of 95% of the population. There is no international consensus on calcium recommendations. The recommendation in the UK and European Commission are similar, but may be different from specific EU countries and the USA.

Children

Children need to absorb 70–150 mg of calcium/day for growth and bone mineralisation. Adolescent females and males require at least 250 mg and 300 mg/day, respectively (Department of Health, 1998). Taking into consideration the percentage of calcium absorbed, the RNI and recommended daily amount (RDA) are set between 350 and 1300 mg/day (see Appendix A2). Results from observational and intervention studies indicate that a higher intake of dietary calcium or dairy products, with and without vitamin D, significantly increases total body and lumbar spine BMC in children and reduces the risk of fractures (Goulding *et al.*, 2004; Manias *et al.*, 2006). This may be particularly relevant in individuals with low

calcium intakes, or at specific stages of development. However, data are conflicting because of the 'bone remodelling transient' and/or a change in a rate of bone remodelling occurring when calcium intake is increased above the habitual intake (Prentice, 2004). This may result in an initial increase in BMD shortly after the onset of supplementation, with little additional effect of the intervention thereafter or after cessation of the supplementation. The current advice is to ensure a calcium intake close to the RNI or RDA and that calcium supplementation in healthy children is unlikely to result in a decrease in fracture risk (Winzenberg *et al.*, 2006; Department of Health, 1998).

Young adults

From about age of 35–40 years, bone mineral is lost at an average rate of 0.3–0.4% of bone mass/year. During this time, a healthy balanced diet should be followed, while remaining physically active and maintaining a healthy body weight.

Older age

A phase of rapid bone loss occurs in women during the first 5–10 years after the menopause, after which bone loss occurs at a slower rate (see Chapter 3.1.3). Calcium supplementation has little effect on BMD in women who are within the first 5 years after the menopause (Department of Health, 1998), although calcium may be effective in reducing bone loss during later post menopause (>5 years) (Dawson-Hughes *et al.*, 1990). A meta analysis reported that calcium supplementation as a stand alone intervention has a small, but positive, effect on bone density and a trend toward reduction in vertebral fractures (Shea *et al.*, 2002). Calcium supplementation over 4 years may reduce bone loss from the hip and femoral neck in both men and women with low dairy intakes (McCabe *et al.*, 2004). However, the long-lasting effects of calcium supplementation are not clear. Speculation has also arisen regarding calcium supplementation (but not dietary calcium intake) and an increased risk of cardiovascular disease (Bolland *et al.*, 2011; Li *et al.*, 2012). Observational studies reported that a higher lifetime and current calcium intake are associated with a reduced risk of osteoporosis (Nieves *et al.*, 2008). Men are also affected by age related bone loss. A cross sectional analysis demonstrated that dairy calcium intake was positively associated with total hip and femoral neck BMD in men aged older than 60 years (McCabe *et al.*, 2004).

Dietary sources

Calcium is present in a wide range of foods, although the bioavailability may vary appreciably. Dairy products, such as milk, yoghurt and cheese, are all good sources of bioavailable calcium, and provide more calcium per calorie than any other typical food in a western diet (Heaney, 2000). Fish that is consumed whole with the soft edible bones (such as whitebait, canned sardines or canned salmon) is also a good source of calcium. In some countries there is statutory fortification with calcium, e.g. in the UK, there is a requirement that flour is fortified with calcium, in addition to optional fortification of certain products by the food industry. For those following a

vegan diet, pulses, whole grains, nuts and seeds, dried fruit (such as apricots), tofu and green vegetables, such as spinach, broccoli and kale, provide a source of calcium, although the bioavailability is not as high as from dairy products. For those who are unable to consume foods that provide good sources of calcium, e.g. due to milk allergy or because they are vegan, foods that are fortified with calcium or calcium supplements are advisable (see Chapter 3.6). The British Dietetic Association (2005) recommends a point system whereby each point is 50 mg of calcium and at least 14 points daily should be consumed (see Appendix A5). Additional considerations for dietary advice include:

- Low fat dairy products contain similar amounts of calcium as full fat products and may be more suitable for those on a cardioprotective diet.
- Gluten free bread varies in calcium content, and this should be taken into consideration when advising a coeliac patient.
- Soya products are good alternatives to cow's milk for dairy free or vegan diets; calcium enriched options should be advised. However, phytic acid in soya reduces the calcium bioavailability to approximately 75% that of cow's milk.
- Calcium from drinking water is well absorbed, but the contribution of water to nutrient intake is generally not assessed. The calcium content of water varies from region to region (0–300 mg/L) (Department of Health, 1998).

Vitamin D

Vitamin D is essential for the development and maintenance of a healthy skeleton and for muscle function. Classical vitamin D deficiency causes rickets in children and osteomalacia in children and adults; it is associated with increased bone loss in older people. It is also associated with muscle weakness and a propensity to fall (Prentice *et al.*, 2008, Bischoff-Ferrari *et al.*, 2005; 2006; Francis, 2007). Intervention studies have reported conflicting results and may be discordant with observational studies. In addition, data in younger people are scarce (Ross *et al.*, 2010). Meta analyses of vitamin D supplementation trials in older adults investigating the effect on fracture risk and falls have concluded that vitamin D supplementation with >700 IU/day (17.5 µg/day) is needed for a beneficial effect (Bischoff-Ferrari *et al.*, 2005; 2006; Francis, 2007).

Vitamin D status is assessed by the measurement of the plasma concentration of 25(OH)D, which serves as a reservoir for further hydroxylation to the active metabolite 1,25(OH)₂D. Vitamin D deficiency is defined as a plasma concentration of 25(OH)D of <25 nmol/L in the UK and <40–60 nmol/L in the USA (Department of Health, 2007; Ross *et al.*, 2010), although other thresholds have been proposed (Prentice *et al.*, 2008; Ross *et al.*, 2010).

There are two forms of vitamin D, D₃ and D₂. Vitamin D₃ can be obtained from the diet and by cutaneous synthesis following exposure to sunlight (Fraser, 2004; Lips, 2007; Prentice, 2008). Very few foods are natural sources of vitamin D₃, but it is available in supplements and used

in food fortification (Ovesen *et al.*, 2003). Vitamin D₂ is derived from plant sources, and may be the preferred form for vegans. While vitamin D₃ and D₂ are considered to have the same antirachitic activity, recent studies have shown that vitamin D₃ may increase plasma 25(OH) D more efficiently than vitamin D₂ (Ross *et al.*, 2010; Department of Health, 2007), but this may be overcome by more frequent intake of vitamin D₂.

The proportion of vitamin D that is derived from sun exposure versus diet varies considerably worldwide, across population groups and between individuals, mainly because of wide differences in skin exposure to ultraviolet B (UVB) radiation, cutaneous synthesis, e.g. due to ageing and skin pigmentation, and in food fortification practices and supplement use (Lips, 2007; Fraser, 2004). Older people are vulnerable to vitamin D insufficiency because cutaneous synthesis becomes less efficient, and declining kidney function is associated with impaired synthesis of active forms of vitamin D. Those who are housebound or living in institutions are at risk due to limited opportunities for sun exposure. Limited and unvaried diets are common in elderly people and may exacerbate the problem. If cutaneous synthesis is insufficient, meeting the recommended intakes for vitamin D through the use of supplements may be needed.

In the UK and the USA, the RNI and RDA for vitamin D (see Appendix A2) are based on the requirements for bone health and assume adequate intakes of other nutrients. In the UK, a RNI is not set for people between 4 and 64 years of age because it is assumed that skin synthesis will generally ensure adequacy. Those at risk of inadequate sunlight exposure should ensure sufficient dietary vitamin D or consider supplementation. A RNI of 10 µg (400 IU)/day has been made for pregnant and lactating women, individuals confined indoors and for those in the population aged over 65 years. In contrast, the US RDA assumes a moderate contribution from cutaneous produced vitamin D in the general public; a RDA is formulated for all age groups. The European Union population reference intake is 0–10 µg/day for every age group.

Other nutrients and food groups

Protein and acid–base balance

Protein intake affects bone in several ways as it provides the organic component of the structural matrix of bone, increases the anabolic hormone insulin like growth factor 1 (IGF1), may increase urinary calcium and is reported to increase intestinal calcium absorption (Heaney & Layman, 2008). Amino acid precursors from dietary protein are required to build and maintain bone structure (Darling *et al.*, 2009); an inadequate anabolic drive due to insufficient dietary protein may decrease bone strength (Bonjour, 2005; Heaney & Layman, 2008). Adequate dietary protein is therefore essential for optimal gain of bone mass during childhood and adolescence, and preservation of bone mass with ageing. Elderly patients with hip fracture are often undernourished and one study has shown that those given daily oral nutritional supplements (20 g of protein; 254 kcal) showed improved clinical outcome (Delmi *et al.*, 1990).

In the general population, however, there is inconsistent evidence about the relationship between high and low protein intakes and bone health. The effect of protein may be biphasic, with potentially detrimental effects at high intakes because of its effects on calcium excretion in the urine (Prentice *et al.*, 2006). Dietary protein is a major contributor to endogenous acid production, which is believed to influence the balance between osteoblastic and osteoclastic activity and increase urinary calcium excretion, although, this may be important only when calcium intakes are low. The overall evidence shows that adequate dietary protein has a small but favourable effect (Darling *et al.*, 2009); therefore, dietary protein intakes should be advised within recommendations, particularly for the elderly.

Phosphorus

Approximately 85% of total body phosphorus is found in the skeleton. In western diets, phosphorous intake is usually adequate. The evidence on whether dietary phosphorus intake has any effect on bone health is inconsistent, although a low calcium to phosphorus ratio (molar ratio ≤ 0.50), has been reported to be detrimental (Kemi *et al.*, 2010).

Potassium and sodium

Although bone does not contain appreciable amounts of potassium and sodium, these nutrients may impact on bone health through a role in maintaining calcium homeostasis. A high potassium diet is believed to reduce urinary calcium excretion. In contrast, a high dietary sodium intake is believed to be associated with increased urinary calcium excretion in the short term, while long term outcomes are less certain (Teucher *et al.*, 2008).

Potassium is ubiquitous in the diet, but is most abundant in green and root vegetables, fruit, legumes and milk/yoghurt. Due to their high potassium and low sodium content, in addition to their contribution to an alkaline environment, a diet rich in fruit and vegetables is thought to be beneficial for bone health (Lin *et al.*, 2003; New, 2004).

Magnesium and zinc

Magnesium is widely distributed in soft and bony tissue; 50–60% of total body magnesium and 30% of total body zinc is found in bone. The exact role of magnesium in bone health is not known, although severe magnesium deficiency may disrupt calcium homeostasis. Zinc deficiency is associated with reduced bone mass and stunted growth, but human studies are lacking (Department of Health, 1998).

Vitamin K

Vitamin K refers to a group of fat soluble compounds and acts as a cofactor for the carboxylation of a protein (osteocalcin) involved in bone formation. The RNI of $1 \mu\text{g}/\text{kg}$ of body weight/day is based on the level that are sufficient to maintain blood coagulation, but this may be suboptimal for adult bone health (Cashman & O'Connor, 2008). Low dietary intake of vitamin K is associated with low

BMD and increased risk of fracture in older women. Supplementation studies with vitamin K1 in postmenopausal women showed a reduction of bone loss or improvement of BMD in some but not all sites (Braam *et al.*, 2003; Bolton-Smith *et al.*, 2007).

Vitamin C

Vitamin C is required for collagen hydroxylation. There are limited studies in this area but cross sectional data suggest a trend to higher BMD with increased vitamin C intake in adolescents and middle aged women, but not in postmenopausal women (Department of Health, 1998).

Other dietary factors

Carbonated drinks

Associations have been found between high consumption of carbonated drinks and low BMD and increased risk of fracture in adolescents (Manias *et al.*, 2006). This was initially attributed to their influence on the acid–base balance (particularly colas containing phosphoric acid), but this has since shown to be modest compared to other foods. It is likely that the associations with high carbonated drink consumption may be partly attributed to confounding environmental factors, the displacement of milk from the diet and/or an effect of caffeine.

Vegetarian and vegan diets

Cross sectional and longitudinal population based studies do not suggest that there is a real BMD difference between vegetarians and omnivores, other than that which may be accounted for by differences in weight and lifestyle (New, 2004). The impact of a vegetarian diet on bone health is however complex to evaluate, since the composition of diets of vegetarians and omnivores may differ considerably with respect to their calcium, protein, alkali, vitamin K and phytoestrogen content. In addition, there may be differences in key lifestyle characteristics, such as levels of physical activity (New, 2004). Veganism is associated with a diet that contains a low level of bioavailable calcium (Sanders, 1999) and low protein intakes, which may be detrimental to bone (see Chapter 3.6).

Lactose intolerance

People with lactose intolerance may have a reduced calcium intake from dairy sources. The limited evidence available suggests that patients with lactose intolerance are not at an increased risk of osteoporosis, provided that their calcium requirements are met (Enattah *et al.*, 2005) through non-dairy sources of calcium or supplements (see Chapter 7.4.6).

Other factors influencing bone health

Body composition

Bone mineral density is influenced by overall body size and weight; a higher lean to fat ratio is associated with a higher BMD in younger women and in men, whilst the reverse is true for older women (Department of Health,

1998). Epidemiological evidence and a meta analysis of 12 prospective, population based cohorts including 60000 men and women, showed that total number of sustained fractures, osteoporotic fractures and hip fractures are all inversely related to body mass index (BMI) (De Laet *et al.*, 2005). Its association with muscle weakness, nutritional deficiencies of protein or vitamin D, decreased padding over the greater trochanter of the hip, or a greater liability to fall may explain the role of a low BMI as a risk factor for hip fracture (De Laet *et al.*, 2005).

Although a high BMI is associated with a lower risk of fracture in older people, recent evidence suggests a higher risk of fractures such as at the wrist and ankle in obese patients. Obesity should therefore not be regarded as a protective factor for fracture risk. Rather, underweight should be regarded as a significant risk factor (De Laet *et al.*, 2005) and a healthy body weight within the normal range should be encouraged.

Recent weight loss and hip fracture risk

Weight loss, irrespective of current weight, is associated with an increased risk of fracture, and may be greater for those that suffered involuntary weight loss (Ensrud *et al.*, 1997; 2003). In older women the association between weight loss and the rate of bone loss and fracture risk at the hip was found to be independent of other known risk factors (Ensrud *et al.*, 2003). This may be explained by the decline in mechanical load, a decrease in nutritional intake, including calcium and protein, or be linked to alterations in levels of hormonal factors.

Subgroups of the population at particular risk

Several subgroups of the population are vulnerable to the development of osteoporosis. Anorexia nervosa is associated with a lower bone mass and an increased risk of fractures. Amenorrhoea is thought to play an important role in the development of osteoporosis; other risk factors include IGF1 deficiency, low androgen levels and hypercortisolaemia (Misra & Klibanski, 2011) (see Chapter 7.10.1).

Inflammatory bowel disease (IBD) is associated with a modest decrease in BMD and an increase in fracture risk related to malabsorption of nutrients and cumulative corticosteroid use. For patients with Crohn's disease and ulcerative colitis, the relative risk of overall fracture is 1.3 and 1.2 and for hip fractures is 1.5 and 1.4, respectively, compared to the general population (Lewis & Scott, 2007). There is also a modest increased risk of fracture in coeliac disease (Lewis & Scott, 2007); BMD is observed to be more reduced in those with severe compared with mild villous atrophy and there is a significant improvement in BMD after introduction of a gluten free diet. Adults with IBD or coeliac disease are recommended to ensure a daily intake of calcium (from dietary sources or supplements) of 1000mg/day (1200mg for postmenopausal women and men >55 years) and to be vitamin D replete (Lewis & Scott, 2007) (see Chapter 7.4.7 and Chapter 7.4.8). Chronic liver disease is associated with

increased risk of osteoporosis. Therefore, the proposed guideline for these patients is to consume 1000mg of calcium/day and 800IU of vitamin D/day (Collier *et al.*, 2002) (see Chapter 7.4.12).

Patients with rheumatoid arthritis (RA) also exhibit an increased rate of osteoporosis; reduced BMD in these patients relates to their age, postmenopausal status and disease activity, severity and duration (Coulson *et al.*, 2009; Pye *et al.*, 2010). Fracture risk in this patient group is associated with medication use; steroid and prednisone therapy increase and tumour necrosis factor (TNF) inhibitors decrease overall fracture risk. Although the majority of RA patients have one or more risk factors for osteoporosis, the minority receives preventive treatment (Coulson *et al.*, 2009) (see Chapter 7.9.3).

Organ transplantation is associated with an increased risk of osteoporosis and fractures. This may be related to the primary disease requiring organ transplantation or medication use. Before transplantation it is recommended to ensure adequacy of calcium intake and vitamin D status, encourage weight bearing exercises and treat prevalent osteoporosis (Cohen *et al.*, 2004). The most rapid rates of bone loss occur during the early post transplantation period (6–12 months); rapid resumption of weight bearing exercise, supplementary calcium (1000–1500mg/day in divided doses), at least 400–800IU of vitamin D/day, in addition to treatment with bisphosphonates or calcitriol is recommended (Cohen *et al.*, 2004).

The presence of chronic obstructive pulmonary disease (COPD) is a risk factor for the development of osteoporosis. Chronic obstructive pulmonary disease may also be associated with other risk factors for osteoporosis, such as poor capability for physical exercise and corticosteroid use. Patients with COPD are also at higher risk of associated comorbidities such as a low BMI and, impaired nutritional status, and are more likely to be tobacco smokers and of high age (Vrieze *et al.*, 2007). Intervention studies specifically designed for patients with COPD are currently lacking and no specific guidelines have yet been established for the treatment of osteoporosis in this group (Lehouck *et al.*, 2010) (see Chapter 7.1).

Management

The aim of the treatment of osteoporosis is to reduce the risk of falls and fractures. Treatment includes pharmacological approaches, lifestyle advice and dietary interventions. Some pharmaceutical interventions also require associated nutritional interventions to optimise the treatment effects and to prevent side effects.

Lifestyle advice

Exercise

Exercise, particularly weight bearing exercise, can help to build bone and increase peak bone mass in youth and help to maintain bone tissue in adults. It may also help to improve posture, balance and muscle power, all of which help to prevent falls. People with osteoporosis are more likely to fracture a bone when they fall, but as they

are mostly older patients they are also at a higher risk of falling due to decreased muscle power and poorer balance (National Osteoporosis Foundation, 2010). An individualised exercise programme under the supervision of a specialist should be directed to prevent further bone loss and fractures by weight bearing exercise, and a reduction of the risk of falls by increasing muscle power and balance. Exercise after a fracture aims to relieve pain and to help rehabilitation (National Osteoporosis Foundation, 2010).

Pharmacological treatments

These agents may inhibit bone resorption (antiresorptive) or stimulate bone formation (anabolic). Antiresorptive treatments act to prevent bone loss and slow the bone remodelling cycle, thereby reducing the relative risk of fractures. Anabolic agents stimulate bone formation and reduce bone resorption. In the UK, the following drug therapies for osteoporosis are available (brand names are given in parentheses):

- *Bisphosphonates*:
 - Alendronate (Fosamax).
 - Cyclical etidronate (Didronel PMO).
 - Ibandronate (Bonviva).
 - Risedronate (Actonel).
 - Zoledronic acid (Aclasta).
- *Selective oestrogen modulator (SERM)*:
 - Raloxifene (Evista).
 - Human RANK ligand antibody.
 - Denosumab (Prolia).
- *Other*:
 - Hormone replacement therapy (HRT).
 - Calcitonin.
- *Anabolic agents*:
 - Strontium ranelate (Protelos).
 - PTH treatment (Preotact, Forsteo).

Pharmacological treatment strategies often include the recommendations of calcium and vitamin D supplements to ensure adequacy of these nutrients and to maximise benefit or to prevent hypocalcaemia. The recommended dosages can exceed the RNI or RDA for the age group. Patients with a poor kidney function may be prescribed calcitriol (Rocaltrol) or alfacalcidol, instead of vitamin D. The methods and frequency of administration of these drugs is highly dependent on their mode of action and includes oral, intramuscular and intravenous administrations. They may be also be used in combination or as alternating therapies (Bilezikian, 2008). Oral bisphosphonates must be taken fasted and may be associated with upper gastrointestinal side effects. Compliance to osteoporosis treatment needs to be considered in the evaluation of the patient.

Nutritional care of the hip fracture patient

Fractures of the proximal femur (hip) are a cause of substantial morbidity and mortality in older people (Avenell & Handoll, 2010) and may have long term effects. It has been shown that 9 months after their hip fracture, people

still have a poorer quality of life than age and sex matched controls (Cranney *et al.*, 2005), and many fail to return to their previous state of mobility.

Nutrition status of hip fracture patients

Protein energy malnutrition is common among elderly patients hospitalised with an acute hip fracture (Nematy *et al.*, 2006; Bastow *et al.*, 1983; Delmi *et al.*, 1990; Lumbers *et al.*, 2001). Rapid deterioration in nutritional status due to surgery and hospitalisation is common (Corish & Kennedy, 2000; Nematy *et al.*, 2006; Bastow *et al.*, 1983; Delmi *et al.*, 1990; Eneroth *et al.*, 2005). Protein energy malnutrition is associated with an increased risk of complications (Eneroth *et al.*, 2006; Lumbers *et al.*, 1996; Houwing *et al.*, 2003) and there is evidence that nutritional support, particularly when overseen by a specialist dietitian and dietetic assistant, lowers the risk of postoperative complications, particularly in underweight patients (Duncan *et al.*, 2006; Delmi *et al.*, 1990; Eneroth *et al.*, 2005). The European Society for Parenteral and Enteral Nutrition (ESPEN) guidelines (2006) recommend oral nutritional supplements (ONS) for this group (Volkert *et al.*, 2006), but enteral feeding also may be considered. Compliance to ONS is often low. This may have contributed to the conclusion in the recent Cochrane review on nutritional supplementation for hip fracture aftercare that the evidence for the effectiveness of protein and energy feeds is weak (Avenell & Handoll, 2010) (see Chapter 6.3).

Assessment

Nutritional assessment of the hip fracture patient will include the following.

Anthropometry

Current weight, usual weight and percentage weight change, current height (and height as a young adult) or demispan and BMI should be measured. When there are difficulties with obtaining measurements of weight and height, the mid upper arm circumference (MUAC) can be used as an index of malnutrition; this correlates well with BMI in this patient group (Maffulli *et al.*, 1999).

Biochemistry and fluid balance

To estimate metabolic stress the following should be assessed; elevated temperature, raised white cell count, elevated C-reactive protein, raised blood urea and low serum albumin.

Clinical assessment

Symptoms including Glasgow Coma Score (GCS), degree of dysphagia, appetite, anorexia, nausea, taste disturbances, pain, cognitive impairment should be assessed.

Dietary assessment

This should include a diet history and food frequency questionnaire to assess the adequacy of macro- and micro-nutrient intake prior to admission. A 24-hour recall after admission and surgery are important to assess reduced voluntary oral intakes post surgery (Sullivan *et al.*, 2004; Nematy *et al.*, 2006).

Economic and social assessment

This should include social history, family support and discharge plan (home or medium to long term care).

Nutritional management

Patients undergoing orthopaedic surgery have increased metabolic requirements, which are often unrecognised (Eneroth *et al.*, 2006). Estimation of total energy requirements of patients may be calculated by estimating basal metabolic rate (BMR), adding a stress factor of 20% (to account for the increased energy requirements because of surgical correction of the fractured femoral neck) and adding another 10–25% (based on the level of mobility) to allow for rehabilitation, physical activity and diet induced thermogenesis (Nematy *et al.*, 2006) (see Chapter 6.1).

Dietary advice should aim to achieve a high protein, high energy diet in small and frequent portions, potentially with the use of supplements and fortified foods. Monitoring and discharge planning are an important part of the dietetic care of a hip fracture patient.

7.9.2 Arthritis

Dorothy J Pattison

Key points

- Early dietary guidance and an exercise programme are effective in reducing symptoms of osteoarthritis and may delay the need for joint replacement.
- Glucosamine or chondroitin products are not recommended for the treatment of osteoarthritis.
- Fish oil supplements rich in n-3 polyunsaturated fatty acids have been found to ameliorate pain and symptoms of rheumatoid arthritis.
- Specific food avoidance cannot be recommended for rheumatoid arthritis; patient experiences should not be ignored and dietary assessment and advice should be given accordingly.
- People with rheumatoid arthritis are at high risk of comorbidities including cardiovascular disease and osteoporosis.

The term arthritis refers to a number of different conditions that can affect the joints at any stage of life. Two key features of arthritis are joint pain and inflammation leading to tenderness, swelling and stiffness. Arthritis can be divided into inflammatory, non-inflammatory and connective tissue arthritis groups. Inflammatory arthritis may be acute, e.g. septic arthritis, or chronic, e.g. rheumatoid arthritis (RA), or acute on chronic, e.g. gout. The most common non-inflammatory arthritis is osteoarthritis (OA). Connective tissue diseases, as the name suggests, are inflammatory conditions affecting the connective tissues (tendons, ligaments, dermis), e.g. systemic lupus erythematosus (SLE) and fibromyalgia. Osteoarthritis and RA are the most prevalent forms of arthritis presenting to rheumatology clinics in the UK.

This chapter will discuss the dietary management of OA, RA and associated comorbidities. The dietary man-

agement of gout and osteoporosis are dealt with in Chapter 7.9.3 and Chapter 7.9.1, respectively.

Osteoarthritis

Osteoarthritis refers to a clinical syndrome of joint pain accompanied by varying degrees of functional limitation and reduced quality of life. It is the most common form of arthritis and one of the leading causes of pain and disability worldwide. Osteoarthritis usually affects the distal two joints of the fingers and the base of the thumb as well as the knees, hips and spine. Risk factors for OA include age, gender, obesity, trauma and genetics. The primary site for OA is the cartilage at the ends of bones in a joint. Surface cartilage breaks down and erodes until the bones become exposed and damaged, causing pain, swelling and reduced movement. Osteoarthritis is a metabolically

active repair process that takes place in all joint tissues and involves localised loss of cartilage and remodelling of bone. Injuries may trigger the need for the joint tissues to repair. In some people, either because of devastating injury or an error in the ability to repair, the process cannot compensate, resulting in continuing tissue damage and eventual symptomatic OA. Joint failure can be minimal or complete depending on its severity. Although pain, swelling, stiffness and a reduction in physical activity are all typical outcomes of OA, structural changes in the joint can occur without accompanying symptoms.

Clinical management

The majority of published evidence relates to the management of knee OA, although many patients have multiple joint involvement (NICE, 2008). Treatment primarily consists of alleviating pain, using analgesics, e.g. paracetamol, sometimes in combination with a low dose non-steroidal anti-inflammatory drug (NSAID). Topical application of a NSAID preparation may also provide relief. An injection of corticosteroids directly into the joint is sometimes used to relieve severe local pain and inflammation. If pain becomes debilitating, joint replacement surgery is a successful procedure used to improve the quality of life (NICE, 2008). Physiotherapy and occupational therapy interventions have a major focus on self management education and have integral, evidence based roles in disease management.

Dietary management

Dietary intervention for OA includes the management of obesity, in particular prior to joint replacement surgery, and the management of related comorbidities.

Obesity

Every step taken increases the load on the hip or knee joint by three to five times body weight; therefore, the physical stresses imposed on the joints by excessive body weight are considerable (Aspden, 2011). Since OA primarily affects load bearing joints, obesity can worsen symptoms and may accelerate joint degradation. Many patients with OA are already overweight at the time of diagnosis and others become increasingly overweight as a result of reduced physical activity and/or inappropriate dietary intake. Weight reduction or maintenance of an ideal body weight or preventing progression to obesity is an integral part of management. Clinical trials have demonstrated that weight reduction in combination with increased physical activity can improve symptoms such as pain and stiffness, primarily in knee OA (Huang *et al.*, 2000; Messier *et al.*, 2004).

It is generally accepted that obesity predisposes to OA. However, OA in the joints of the hand, primarily nodal OA affecting middle aged women, has been shown to occur more frequently in obese people, which cannot be attributed to the effect of increased physical load. Recent research into the causes of OA and its progression has focussed on the biological activity of adipose tissue OA.

It is believed that a reduction in adipose tissue, rather than body weight alone, is responsible for improvement in symptoms (Aspden, 2011). Toda *et al.* (1998) found that reducing fat mass gave greater symptomatic relief than could be explained by the reduction in body weight alone. A UK study confirmed that metabolic factors such as hypertension, hypercholesterolaemia and blood glucose levels are associated with OA independent of obesity, indicating that important systemic and metabolic components are involved in the aetiology of OA (Hart *et al.*, 1995). Weight loss can ameliorate symptoms and delay the need for joint replacement (Niu *et al.*, 2009). Therefore, dietary modification may be indicated in cases where hyperlipidaemia and other factors of the metabolic syndrome are present.

Nutrition and surgery

Some patients requiring surgical joint replacement may be at increased risk of nutritional depletion. This may be particularly relevant in the frail and elderly, especially if functional loss has already limited dietary intake preoperatively. Lower levels of haemoglobin, ferritin, albumin and protein intakes have been demonstrated in OA and RA patients 10 days after joint replacement surgery compared to preoperative levels (Haugen *et al.*, 1999). Improved postoperative recovery has been shown in elderly patients (decreased hospital length of stay) undergoing hip replacement and given perioperative nutritional supplements as part of a rapid recovery programme for lower extremity arthroplasty patients (Berend *et al.*, 2004).

Dietary supplements

Glucosamine and chondroitin

Glucosamine is found naturally in the body; it plays an important role in the synthesis of glycosaminoglycans and glycoproteins. These are important for ligaments, tendons, cartilage and the synovial fluid of joints. It has been suggested that the way in which these joint structures are built and maintained contributes to the development and the progression of OA. Studies in animals have found that glucosamine can both delay degradation and repair damaged cartilage. However, results from randomised controlled trials (RCTs) on the effectiveness of chondroitin and glucosamine are conflicting. Trials that reported sizeable effects on joint pain were often of poor quality and/or small sample size, whereas larger, methodologically robust trials generally found only small or no effect (NICE, 2008). A meta analysis of 20 studies of glucosamine in the management of OA of the knee and hip using a preparation of glucosamine sulphate (1500mg/day) in patients with symptomatic OA failed to show benefit in terms of pain and function (Towheed *et al.*, 2005). A more recent meta analysis of RCTs of glucosamine, chondroitin or a combination of both in patients with hip or knee OA found no clinically relevant effect of either supplement alone or in combination on perceived joint pain or minimal joint space width (Wandel *et al.*, 2010). Both meta analyses reported that glucosamine and chondroitin were safe.

Herbal and other dietary supplements

Some pharmacological treatments for OA are ineffective in some patients and some, such as NSAIDs, often have serious side effects. Thus, patients frequently turn to complementary/alternative medicines.

Whilst many manufacturers of dietary supplements claim that their product will reduce symptoms or even alter the course of disease, there is only weak scientific evidence to support the use of nutritional supplements in the management of OA. Most types of supplements promoted for the treatment of OA are unlikely to cause harm, but some plant based remedies can be toxic.

Long *et al.* (2001) conducted a systematic review of herbal medicines and plant extracts (administered orally or topically) in OA. Twelve RCTs and two systematic reviews were included. There was no compelling or only weak evidence, i.e. at least one RCT) for significant clinically relevant benefits for six oral preparations; promising evidence, i.e. at least two RCTs with favourable outcomes, for Devil's claw (*Harpagophytum procumbens*) and avocado soyabean unsaponifiables (ASU); and moderately strong evidence, i.e. three RCTs or more, for phytodol (Long *et al.*, 2001). As yet, there is no convincing evidence that fish oil supplementation confers clinical benefit in the management of OA.

Rheumatoid arthritis

Rheumatoid arthritis is an inflammatory disease that largely affects the synovial joints. Synovial joints are moveable and contain synovial fluid; they are predominant in limbs where mobility is important. Rheumatoid arthritis typically affects the small joints of the hands and the feet, usually symmetrically. It is a systemic disease and so can affect several organs, including the heart, lungs and eyes. The prevalence of RA in the UK is around 400 000 (Wiles *et al.*, 1999), with approximately 12 000 people developing the disease per year (Symmons *et al.*, 2002). Rheumatoid arthritis occurs three times more frequently in women than men and can develop at any stage of life, with a peak age of incidence in the UK for both genders between 50 and 60 years. Drug treatment aims to relieve symptoms and to modify the disease process, thus preventing structural damage and progressive functional loss. Approximately one-third of people stop work because of the disease within 2 years of onset (Young *et al.*, 2002). Clearly, RA is costly to the UK economy and to individuals (NICE, 2009).

Clinical management

Current drug treatment includes the use of paracetamol and/or codeine for pain relief. Non-steroidal anti-inflammatory drugs (ibuprofen, naproxen and diclofenac) are taken to relieve pain and reduce joint swelling. More recently, COX 2 inhibitors have been developed, e.g. celecoxib and etoricoxib, which relieve pain and stiffness as well as reducing inflammation. Traditional NSAIDs can increase the risk of stomach problems, e.g. peptic ulceration,

whereas COX 2 inhibitors carry a lower risk of such problems, but are associated with a greater risk of cardiovascular complications. These drugs do not act on the progression of RA.

National clinical guidelines for the management of RA recommend early introduction of the traditional second line disease modifying antirheumatic drugs (DMARDs), primarily the immunosuppressant drugs methotrexate and sulphasalazine, and also hydroxychloroquine and leflunomide. Corticosteroids are used to provide rapid relief of symptoms such as pain, stiffness and joint swelling. They are used on a short term basis due to the associated side effects of weight gain, muscle weakness and loss of bone mass (NICE, 2009).

In the last two decades, the concerted effort to identify the main immune modulators of RA at a cellular level, including cytokines and TNF, has resulted in the development of biological agents that block their activity. These specifically designed immunological proteins inhibit the inflammatory pathways that cause RA, and include agents such as etanercept, infliximab, adalimumab and rituximab.

Physical therapy

Tiredness and fatigue are major problems experienced by people with RA. Patients should be encouraged to keep active within their capabilities, but to rest sufficiently and have a nutritionally adequate and healthy eating pattern as part of the management of RA. Physical therapies include physiotherapy, occupational therapy and podiatry, and predominately aim to control pain, minimise joint stiffness and limit joint damage, to facilitate the best possible function and health related quality of life, with the least adverse treatment effects.

Diet

Several studies have shown poor eating patterns and nutritionally inadequate diets in people with RA (Morgan *et al.*, 1997; Stone *et al.*, 1997; Goff & Basari, 1999). There are various explanations for these consistent findings:

- The pain and fatigue associated with RA can considerably impair appetite, particularly during acute flare ups, a characteristic of the condition.
- Joint pain and deformity have adverse effects on mobility, functional ability and manual dexterity. Consequently, shopping, food preparation, cooking and even eating can become difficult, complex and tiring.
- Medications taken to control the disease can cause nausea and anorexia or interact with nutrients, e.g. methotrexate blocks the action of folic acid and patients require folate supplements.
- Popular diets and alternative lifestyle regimens are widely available to people with RA, but they are generally based on personal experiences, not scientifically proven and are very likely to compromise nutrient intake.

If pain and disability cause feeding problems, a rheumatology occupational therapist can assess the patient, if necessary in their home, and advise on adapted eating utensils and home modifications to improve ability in the kitchen and maintain a desirable nutritional status.

Dietary supplements

Antioxidants

Epidemiological studies assessing dietary intake prior to the onset of inflammatory arthritis, particularly RA, have identified low dietary intakes of antioxidant nutrients such as vitamin C and beta cryptoxanthin in adults who developed inflammatory arthritis compared with those who did not (Pattison *et al.*, 2004a; 2005). Heliövaara *et al.* (1994) found lower serum levels of antioxidants in healthy individuals who went on to develop RA than in those who did not develop RA. However, it is unclear if the serum levels of antioxidants are low due to poor dietary intake prior to the onset of RA or are depleted via activity in the body's endogenous immune defence system.

A recent systematic review of studies of antioxidants, vitamins A, C and E, and selenium supplements in RA, osteoarthritis or other inflammatory conditions, concluded that there is no robust evidence to show antioxidant supplements confer any symptomatic benefit in the management of the above conditions (Canter *et al.*, 2007). This is not to say that individual patients obtain symptomatic improvement with these supplements, but in recommended doses they do no harm.

Fatty acids

The polyunsaturated fatty acids (PUFAs), n-6 and n-3 are precursors of inflammatory mediators, including prostaglandins and leucotrienes. There are different series of prostaglandins and leucotrienes with various pro- or anti-inflammatory properties. Prostaglandins of the two series, e.g. PG2 and PGI2, are the most potent inflammatory prostaglandins and originate from the n-6 PUFA arachidonic acid, whereas the n-3 PUFAs are metabolised to less inflammatory eicosanoids.

The potential benefits of changing the combination of fats in the diet of people with RA have been of interest to rheumatologists and researchers for many years, particularly increasing the intake of long chain n-3 PUFAs found in fish oils, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Adam, 1995). The most likely mechanism through which n-3 PUFAs act as anti-inflammatory agents is by competing with arachidonic acid for incorporation into inflammatory cell membranes and for metabolism by the enzymes of eicosanoids synthesis, thus reducing the production of the two series prostaglandins and four series leucotrienes (Calder, 2006) (Figure 7.9.3). n-3 PUFAs have other anti-inflammatory effects, independent from altered eicosanoids production, such as a decrease in the production of proinflammatory cytokines, e.g. interleukin 1 β and 1 α (IL1 β , IL1 α), TNF, and of reactive oxygen species. Eicosapentaenoic acid is also the

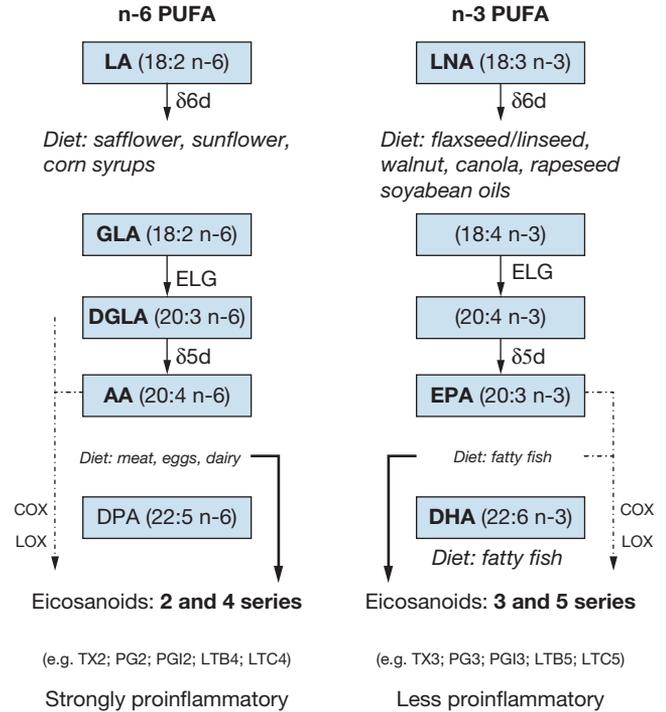

Figure 7.9.3 Metabolism of n-6 and n-3 fatty acids

precursor of the less inflammatory series three prostaglandins and series five leucotrienes (Calder, 2006).

There is strong evidence for the clinical efficacy of n-3 PUFAs in RA. Several reviews of trials of fish oil have found benefit from supplementation. A meta analysis by Fortin *et al.* (1995) concluded that dietary fish oil supplements for 3 months significantly reduce tender joint count and duration of early morning stiffness. A more recent meta analysis of 17 RCTs assessed the pain relieving effects of n-3 PUFAs in RA and in joint pain secondary to inflammatory bowel disease (Goldberg & Katz, 2007). Outcome measures included patient assessed pain, physician assessed pain, duration of morning stiffness, number of painful and/or tender joints, Ritchie articular index and NSAID consumption. Supplementation for 3–4 months significantly reduced patient reported joint pain, minutes of morning stiffness, number of painful and/or tender joints and NSAID consumption. The authors concluded that n-3 PUFAs were a useful adjunctive treatment for the joint pain associated with RA. Galarraga *et al.* (2008) undertook a randomised, double blind placebo controlled study to determine whether long chain n-3 rich cod liver oil could reduce the daily NSAID requirement of patients with RA by at least 30% without worsening of their disease activity. Patients in the treatment group received 10g of fish oil supplement/day, containing 2.2g of n-3 PUFAs (1.5g of EPA + 700mg of DHA), for 9 months. Compared with 10% in the placebo group, 40% of patients in the treatment group were able to reduce NSAID consumption by 30%. The key message from this study was that fish oil supplementation should be considered in RA patients to help reduce NSAID intake in order to attenuate the associated

risk of gastrointestinal and cardiovascular adverse events (Galarraga *et al.*, 2008).

Research has demonstrated an increase in the benefits gained from increasing n-3 PUFA intake if there is a simultaneous reduction in the dietary intake of n-6 PUFAs, thus increasing the ratio of n-3 PUFAs to n-6 PUFAs (Adam *et al.*, 2003). Consequently, altering dietary PUFA composition in favour of an increase in n-3 fatty acid intake could reduce or modify the inflammatory process and potentially dampen down disease activity. It is of some relevance then that over the last 100 years or so the western diet has become rich in n-6 PUFAs, whilst at the same time the consumption of n-3 PUFAs has greatly decreased (Simpoulous, 2009).

Food intolerance and exclusion diets

The withdrawal of food in patients with RA results in decreased production of the chemical mediators of inflammation; on the reintroduction of foodstuffs, the symptoms return (Buchanan *et al.*, 1991). Similarly, trials of elemental diets in RA patients have provided little objective evidence of benefit, with only temporary improvement in symptoms (Kavanaghi *et al.*, 1995).

Food intolerances have been demonstrated in some RA patients. Commonly reported intolerances include milk, corn, wheat and azo dyes, but there is no evidence that prevalence is greater than in the general population (Buchanan *et al.*, 1991; van de Laar & van der Korst, 1992). However, many patients self impose food restrictions to gain self empowerment in the management of their condition. Goff & Basari (1999) have reported that 67% of RA patients avoided a certain food or a number of foods, most commonly citrus fruit, tomatoes, vinegars, pickles, dairy products, red meat and alcohol. Clearly, the greater the number of foods avoided, particularly dairy products, then the greater the risk of nutritional imbalance or even deficiency.

Other supplements

As in many people with chronic diseases, the use of alternative and complementary dietary therapies is popular in patients with RA; supplement use is particularly common. A survey of patients with RA found that half of the respondents took some form of dietary supplement, the most common being cod liver oil. Other supplements frequently mentioned included evening primrose oil, iron, garlic, apple cider vinegar, vitamin C, selenium, B vitamins, calcium, general multivitamins and antioxidant supplements (Goff & Basari, 1999). None of the above supplements is supported by strong evidence of clinical efficacy in symptomatic RA. A systematic review of extract of New Zealand green lipped mussel found little evidence of efficacy in the management of RA (Cobb & Ernst, 2006). The results of a Cochrane review of herbal interventions compared with placebo in RA found seven studies that indicated benefits of gamma-linoleic acid (GLA) supplementation from evening primrose oil, borage seed oil or blackcurrant seed oil. Gamma-linoleic acid supplementation resulted in reduced pain intensity

and improved disability, but an increase in adverse events, mainly gastrointestinal (Cameron *et al.*, 2011).

Vegetarian and vegan diets

A systematic review identified a small number of studies in which periods of fasting were followed by a vegetarian diet for up to 4 months' duration. The pooled analysis found improvement in symptoms of RA, such as duration of morning stiffness, number of tender and swollen joints, and pain (Müller *et al.*, 2001). However, the results could be confounded by the period of fasting prior to the vegetarian diet, which may have dampened inflammatory activity. Strict vegan diets comprising uncooked foods rich in lactobacilli have been reported by patients to improve symptoms, but these studies have not been substantiated by more objective measures of disease activity (Nenonen *et al.*, 1998).

Although symptomatic improvements are experienced after fasting and/or an elemental diet or vegetarian diet, the reasons for this are unclear. Possible explanations may be:

- The elimination of foods to which the patient is allergic or intolerant, e.g. a gluten free, vegan diet regimen given to patients with active RA reduced IgG antibody levels against gliadin, compared to the non-vegan diet controls (Hafström *et al.*, 2001).
- Inflammatory activity is attenuated by caloric restriction or reduction in gut involvement, but the effects could be a result of a coincidental remission (part of the course of the condition), weight loss or a placebo effect (Kavanaghi *et al.*, 1995).

Comorbidities

Cardiovascular disease

Patients with RA are at an increased risk of cardiovascular disease (CVD), especially ischaemic heart disease (IHD) and heart failure, and over 50% of premature deaths in RA are due to CVD (Symmons & Gabriel, 2011). Recent studies suggest that CVD mortality and morbidity in RA are of similar magnitude to those seen in people with type 2 diabetes mellitus (van Halm *et al.*, 2009). It may be that the increase in CVD observed in RA is due to the traditional risk factors for CVD (see Chapter 7.14.1) being more frequent in individuals with RA than in the general population, or they have an additional deleterious effect. Alternatively, some of the excess CVD risk might be explained by the adverse impact of the inflammation and immune changes of RA on blood vessel walls (Symmons & Gabriel, 2011).

Although hyperlipidaemia is less frequent in RA than the general population, a meta analysis confirmed that dyslipidaemia might affect up to half of all patients with RA, principally low levels of high density lipoprotein (HDL) cholesterol (Steiner & Urowitz, 2009). Further studies are required to assess the value of dietary modification for dyslipidaemia and obesity. However, until more is known, the best strategy is to manage risk factors as for the general population, along with aggressive

treatment of disease activity. Further work is needed to establish whether using lower targets for cholesterol and blood pressure management will be of benefit in terms of CVD risk (Peters *et al.*, 2010).

Osteoporosis

Patients with RA and other forms of inflammatory arthritis are at an elevated risk of developing osteoporosis. This may be due to adverse effects on bone metabolism from the increased production of proinflammatory cytokines or the increasing loss of bone mass caused by corticosteroid treatment. Lack of weight bearing exercise, insufficient sunlight exposure and poor dietary intake are all detrimental to bone health (see Chapter 7.9.1).

Healthy eating

Despite folklore a specific diet for arthritis has never been proven. As with all patients, a full dietary assessment will identify dietary inadequacies and their causes. In the absence of a specific intervention for RA, dietary advice should focus on achieving optimal nutritional status through a nutritionally balanced diet.

However, there is evidence to support the role of n-3 fatty acids in the amelioration of inflammation and RA symptoms, as well as some epidemiological evidence for a role for antioxidants in reducing the risk of inflammatory arthritis (Cerhan *et al.*, 2003; Pattison *et al.*, 2004a; 2005). Although conflicting results have been reported, high red meat consumption may have a role in increasing the risk of developing RA (Grant, 2000, Pattison *et al.*, 2004b; Benito-Garcia *et al.*, 2007). The Mediterranean type diet has received a growing amount of attention in recent years because of its association with healthy populations living within the Mediterranean basin. Two studies of very different designs have investigated the effect of a diet based on the characteristics of a Mediterranean diet in people with RA (Sköldstam *et al.*, 2003; McKellar *et al.*, 2007). In a small randomised, controlled, parallel study, RA patients followed a modified Mediterranean diet for three months. Participants reported a significant reduction in disease activity, functional ability and improved vitality compared with those who followed the control diet (Sköldstam *et al.*, 2003). Despite an increase in reported consumption of antioxidant rich foods in the Mediterranean diet group, the levels of plasma antioxidants and urinary malondialdehyde (MDA), a marker of oxidative stress, did not change. However, the plasma levels of vitamin C, retinol and uric acid were inversely correlated to variables related to RA disease activity (Hagfors *et al.*, 2003). In a community based project in socially deprived areas, a 6-week educational programme with an emphasis on cooking and eating a Mediterranean type diet was studied. Women in the intervention group reported a healthier dietary intake and showed significant improvement in patient global assessment at 6 months, pain score at 3–6 months, duration of early morning stiffness at 6 months and Health Assessment Questionnaire (HAQ) score at 3 months (McKellar *et al.*, 2007).

Other forms of arthritis and arthralgia

Vitamin D and joint pain

Recently, there has been increased interest in the role of vitamin D in musculoskeletal conditions as the measurement of vitamin D levels is now readily available. In a recent study, 70% of consecutive new patients to general rheumatology clinics had vitamin D deficiency (defined as ≤ 53 nmol/L) and 26% had severe deficiency (defined as ≤ 25 nmol/L) (Haroon *et al.*, 2011). In patients diagnosed with OA and inflammatory joint disease, 62% and 69%, respectively, were deficient in vitamin D.

Osteomalacia is a bone disease caused by chronic and severe calcium, vitamin D or phosphate depletion of any cause. Bone pain, muscle weakness, tenderness and difficulty walking are common manifestations. In past years the most common causes of osteomalacia were malabsorption or prolonged lack of exposure to sunlight. However, nutritional deficiency is now a more common issue.

The multidisciplinary rheumatology team

People with arthritis and other musculoskeletal conditions need a wide range of high quality support and treatment, ranging from simple advice to highly specialised treatments. Multidisciplinary services are central to the management of arthritis, including a need for rapid referral to other specialists. The multidisciplinary team usually includes a rheumatologist, nurse specialist, physiotherapist, occupational therapist, dietitian, podiatrist, health psychologist, social worker and pharmacist. While full time roles are not warranted for all specialists, clearly defined access to all should be available. The multidisciplinary team has been shown to be effective in optimising management of patients with arthritis (Vliet Vlieland & Hazes, 1997).

7.9.3 Gout

Joan Gandy

Key points

- Gout is the most common form of inflammatory arthritis and is associated with poor quality of life.
- Risk factors that are associated with the increase in gout prevalence include offal, seafood, alcohol and fructose corn syrup.
- Other risk factors include obesity, hypertension and other features of the metabolic syndrome.
- Recommendations for the management include weight management, healthy eating, exercise and staying well with avoidance of dietary risk factors such as offal.

Gout is the most common form of inflammatory arthritis in men (Roddy & Doherty, 2010) and is associated with poor quality of life (Roddy *et al.*, 2007). It is caused by uric acid crystallising as monosodium urate (MSU) in joints, and sometimes other tissues, causing inflammation, swelling and severe pain; often experienced as excruciating attacks of pain. The metatarsal phalangeal joint (the joint between the big toe and ball of the foot) is most commonly affected. Gout is associated with high plasma levels of uric acid, hyperuricaemia, over a long period. It is present in most gout sufferers; however, high levels do not lead to gout in everyone and levels can be normal during an attack (Campion *et al.*, 1987; Zhang *et al.*, 2006a). For gout to occur there is usually sustained hyperuricaemia, MSU crystal formation and inflammation caused by interaction between MSU and inflammatory processes. The upper limit for urate is 0.42 mmol/L for men and 0.36 mmol/L for premenopausal women.

In humans uric acid is the end product of purine metabolism. Purines are the bases guanine and adenine, which with thymine and cytosine form the genetic code material of RNA and DNA. Hyperuricaemia is caused by one of the following mechanisms, or a combination of them:

- Increased endogenous production of uric acid.
- Decreased renal excretion of uric acid.
- Increased dietary intake of purine.

Prevalence

The incidence of gout in the UK is 2.68 per 1000 person years (4.42 in men and 1.32 in women) (Soriano *et al.*, 2011). Prevalence varies between countries and populations, with New Zealand Maoris having a particularly high prevalence of 6.4%. This variation is probably due to genetic, environmental and dietary factors. Gout is uncommon in premenopausal women as oestrogen increases uric acid excretion. Prevalence increases in men and women with age, with mean ages of onset of 60.1 and 67.7 years, respectively.

Diagnosis

Severe pain, swelling and erythema (redness) over a joint are strongly suggestive, but not diagnostic, of gout. A clinical diagnosis should be confirmed by demonstration of MSU crystals in the synovial fluid of the joint (Zhang *et al.*, 2006a). In chronic gout, large crystal deposits may form on joints (tophi) and joints may become eroded (Schumacher, 2008). Risk factors for gout and associated conditions should also be assessed.

Risk factors and associated conditions

Hyperuricaemia, age and genetic factors influence the risk of developing gout. Other risk factors for gout include:

- Dietary factors.
- Alcohol consumption.
- Metabolic syndrome and its components.
- Diuretic use.
- Renal disease.

Dietary factors

An association between diet and gout has been recognised anecdotally for many years. This has now been confirmed in large well designed epidemiological studies, such as the Health Professionals Follow-up Study (HPFS), which followed over 50 000 men for 10 years. Consumption of seafood and meat was associated with relative risks for gout of 1.51 and 1.41, respectively (Choi *et al.*, 2004a). There was no association with purine rich vegetables. Low fat dairy products were protective as was coffee consumption (Choi *et al.*, 2007a). The relative risk (RR) of gout for participants drinking two or more sugar sweetened soft drinks was 1.85; the RR was similar for fructose consumption, although there was no increased risk associated with the consumption of diet soft drinks (Choi & Curhan, 2008).

It has been suggested that vitamin C may be protective and a further analysis of the HPFS (Choi *et al.*, 2009) showed a RR of developing gout of 0.55 in participants who consumed >1500 mg of dietary vitamin C/day compared with those consuming <250 mg/day.

It is important to remember that these are associations that are suggestive of links between diet and the risk of developing gout. Well designed, randomised trials are needed to confirm the role of dietary factors in the prevention and treatment of gout.

Alcohol

Alcohol consumption has a graded relationship. The type of alcoholic drink influenced the risk of developing gout, with the highest risk being amongst beer drinkers, followed by spirit drinkers (Choi *et al.*, 2004b). While the amount of alcohol consumed was important, the high amount of purines in beer may also have influenced the results. Data from the Framingham Heart Study showed that women who were heavy drinkers had a three-fold higher risk of developing gout than abstinent or light drinkers (Bhole *et al.*, 2010). Heavy drinking men were twice as likely to develop gout as abstinent or light drinking men. A dose dependent relationship between the amount of alcohol consumed in the 48 hours before an acute attack and an attack has also been shown (Zhang *et al.*, 2006b).

Metabolic syndrome

There is an association between gout and the metabolic syndrome and its individual components; obesity, hypertension, type 2 diabetes and dyslipidaemia. In the National Health and Nutrition Examination Study, the prevalence of metabolic syndrome amongst patients with gout was 62.8% compared with 25.4% in the age and gender

matched group without gout (Choi *et al.*, 2007b). In a large analysis of over 170 000 gout patients, Primates *et al.* (2011) reported that more than half (58.1%) had one or more of the comorbidities of metabolic syndrome; diabetes (15.1%), dyslipidaemia (27.0%) and hypertension (36.1%) were the most common. The presence of these comorbidities was associated with increased risk of an acute attack, with women being particularly vulnerable. Gout is associated with an increased risk of myocardial infarction (Kuo *et al.*, 2013), heart failure and cardiac associated mortality (Krishnan, 2012). Lifestyle and dietetic management of the components of metabolic syndrome is becoming increasingly important.

Diuretic use

There is an association between the use of diuretics and gout, although this relationship is confounded by the reason for the use of the diuretics, e.g. hypertension, which may also increase the risk of gout (Choi *et al.*, 2005; Mikuls *et al.*, 2005). There is some evidence to suggest that diuretic use may be associated with acute gout attacks (Hunter *et al.*, 2006).

Renal disease

Chronic renal disease greatly increases the risk of gout (Mikuls *et al.*, 2005), as does dialysis and transplantation.

Clinical management

Acute episodes of gout are managed with non-steroidal anti-inflammatory drugs (NSAIDs) or colchicine. Once the acute phase has subsided, the condition can be kept under control with long term drug treatment:

- Allopurinol – a xanthine oxidase inhibitor that reduces uric acid production.
- Febuxostrate – a xanthine oxidase inhibitor. The National Institute for Health and Care Excellence (2008) recommends its use when allopurinol is contraindicated.
- Uricosuric drugs, e.g. probenecid or sulfinpyrazone, increase urinary uric acid excretion.

Dietary and lifestyle management

There is a paucity of evidence from large, well designed studies to support the use of dietary modifications in the management of gout. Recommendations for the dietary and lifestyle management of gout are mainly based on epidemiological and observational studies, and expert opinion (Jordan *et al.*, 2007; Zhang *et al.*, 2006a). In 2012 the American College of Rheumatology published guidelines for the management of gout and in which it also considered reducing risk factors for comorbidities, including the metabolic syndrome and its components, insulin resistance, type 2 diabetes (see Chapter 7.12), dyslipidaemia (see Chapter 7.14.3), hypertension (see Chapter 7.14.4) and obesity (see Chapter 7.13.2) (Khanna *et al.*, 2012). The recommendations are summarised in Table

Table 7.9.3 General health, diet and lifestyle recommendations for patients with gout [modified from Khanna *et al.* (2012)]

Weight loss for obese/overweight patients to achieve a BMI that promotes general health Healthy overall diet Exercise (achieve physical fitness) Smoking cessation Stay well hydrated		
Avoid	Limit	Encourage
Organ meats (offal) high in purines, e.g. liver, kidney, sweetbreads	Serving sizes of: Beef, lamb, pork Seafood with high purine content, e.g. sardines, shellfish, anchovies, fish roe, mackerel, sprats, whitebait	Low fat or non-fat dairy products
High fructose corn syrup sweetened fizzy drinks, other beverages or foods	Serving of naturally sweetened fruit juice Table sugar, sweetened beverages and desserts Table salt Sauces, gravies Meat and yeast extracts Quorn	Vegetables*
Alcohol >2 units/day in men and >1 unit/day in women in all gout patients Any alcohol during periods of frequent gout attacks or poorly controlled advanced gout	Alcohol, particularly beer, but also wine and spirits in all gout patients	

*Some vegetables are moderate sources of purines, e.g. asparagus, cauliflower and spinach; however, there is no convincing evidence to recommend their avoidance.

7.9.3. The evidence for restricting purines comes mainly from epidemiological studies such as the HPFS. However, a recent case crossover study of 633 participants with gout showed that acute purine intake increased the risk of an attack five-fold. The restriction of purines is also supported by expert guidelines (Jordan *et al.*, 2007; Khanna *et al.*, 2012).

Given the comorbidities associated with gout, including the metabolic syndrome and cardiac morbidities, dietetic management is likely to become increasingly important in this form of arthritis.

7.10

Mental health

7.10.1 Eating disorders

Kate Williams

Key points

- Dietitians in all areas of clinical practice should be alert to signs of undiagnosed disordered eating and be able to offer guidance on further investigation and support.
- Dietitians working in the field of eating disorders management should be part of a multidisciplinary team, and have appropriate support and supervision.

Eating disorders are syndromes in which abnormalities of eating behaviour, which are driven by psychological factors, are severe and persistent enough to impair health and nutrition; interfere with social eating; and give rise to distress in the sufferer and those close to them. In all areas of clinical practice, dietitians discuss with their patients the detail of eating behaviour, so are often able to identify disordered eating. Although some people with eating disorders may go to great lengths to conceal them, many may welcome the opportunity to raise their concerns and begin to get help. It is important for dietitians to enable patients to talk honestly about their eating, identify possible eating disorders and offer support to get the help they need. Disordered eating may severely interfere with the dietetic treatment of other conditions, so dietitians need to be alert to the possibility of disordered eating in all areas of clinical practice in order to achieve good outcomes of treatment.

As changing eating behaviour and improving nutrition are central to recovery from eating disorders, dietitians can make important contributions to the care and treatment of people with these conditions. There are few areas of dietetic practice that demand more skill in engaging and motivating patients, and communicating with colleagues. A warm, empathic and non-judgemental therapeutic relationship can empower a patient to discuss anxiety and distress about eating, and use help and support. For a guide to developing and using these

skills, see Gable (2007). For detailed reviews of the contribution of the dietitian to the management of eating disorders, see Hart *et al.* (2011), American Dietetic Association (ADA) (2011), Garrett *et al.* (2005) and Herrin (2003).

Background and historical perspective

In anorexia nervosa the central feature is deliberate and persistent restriction of food intake. It, or at least a condition with very similar features, has been described for hundreds, possibly thousands, of years (Vandereycken & van Deth, 1994; Brumberg, 1988; Grimm, 1996). Anorexia nervosa was first named in the medical literature in the late 19th century by Gull (1874; 1888) and Lasègue (1873). Strikingly, these descriptions do not refer to the fear of fatness as an essential feature; this seems to have emerged in western cultures during the 20th century, alongside increasing social valuation of thinness, especially in women (Bruch, 1973). The condition may present differently in some individuals, especially those from non-western cultures (Nasser, 1997).

Bulimia nervosa is a condition in which there is a cycle of restriction of food intake, followed by binge eating and extreme efforts to compensate for the feared fattening effects of the binge, commonly by repeated restriction of eating, vomiting, excessive use of laxatives or over exercising. Russell first described it in the medical literature

in 1979. He characterised it initially as a development of anorexia nervosa (Russell, 1979). It quickly became clear that it might arise without any previous episodes of anorexia. The change from restricting anorexia to bulimia nervosa is not unusual (Fairburn & Harrison, 2003) and people with eating disorders may display different symptoms at different times. Partial syndromes are a common presentation.

In 1992 Spitzer *et al.* proposed diagnostic criteria for binge eating disorder, in which the individual regularly binge eats, but does not compensate for the binges. The binge eating is distinguished from normal occasional overeating by its persistence and frequency, and the psychological distress associated with it. It is generally associated with obesity, which may be severe.

Diagnostic criteria and classification

Two published sets of diagnostic criteria for eating disorders are in use; the International Classification of Diseases, published by the World Health Organization, and the Diagnostic and Statistical Manual of Mental Disorders (DSM), published by the American Psychiatric Association (1994). These documents set out criteria for the diagnosis of the major disorders, anorexia nervosa and bulimia nervosa, and for some partial syndromes (Table 7.10.1). DSM IV also proposes diagnostic criteria for binge eating disorder for research purposes (Box 7.10.1). These strict definitions allow the identification of the disorders for research and other purposes, but in clinical practice dietitians may encounter many people with disordered eating who do not exactly meet any of these criteria, but need help to recover. The next revision of DSM (DSM V) is likely to include diagnostic criteria for binge eating disorder as one of the eating disorders not otherwise specified (EDNOS).

Features and processes of eating disorders

It can be difficult to understand disorders that provoke behaviour that seems very abnormal and damaging. It may be helpful for the practitioner seeking to develop an empathic relationship with a person with an eating disorder to have some awareness of the way the disorders develop and become entrenched.

Anorexia nervosa

The central feature of anorexia nervosa is restriction of food intake severely enough to keep body mass index below 17.5 kg/m² and often much lower, with the resulting constellation of features of starvation. This is accompanied by a conviction that the restriction of food intake is appropriate for the individual, usually because they feel the need to reduce their weight.

It is known that there are genetic predisposing factors (Bulik *et al.*, 2007; Gorwood *et al.*, 2003). Some personality traits and thinking styles are known to increase vul-

nerability to developing anorexia nervosa. A tendency to perfectionism, rule bound and rigid thinking, and attention to detail at the expense of a broader and more flexible approach can predispose to the disorder (Treasure *et al.*, 2010). Distressing experiences in early life such as emotional or physical neglect, or physical or sexual abuse add to the risk. A very usual trigger in western cultures is dieting, which is tried by the great majority of adolescent girls and many boys. Well publicised diets offer many detailed rules, and may seem gratifying to a person with a perfectionistic, rigid and detail focussed approach. In vulnerable individuals, dieting may become entrenched because of anxiety about breaking self imposed rules, and perfectionism and self criticism driving continually increasing efforts. The pursuit of weight loss can seem rewarding and offer a distraction from persistent emotional distress, becoming increasingly extreme and fixed behaviour. Any increase in food intake may result in rapid weight gain because of repletion of glycogen stores with associated water, and so add to the belief that breaking the rules of the diet will result in uncontrollable weight increase.

From this experience develops a profound fear of fatness and weight gain, and body image distortion, although other anxieties may predominate in some individuals. In many individuals, the increasing hunger and food craving lead to binge eating, with anxiety driven attempts to compensate for the binge with purging or exercise (Fairburn & Harrison, 2003). The behaviour may become very fixed because it begins at a time of rapid brain development, and the malnutrition itself may interfere with this process, in particular the maturation of emotional regulation, so that the person may find it difficult to counter the anxiety and other emotions that drive the abnormal behaviour (Treasure *et al.*, 2010; Harrison *et al.*, 2009).

Bulimia nervosa

The major feature of bulimia nervosa is a cycle of restriction of eating, which may be very severe, followed by food craving and uncontrolled excessive eating. This raises anxiety about the possible weight increase the binge might cause, provoking attempts to compensate, most commonly by self induced vomiting, excessive use of laxatives or excessive exercise, and further restriction of eating. This binge–starve cycle is driven by over valuation of thinness, and attempts to lose weight as a means to improve low self esteem. Low mood can deprive the individual of the motivation to change (Ruhasing *et al.*, 2003). Predisposing factors include poor impulse control and, like in anorexia nervosa, distressing early experience increases risk. Attempts to diet, commonly beginning in the early teenage years, may be unsuccessful in response to hunger and food craving, setting up the binge–starve cycle (Figure 7.10.1). It is possible that binge eaters have an increased drive to seek rewarding behaviour, and that the binge–starve cycle can become entrenched as food deprivation increases the reward of eating, so the drive to binge becomes increasingly

Table 7.10.1 Diagnostic criteria for eating disorders

ICD-10 (World Health Organization, 1992)	DSM-IV (American Psychiatric Association, 1994)
<p>Anorexia nervosa</p> <p>For a definite diagnosis, all the following are required:</p> <ol style="list-style-type: none"> Body weight is maintained at least 15% below that expected (either lost or never achieved) or BMI ≤ 17.5 or less. Prepubertal patients may fail to make the expected weight gain during the period of growth The weight loss is self induced by avoidance of 'fattening foods'. One or more of the following may also be present: self induced vomiting; self induced purging; excessive exercise; use of appetite suppressants and/or diuretics There is body image distortion in the form of a specific psychopathology whereby a dread of fatness persists as an intrusive, overvalued idea and the patient imposes a low weight threshold on him/herself A widespread endocrine disorder involving the hypothalamic–pituitary–gonadal axis is manifest in women as amenorrhoea and in men as a loss of sexual interest and potency. (An apparent exception is the persistence of vaginal bleeds in anorexic women who are receiving hormonal replacement therapy, most commonly taken as the contraceptive pill.) There may also be elevated levels of growth hormone, raised levels of cortisol, changes in the peripheral metabolism of the thyroid gland, and abnormalities of insulin secretion If onset is prepubertal, the sequence of pubertal events is delayed or even arrested (growth ceases; in girls the breasts do not develop and there is primary amenorrhoea; in boys the genitals remain juvenile). With recovery, puberty is often completed normally, but menarche is late <p>Bulimia nervosa</p> <p>For a definite diagnosis, all of the following are required:</p> <ol style="list-style-type: none"> There is persistent preoccupation with eating, and an irresistible craving for food; the patient succumbs to episodes of overeating in which large amounts of food are consumed in short periods of time The patient attempts to counteract the 'fattening' effects of food by one or more of the following: self induced vomiting; purgative abuse; alternating periods of starvation; use of drugs such as appetite suppressants, thyroid preparations or diuretics. When bulimia occurs in diabetic patients, they may choose to neglect their insulin treatment The psychopathology consists of a morbid dread of fatness, and the patient sets her/himself a sharply defined weight threshold, well below the premorbid weight that constitutes the optimum or healthy weight in the opinion of the physician. There is often, but not always, a history of an earlier episode of anorexia nervosa, the interval between the two disorders ranging from a few months to several years. This earlier episode may have been fully expressed, or may have assumed a minor cryptic form with a moderate loss of weight and/or a transient phase of amenorrhoea 	<ol style="list-style-type: none"> A refusal to maintain body weight at or above a minimally normal weight for age and height, e.g. weight loss leading to maintenance of body weight <85% of that expected; or failure to make expected weight gain during a period of growth, leading to a body weight <85% of that expected) Intense fear of gaining weight or becoming fat, even though underweight Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self evaluation, or denial of the seriousness of the current low body weight In postmenarcheal females, amenorrhoea, i.e. the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhoea if her periods occur only following hormone, e.g. oestrogen, administration) <p>Type of anorexia nervosa is also specified as:</p> <p>Restricting type: during the current episode of anorexia nervosa, the person has not regularly engaged in binge eating or purging behaviour, i.e. self induced vomiting or the misuse of laxatives, diuretics or enemas)</p> <p>Binge eating/purging type: during the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behaviour, i.e. self induced vomiting or the misuse of laxatives, diuretics or enemas)</p> <ol style="list-style-type: none"> Recurrent episodes of binge eating. An episode of binge eating is characterised by both of the following: <ol style="list-style-type: none"> Eating in a discrete period of time, (e.g. within 2 hours, an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances A sense of lack of control over eating during the episode, e.g. a feeling that one cannot stop eating or control what or how much one is eating Recurrent inappropriate compensatory behaviour in order to prevent weight gain, such as self induced vomiting; misuse of laxatives, diuretics, enemas or other medications; fasting or excessive exercise The binge eating and inappropriate compensatory behaviours both occur on average at least twice a week for 3 months Self evaluation is unduly influenced by body shape and weight The disturbance does not occur exclusively during episodes of anorexia nervosa

powerful (Davis *et al.*, 2008; Thanos *et al.*, 2008; Wang *et al.*, 2011).

Partial and mixed syndromes, including binge eating disorder

In any individual, the symptoms of an eating disorder may change over time, so that they move from one diagnostic category to another (Fairburn & Harrison, 2003). In clinical

practice, the most commonly occurring eating disorders are partial syndromes that do not fully meet diagnostic criteria for anorexia nervosa or bulimia nervosa. Management strategies can be agreed on the basis of the most damaging or distressing symptoms. Binge eating disorder is characterised by repeated episodes of binge eating, without significant compensatory behaviours other than repeated attempts at dieting (Spitzer *et al.*, 1992). Levels of concern about weight and shape are

Box 7.10.1 Research criteria for binge eating disorder (American Psychiatric Association 1994)

- A. Recurrent episodes of binge eating. Binge eating is characterised by two of the following:
- Eating in a discrete period of time, e.g. 2 hours, an amount of food that is definitely larger than most people would eat during a similar period of time and in the same circumstances
 - A sense of lack of control over eating during the episode, e.g. a feeling that one cannot stop eating or control how much one is eating
- B. The binge eating episodes are associated with three or more of the following:
- Eating much more rapidly than normal
 - Eating until feeling uncomfortably full
 - Eating large amounts of food when not feeling physical hunger
 - Eating alone because of being embarrassed by how much one is eating
 - Feeling disgusted with oneself, depressed or very guilty after overeating
- C. Marked distress regarding binge eating is present
- D. The binge eating occurs on average at least 2 days per week for 6 months
- E. The binge eating is not associated with the regular use of inappropriate compensatory behaviours, e.g. purging, fasting, excessive exercise, and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa

similar to those in the other eating disorders, and higher than in obese people without binge eating disorder (Wilfley *et al.*, 2003). Childhood obesity, negative early experience and low self esteem are predisposing factors (Fairburn *et al.*, 1998).

Epidemiology and public health aspects

Incidence and prevalence

Researchers considering incidence and prevalence of eating disorders often urge caution, and suggest that published figures may be underestimates for a number of reasons, including secrecy about symptoms and reluctance to seek treatment (Rooney *et al.*, 1995; Hudson *et al.*, 2007; Hoek & Hoeken, 2003; Hoek, 2006). For example, Keski-Rahkonen (2007) found that in a community sample, half of the cases of anorexia nervosa had not been detected by healthcare services.

Hoek & Hoeken (2003) and Hoek (2006) reviewed the literature on incidence and prevalence, and found that the highest incidence of anorexia nervosa was at age 15–19 years, and in Europe and the USA prevalence of anorexia in that age group was around 0.3%. The female to male ratio was more than 10 to 1. Outside western societies, the prevalence is lower, but there is some evidence that it is increasing with the spread of western

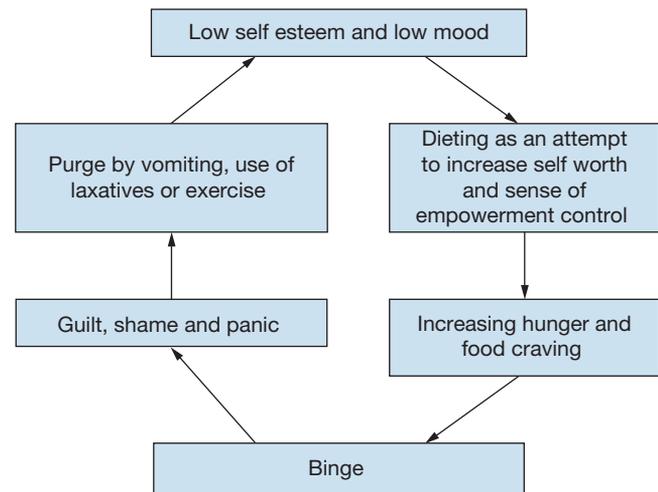

Figure 7.10.1 Binge–starve cycle in bulimia nervosa

cultural norms. Anorexia has long been recognised as having the highest mortality of any mental disorders (Harris & Barraclough, 1998), and Hoek’s review (2006) of more recent evidence confirms this. Significant causes of death include suicide and cardiac complications. There are concerns about the risk of death resulting from inappropriate refeeding practice (Royal College Psychiatrists, 2010). For bulimia nervosa, Hoek & Hoeken (2003) and Hoek (2006) found an incidence at about 1% among young women. Over whole populations, they found incidence rates of at least 8 per 100 000 person years for anorexia nervosa and 12 for bulimia nervosa.

Prevention

Prevention of eating disorders presents a complex challenge. It is clear that protection of children from abuse and neglect is helpful in the prevention of eating disorders and other mental health problems. Direct interventions aimed at preventing eating disorders in vulnerable populations have been counter productive (Carter *et al.*, 1997; Mann *et al.*, 1997). There is continuing controversy about the part played by cultural influences. In their general practice, dietitians should emphasise eating to support general health and nutrition, rather than focussing too narrowly on control of body weight (ADA, 2011).

Medical and nutritional effects of eating disorders

Anorexia nervosa

Much of the information about the physical and psychological effects of starvation in otherwise healthy individuals comes from the classic work of Keys *et al.* (1950), known as the Minnesota Experiment, in which healthy male volunteers ate approximately half of their energy requirement for a 12-week period (Keys *et al.*, 1950; Kalm & Semba, 2005). Starvation results in general malnutrition, affecting all tissues and organs (Mitchell & Crow, 2006). The main tissue loss is adipose tissue and muscle

mass. Internal organs are not affected until the more advanced stages of malnutrition, when liver, heart and brain reduce in mass, with resulting loss of function (Treasure *et al.*, 2010; Winston & Stafford, 2000; Casiero & Frishman, 2006), and gut function is compromised (Robinson, 2000; Robinson *et al.*, 1988).

Endocrine function can be severely disturbed as an adaptation to starvation, affecting the thyroid and adrenal glands and the gonads via the hypothalamus and pituitary axis (Lawson & Klibanski, 2008; Connan *et al.*, 2000). Suppression of thyroid function results in bradycardia, hypotension and hypothermia, with subjective cold sensitivity and poor sleep. The reduction in fat mass reduces leptin secretion, while cortisol secretion is increased. The tendency to central deposition of adipose tissue that is usually a feature of hypercortisolaemia is absent because adipose tissue is depleted, but during recovery a common cause of distress is central distribution of the repleting fat mass (Lawson & Klibanski, 2008). Suppression of sex hormones results in amenorrhoea in women, and a range of other effects. These endocrine changes underlie the increased risk of osteoporosis that accompanies the nutritional deficit. The development of the illness during adolescence, when bone density should be increasing rapidly, adds further to the risk (Teng, 2011). This is a major physical complication of anorexia nervosa, and may not completely reverse with recovery of endocrine function, healthy body weight and good nutrition (Serpell & Treasure, 1997; Zipfel *et al.*, 2000; Teng, 2011).

The effects on the gut can make increasing food intake uncomfortable and add to its aversiveness. The direct effects of persistent vomiting may damage teeth and the soft tissues of the mouth. Iron and riboflavin deficiency can cause glossitis and angular cheilosis, making eating uncomfortable (Newton & Travess, 2000; Frydrych *et al.*, 2005). Peristalsis is slow, causing delayed gastric emptying (Robinson *et al.*, 1988), bloating and constipation.

The volunteers in the Minnesota Experiment also showed increases in depression, preoccupation with food to the exclusion of other interests, obsessive and bizarre eating behaviour, and social isolation (Keys *et al.*, 1950). These psychological effects are all seen in anorexia nervosa.

Bulimia nervosa

Bulimia nervosa can result in erratic body weight. Vomiting and laxative use can cause disturbances in blood electrolytes, in particular low potassium (Fairburn & Harrison, 2003). Bingeing and vomiting can cause damage to the gastrointestinal tract (Ruhsing *et al.*, 2003; Mitchell & Crow, 2006), including gastro-oesophageal reflux, and acid erosion of the teeth (Frydrych *et al.*, 2005).

Binge eating disorder

This disorder is often associated with obesity, which may be extreme, and a history of weight cycling, with many attempts to reduce body weight, often including a variety of commercial diets and medication. The physical com-

plications and excess mortality relate generally to the associated obesity (Bulik & Reichborn-Kjennerud, 2003; Wilfley *et al.*, 2003). People with any eating disorder may find it very difficult to regulate their food intake appropriately. They may experience abnormalities of normal physiological sensations of hunger and satiety (Treasure *et al.*, 2012), and during the development of the disorder may have overridden them by persistent restriction or repeated binge eating, having lost the ability to respond normally. There are changes in the production of gut hormones associated with physiological appetite control, which may further serve to entrench the abnormal eating (Prince *et al.*, 2010). Erratic and distorted food choice and meal pattern may further impair physiological appetite regulation. Persistently abnormal eating may have prevented the learning needed for development of normal eating, or abolished previously learned behaviour. Avoidance of social eating, or the anxiety associated with it, may make it impossible to use social benchmarking to judge appropriate food intake. Eating, or not eating, may be almost entirely in response to emotional cues. As the individual becomes more socially isolated, particularly avoiding social eating, social and learned eating cues may be lost, leaving eating behaviour driven primarily by emotional cues.

Management

Eating disorders have physical, psychological and social features that may all need expert management. It is therefore essential that the resources of a multidisciplinary team are available, and that dietitians do not work alone (NICE, 2004; ADA, 2011). Good communication among the members of the multidisciplinary team is therefore a high priority. There is also a particular need for good communication and effective working partnerships between specialist dietitians in eating disorders and those in acute medical or intensive care services, to which patients with anorexia nervosa may be admitted (Royal College of Psychiatrists, 2010). The dietitian can make a valuable contribution to the team by improving the nutritional knowledge of all team members (Cordery & Waller, 2006) and raising awareness of the risk of refeeding syndrome (Hearing, 2004).

Ambivalence about recovery and fluctuating motivation challenge everyone involved in the work towards recovery. Skills in counselling and motivation enhancement are needed for help and support to be effective (Treasure & Schmidt, 2001). Throughout the treatment process, a collaborative and motivational approach can support behaviour change and recovery (Feld *et al.*, 2001). Recovery from an eating disorder can be a difficult and complex process. This can present challenges to practitioners, so good support and governance are essential. Dietitians working in this area should seek appropriate supervision. Skilled supervision can help dietitians with the development and productive use of their skills, effective collaboration among colleagues, maintenance of professional and personal boundaries, and managing what can be a distressing experience (BDA, 2008; ADA, 2011).

Major elements of treatment include psychotherapy, medication to help manage depression and anxiety, and development of social skills and skills to support managing eating, such as shopping and cooking. The dietitian can contribute by managing nutritional risk, supporting nutritional rehabilitation and providing education on food and nutrition.

Identification in dietetic clinical practice

In general dietetic practice, indications of disordered eating may be apparent before a formal diagnosis is made, or at a level of severity and frequency that do not meet diagnostic criteria, but nevertheless cause distress, damage health and nutrition, and impair dietetic management. It is therefore important that dietitians are alert to signs and symptoms of disordered eating, and are able to manage them, or refer for more specialist support. It is perhaps not surprising that disordered eating arises in situations where anxiety about eating and nutrition is high, e.g. in the management of obesity (de Zwaan, 2001) and diabetes (Fairburn *et al.*, 1991).

Routine dietetic assessment may expose signs that might indicate disordered eating. Anthropometry may reveal reluctance to be weighed, underweight in the absence of known physical cause or obesity associated with a history of weight cycling. Biochemical indicators include low blood potassium, which may result from persistent vomiting or laxative abuse, or low sodium because of water loading to suppress hunger or falsify weight. Diet history may show erratic eating; restriction of amount and variety of food; rigidity and inappropriate rules about eating and food choice; binge eating or other presentations of uncontrolled overeating such as grazing or night eating; deranged eating pattern; and high anxiety about eating. The SCOFF (Morgan *et al.*, 1999) and ESP tools (Cotton *et al.*, 2003) (Table 7.10.2) are very brief questionnaires designed and validated for use in primary care to help identify disordered eating. Dietitians can use them, or selected questions from them, to help confirm concerns about the presence of an eating disorder, and

to encourage their patients to talk about their eating and agree appropriate management.

Dietetic assessment

Although people with eating disorders may present with a great variety of dietetic problems, from severe underweight and malnutrition to severe obesity and weight cycling, the assessment process can be similar for all eating disorders. The aims of assessment are to begin to develop a trusting and productive therapeutic relationship that will support recovery; to develop and maintain motivation to change (Herrin, 2003; Gable 2007, ADA 2011); and to gather the information needed to make a dietetic diagnosis and negotiate a treatment plan (BDA, 2009).

The structure of the process is similar to any dietetic assessment, but may require more time than average because of the ambivalence and anxiety of the patient, and the complexity of the history. It may be helpful to use more than one session to complete the process. Much information may come from previous medical assessment, e.g. diagnoses, results of blood tests and information on medication. However, the most important element is the conversation with the patient, and usually also family members if the patient is living with them, and especially if they are under 18 years of age. The way in which this conversation is conducted will be led to some extent by the patient, but the information needed falls into the standard dietetic assessment framework.

Anthropometry

This includes:

- Weight, height and body mass index (BMI).
- For people under 18 years old, height, weight and BMI centiles. Expected weight for height and for expected height may also be useful.

Being weighed can be distressing for a person with an eating disorder, so clear explanation of the need for body weight should be given, and permission should be sought and recorded carefully.

Biochemistry

This includes:

- *Electrolytes* – low levels of sodium, potassium and magnesium in the context of low body weight may indicate chronic low intake. Low potassium may result from use of laxatives or self induced vomiting. Low sodium is most likely to be due to excessive water intake to suppress hunger or falsify body weight.
- *Iron status* – haemoglobin may be low if food intake has been severely restricted for a long period, but may be protected by reduced iron loss with amenorrhoea. Much more commonly, low ferritin indicates low iron stores.
- *White cell count* – overall white cell count, or one or more elements of total white cells, may be low in chronic semi starvation.

Table 7.10.2 Screening questions for eating disorders

SCOFF (Morgan <i>et al.</i> , 1999)	ESP (Cotton <i>et al.</i> , 2003)
Do you make yourself Sick because you feel uncomfortably full?	Are you satisfied with your eating patterns?
Do you worry you have lost Control over how much you eat?	Do you ever eat in secret?
Have you recently lost more than One stone in a 3-month period?	Does your weight affect the way you feel about yourself?
Do you believe yourself to be Fat when others say you are too thin?	Have any members of your family suffered with an eating disorder?
Would you say that Food dominates your life?	Do you currently suffer with or have you ever suffered in the past with an eating disorder?

- *Urea* – be low in chronic severe restriction of food intake.

Low levels of urea, electrolytes and other biochemical indicators may be masked by dehydration, resulting in false normal results (Caragaro *et al.*, 2005), so care should be taken to interpret blood test results alongside indicators of hydration, such as blood pressure.

Clinical assessment

This includes:

- *Eating disorder diagnosis* and other diagnoses of both physical and psychological disorders.
- *Endocrine function* – indicators include amenorrhoea, hypotension with postural drop, bradycardia, hypothermia and subjective feeling of cold, and poor sleep.
- *Low bone mineral density* – DEXA scan to measure bone density is recommended for people with a history of low weight for 6 months or longer (NICE, 2004).
- *Psychological effects* such as low or labile mood, irritability, impaired memory or concentration.
- *Medication*.

Dietetic assessment

This includes:

- *Detailed history of weight and eating*. It is helpful to take a history at least from the beginning of the eating disorder symptoms, and sometimes from infancy, to consider early feeding difficulties. The history should seek to identify periods of low or high weight, and the degree of abnormality, weight cycling and instability, and any times when weight has been normal and stable. This can help to develop a shared understanding of the way eating, body weight, psychological factors and life events relate to each other.
- *Current diet and disordered eating symptoms*:
 - Restriction of amount and variety of foods eaten, foods avoided, foods that are acceptable.
 - Meal pattern, timing and frequency of eating, and variability of meal pattern.
 - Irrational or exaggerated rules and beliefs about eating.
 - Binge eating, grazing or other uncontrolled overeating; foods used for binge eating.
 - Purging and compensatory behaviour, such as vomiting, laxative use and excessive exercise.
 - Emotional responses to food and eating, such as anxiety or disgust.
 - Social context of eating.
 - Fluid intake, which may be restricted or excessive.
 - Alcohol intake.
 - Nutritional supplements such as vitamins.
- *Impaired appetite regulation and subjective ability to control food intake*.

Economic and social assessment

This includes:

- *Education or employment* – these may help to structure the day and eating pattern, or impede routine if there are changing work shifts or an erratic timetable. Education or employment may be important motivators, or worsen anxiety, distress and low self esteem.
- *Finance* – persistent severe binge eating may generate debt. Worries about money may add to stress associated with buying and using food.
- *Social support* – it is useful to identify family members and friends who can support recovery.
- *Household information* – facilities for food preparation, sharing meals with other members of the household.

Feelings

Assessment of motivation and concerns is essential to begin the process of change. The assessment process can help identify the stage of change (Prochaska & DiClemente, 1983), concerns raised by the eating disorders and reasons for recovery. These will inform the priorities for change in eating behaviour, identify barriers to change and motivators for change, and form a basis for the treatment plan.

Dietetic treatment of eating disorders

Aims and priorities for treatment should be negotiated collaboratively by the dietitian and the sufferer, and carers when appropriate, especially when the sufferer is a child or adolescent. Modest steps towards the treatment aims can then be planned in the form of SMART (specific, measurable, achievable, relevant and time limited) goals. This process should proceed alongside psychological treatment to support changes in thinking and behaviour. Treatment outcomes are likely to include several domains, as shown in Table 7.10.3.

Anorexia nervosa

Evidence for the effectiveness of dietetic interventions is limited, but there is agreement in published guidance that dietetic care is an essential element of management (Hart *et al.*, 2011). Treatment may be provided in a hospital inpatient setting, day care or outpatient service. Regular weight monitoring and medical monitoring are essential at each stage of treatment, to ensure that appropriate management is in place for any problems that arise.

Treatment is in three distinct phases; medical stabilisation and management of refeeding syndrome risk, nutrition rehabilitation and increasing responsibility for normal and healthy eating, and finally, maintenance and relapse prevention.

Phase 1: stabilisation

The early stage of refeeding carries risk, especially if the anorexia is severe, and is uncomfortable and distressing.

Table 7.10.3 Treatment outcomes for eating disorders

Treatment domain	Outcome
Biochemical	Normalised blood urea and electrolytes Normalised white cell count Normalised iron status (haemoglobin and ferritin)
Psychological	Reduced anxiety about eating and weight More stable mood Increased motivation to prevent relapse
Behaviour change domain	Reduced restriction of eating Abolition of binge eating Abolition of purging Healthier food choices Normal fluid intake
Physical domain	Healthy body mass index In children and adolescents, normal growth, or catch-up growth as appropriate Improved bone mineral density
Symptom change domain	Reduced reflux, bloating, constipation Normal sleep Abolished faintness, giddiness Normal body temperature control Normal menstruation
Patient focused domain	Achievement of aims for employment or education Avoiding hospital admission Independent living Improved personal relationships Improved social eating Appropriate physical activity

Gradual increases in food intake, with good information, clear explanations and consistent support can help manage increased anxiety. It may be difficult to strike the optimal balance between keeping food intake low to prevent refeeding syndrome and increasing it quickly enough to reduce the risks imposed by the malnutrition (Royal College Psychiatrists, 2010).

The evidence on the management of refeeding syndrome comes largely from critical care, where patients are acutely ill or physically traumatised (NICE, 2006a), and so are catabolic (see Chapter 7.17.1). People with anorexia nervosa are generally not critically ill, but are severely starved, so rapidly become anabolic with refeeding. This difference in response to increasing food intake may affect the risk of refeeding syndrome, but evidence is lacking. However, there is a clear risk of refeeding syndrome in anorexia nervosa (Birmingham *et al.*, 1996; Fisher *et al.*, 2000), so some caution is needed, and close monitoring is essential. This may be particularly challenging in non-specialist settings such as medical wards or intensive care units, where the Royal College of Psychiatrists (2010) guidance may be especially useful. The consensus is that feeding can safely be begun at about 80 kJ (20 kcal)/kg of body weight/24 hours (Royal College

Psychiatrists, 2010), using a tube feeding formula or food.

To prevent Wernicke–Korsakoff syndrome, prophylactic thiamine should be given daily, following guidance given by NICE (2006a) for the prevention of refeeding syndrome. There is likely to be a general deficiency of micronutrients, so multivitamins and minerals should be given to correct deficiencies and as part of global nutritional rehabilitation (Rock & Vasantharajan, 1995; Setnick, 2010; Hadigan *et al.*, 2000). Total fluid should be controlled, as cardiac capacity may be limited by loss of cardiac muscle mass, and rapid increase in blood volume may risk cardiac failure (Winston & Stafford, 2000). Weight gain may be rapid during the first 7–10 days of refeeding because of rehydration and, sometimes, temporary fluid retention, especially if persistent vomiting or laxative abuse are stopped. Explanation of the effect and reassurance that it is self limiting may be helpful.

Tube feeding

Where tube feeding is the preferred route, bolus feeding is generally easier to manage, as it allows the patient to be mobile, and it is easier to supervise the delivery of the feed and so prevent sabotage. Because the overall volume initially is low, bolus volume can be relatively low, which helps to prevent bloating and discomfort. Six boluses of 100–150 mL/day will allow delivery of an adequate volume of feed for a person of 25–45 kg. At first, an isotonic formula is preferable, as it does not cause osmotic movement of water into the gut, which may be uncomfortable and create a pseudo-dumping syndrome, with faintness due to fall in blood pressure. As feed volume is increased, a higher density feed may help prevent feelings of bloating (Gentile *et al.*, 2010).

Oral feeding

Initially, care should be taken to limit carbohydrate and ensure a high intake of potassium and phosphate, as blood levels can fall rapidly as part of refeeding syndrome (NICE, 2006a). This can be achieved by giving a high proportion of intake as cow's milk as a source of phosphate, and fruit juice as a source of potassium. It may be more comfortable to give fruit juice diluted with water, especially if the mouth is sore. Small meals with a modest amount of food choice can help manage anxiety. Too much choice may be overwhelming.

It should be possible to accommodate vegetarian diets without difficulty. Avoidance of meat and fish is culturally common, and required by some religions, and there is no reason to challenge such a choice at this stage. If vegetarianism has developed as part of the eating disorder pathology, it may be addressed later in treatment. Vegan diets, with no animal products, present some risks as these diets tend to have low energy density, so the patient is faced with a relatively large volume of food. The high fibre content may be uncomfortable and possibly increase the risk of gastric dilatation or rupture (Saul *et al.*, 1981). If a vegan diet is to be used, food provision should be

planned to provide adequate phosphate (most easily by using a soya milk with added phosphate) and to minimise volume and fibre. Monitoring of blood and physical condition should be vigilant, and treatment adjusted according to results.

Phase 2: nutritional rehabilitation

The National Institute for Health and Care Excellence (2004) recommends weight gain at a rate of about 0.5 kg/week for outpatients and 0.5–1.0 kg/week for inpatients, who can be supported and monitored more intensively. Individual variation on this may be negotiated, e.g. for patients with a very long history or if reduction of other symptoms such as purging are to be given priority. Setting and reviewing SMART goals can establish the aims. The aims during this stage are:

- To recover weight, ideally to a healthy weight that will restore normal endocrine function and so reduce the risk of osteoporosis.
- To restore optimal nutritional status and normalise blood indicators of poor nutrition.
- To replete body stores of nutrients.
- To increase confidence and knowledge to support ability to eat normally and independently, as appropriate for age and social circumstances.
- Reduction of physical symptoms of malnutrition.
- Reduction of anxiety about eating and preoccupation with food.
- Reduction of abnormal eating behaviour.
- Abolition of purging.

These goals must be aimed for alongside psychological work to reduce eating disorder psychopathology and symptoms. Strategies to achieve these aims may include:

- Careful calculation of energy intake to achieve weight gain at the agreed rate.
- Multivitamin and mineral supplementation.
- Negotiated meal plans to support regular eating, increasing amount and variety of food, and normalising meal pattern.
- A portion exchange system to develop flexibility.
- Planning eating to prevent anxiety associated with eating, especially when making decisions under pressure.
- Education on healthy, normal eating and body weight.
- Information about specific nutritional deficiencies such as low iron status.
- Education on natural appetite control and support to improve it.
- Practising eating, shopping and cooking with support as appropriate for the person's age, circumstances and

lifestyle, to improve confidence, independence and flexibility.

Phase 3: maintenance of improvement and relapse prevention

There is a risk of relapse of anorexia. People recovering need help to identify possible situations that may increase risk of relapse, and to develop strategies to prevent relapse, and to identify it quickly and reverse it. Some risk situations may involve particular kinds of eating, and the dietitian can help to anticipate and plan for these. Difficulties can arise in some social situations such as celebrations or unexpected eating; periods of religious fasting; and situations where the choice of food may be very limited, such as travelling or staying with friends. Planning for these situations can help to reduce risk. Skills in meal planning and good knowledge of healthy, normal eating can be helpful, in particular learning and practising appropriate use of foods that may be perceived as unhealthy; usually high fat and high sugar foods.

Bulimia nervosa

The main element of treatment for bulimia nervosa is cognitive behavioural therapy (CBT) (NICE, 2004). Dietetic intervention may be helpful alongside this for patients who are finding stabilising eating particularly difficult, or who have poor knowledge or confidence to feed themselves in a healthy way, or who have particular nutritional problems such as iron deficiency anaemia. As part of the CBT, patients will be encouraged to self monitor eating and purging by keeping a diary; this will also usually be used to record all food and fluid intake (Table 7.10.4). The CBT approach asks for recording of the situation, thoughts and feelings before the eating episode (antecedents); the date and time of eating and drinking, and details of type and amount of foods and fluids consumed or avoided (behaviour), and a subjective rating of whether this was a meal, snack or binge; and the thoughts, feelings and events after it (consequences). Learning this ABC approach can be helpful in showing the way dietary restriction leads to hunger and food craving, the powerful impulse to eat and the events or feelings that may then trigger binge eating.

The aims of treatment include:

- Abolition of binge eating and purging.
- Reduction of restriction of amount and variety of food.
- Establishment of regular, stable eating that is healthy and socially normal for the individual.
- Improvement in appetite regulation.
- Stabilisation of body weight in the healthy range.

Table 7.10.4 Example of headings for a self-monitoring diary

Date	Time	Food and drink	Antecedents	Behaviour (meal, snack or binge)	Consequences

- Increased confidence and reduced anxiety about eating.

There may also be a need to manage other influences on appetite, such as the use of alcohol or cannabis.

Strategies to reduce hunger and the drive to binge include:

- Improve understanding of the ways that restriction of food intake drives uncontrolled eating, in particular physiological hunger, which may not be recognised, and the hyper reward of eating when food deprived.
- Ensure adequate calorie intake to maintain weight, or increase it at an agreed rate if underweight. It may be reassuring to explain how this is calculated.
- Education to improve understanding of the factors that affect body weight, in particular the effects of shifts of glycogen and fluid.
- Regular, frequent meals and snacks, normally beginning with at least six eating episodes/day. This helps to prevent excessive hunger, which may increase the drive to binge, and also avoids feelings of fullness, which may provoke an impulse to vomit.
- Using the foods least likely to provoke bingeing or purging. This usually means not using high fat or high sugar foods at first.
- Using foods most likely to reduce hunger. Low energy density, high fibre and low glycaemic index foods may be helpful.
- Identifying times when the risk of binge eating is high, and replacing the binge with regular small snacks.
- Managing shopping and storage of food to have the planned food available, and avoid having binge food easily accessible.
- Planning meals to ensure they are available on time, and to prevent anxiety associated with making decisions quickly.
- Encouraging the use of alternative activities to deal with emotional distress. Activities that are distracting, calming and enjoyable, such as creative activities, social contact and relaxation exercises, may be especially effective.

Strategies to reduce purging and minimise harm include:

- Improved understanding of body weight regulation and the factors that influence it.
- Initially, keeping meals and snacks small, to prevent a feeling of fullness that may provoke vomiting or laxative use.
- Initially, encouraging the use of alternatives to specific foods that the individual finds difficult to tolerate, often high fat, high sugar foods. Excessively strict rules are not helpful.
- Plan activities to follow each meal and snack, as a distraction and to help reduce anxiety.
- Eating with other people may be helpful.
- Planned, appropriate exercise may help improve tolerance of regular eating.
- Stabilise fluid balance with regular fluid intake, and management of dehydrating factors such as vomiting, laxative use, alcohol and excessive caffeine intake.

- Advice on protecting teeth if vomiting does occur. Rinsing with water helps to remove acid from the mouth.
- If blood potassium is low because of vomiting or laxative use, advice on food sources of potassium, while implementing strategies to reduce purging.

As treatment progresses, the variety of foods can be increased. Difficult foods can be reintroduced in a safe context to reduce associated anxiety. Foods such as chocolate or crisps can be taken after a meal to prevent between meal hunger adding to the risk of uncontrolled eating. It may help to choose a single serving package, to control the amount, and to try it in a public place, where binge eating will be difficult. Individuals may be able to plan the safest situation for themselves. Success in using challenging foods in an appropriate way can help to develop confidence to tackle further goals.

Binge eating disorder

There are many similarities between binge eating disorder and bulimia nervosa. As with bulimia nervosa, CBT is commonly used to help people to overcome binge eating, along with diary keeping to help link thoughts, feelings and events to binge eating, and to develop strategies to deal with them.

People with binge eating disorder are generally obese and anxious to reduce their weight. Abolition of binge eating alone generally has little impact on weight. Excessive restriction of food will maintain hunger, so it may be difficult to achieve weight loss while binge eating is active and therefore some individuals may find it easier to reduce binge eating before beginning weight reduction. It may be possible to support patients to begin weight reduction while they are reducing their binge eating behaviour by restoring regular, stable eating while maintaining a modest deficit in energy intake of about 1.7–2 MJ (400–500 kcal)/day, and ideally gradually increasing physical activity as appropriate for the individual.

As eating is stabilised, binge eating reduced and confidence increased, a larger energy deficit may be tolerated, and obesity management strategies, including medication, can be applied by following NICE (2006b) guidance. As obesity is often extreme, bariatric surgery may be appropriate. It is not clear whether binge eating worsens outcome of bariatric surgery (Niego *et al.*, 2007; Bocchieri-Ricciardi *et al.*, 2006). In practice, the waiting time for bariatric surgery may be lengthy, and the time may be well spent in reducing eating pathology and body weight, and supporting the individual to improve the knowledge and confidence to manage their eating post surgery.

7.10.2 Dementias

Phil Addicott and Annette Dunne

Key points

- The prevalence of dementia increases with age. As the population ages, it is estimated that by 2021 over 1 million people in the UK will suffer from dementia.
- Dementia is a progressive degenerative condition with a multifactorial aetiology; there is no effective cure. It is characterised by a decline in memory and the ability to think, communicate and understand, and changes in mood and behaviour.
- Early nutritional assessment and regular monitoring to encourage adequate food and fluid is important. The food should be nutrient and energy dense, according to individual preferences.
- Independence should be encouraged for as long as possible.
- Carers should be valued and supported and involved in decisions that influence the patient.

Dementia is the collective term for conditions resulting from destructive pathological change in brain tissue that cause progressive loss of intellectual function. They are defined by their cognitive and neuropsychological characteristics. Memory decline is the core feature of most disorders, many of which also have impairment of visual spatial skills, language and executive functions. Dementia is characterised by:

- Progressive decline in the ability to remember, learn, understand, communicate and reason.
- Gradual loss of skills including those needed for everyday activities.
- Changes in personality or behaviour.

The behavioural and psychological symptoms in dementia can be summarised as psychosis, depression, anxiety, wandering, restlessness, agitation and aggression. In time, people may lose the ability to care for themselves and become totally dependent on the help of others. In some cases, the decline may be rapid; in others it may occur over a long period of time. Dementia is not in itself fatal and many sufferers can remain in good physical health for years. Eventually, the effects of the disease lead to increasing weakness, and death normally results from infections such as pneumonia or gradual organ failure.

In 2007 the Alzheimer's Society estimated that there are approximately 750 000 people with dementia in the UK, but that this figure is expected to rise to nearly 1 million by 2021. It is anticipated that the prevalence of dementia will increase as the population ages. Dementia usually occurs after the age of 40 years and the incidence increases sharply with age, doubling every 5 years above the age of 40 years. Above the age of 65 years, 4–5 people per 100 are affected. The risk is 1 in 5 over 80 years. The number of people in the UK with younger onset dementia is currently estimated at over 16 000.

A considerable amount of research is being carried out into possible links between diet and dementia. It has been suggested that the risk of Alzheimer's disease increases as levels of homocysteine rise and that this may be related to low plasma levels of folate, vitamins B₁₂ and B₆ (Luchsinger *et al.*, 2008). Screening for folate and vitamin B₁₂ and B₆ deficiency should be considered as part of nutritional assessment in elderly patients. The evidence for the benefits of supplementation of these micronutrients on cognitive function that is already impaired is controversial. A meta analysis (Wald *et al.*, 2010) found no effect on cognitive function, but recommended further research on the effects of long term supplementation of folate and B vitamins on incidence of dementia.

Research into the role of cholesterol in dementia is ongoing and there have been numerous papers examining the potential benefit of statin medication. Haag *et al.* (2009) examined data from the Rotterdam study and found that statin usage was associated with a reduced risk of developing Alzheimer's disease. However, other studies have not found any beneficial effect on cognitive function (Feldman *et al.*, 2010) and statins have not been found

to be effective at preventing Alzheimer's (McGuinness & Passmore, 2010). Despite speculation, there is no reliable evidence that ginkgo, ginseng or coffee have a protective effect, nor that environmental aluminium or eating meat are risk factors for dementia.

Types of dementia

Alzheimer's disease

This was first identified by Alois Alzheimer in 1907 and is the most common form of dementia, accounting for 50–60% of cases (Alzheimer's Society, 2007). Dementia results from the loss of neurones from the cortical areas of the brain, resulting in reduced production of acetylcholine and other neurotransmitters. Therefore, there is impaired transmission of messages connected with thought and memory. The brain atrophies and decreases in weight, and microscopic examination reveals large numbers of neurofibrillary tangles (nerve cells become bunched together) and neuritic plaques (deposits of amyloid protein and other cellular debris).

The cause of Alzheimer's disease is unknown, but there appear to be genetic links, specifically with genetic polymorphisms. The best established is the $\epsilon 4$ allele apolipoprotein E (*APOE4*) gene on chromosome 19. Normally present in approximately 12% of the population, it is found in 40% of people with Alzheimer's disease (Bayer & Reban, 2004). There is a greater incidence of Alzheimer's disease in women, which may be associated with a variant on the *PCDH11X* gene on the X chromosome (Carrasquillo *et al.*, 2008) (see Chapter 5.1).

Vascular dementia

This term applies to a number of different types of dementia caused by stroke, small vessel disease or dementia associated with diseases of the blood vessels supplying the brain with oxygen. A major consideration is whether the disease is primarily one of the large arteries, e.g. causing multiple infarcts, or one of the smaller perforating arteries, causing small vessel disease. Vascular dementia affects people in different ways and causes communication problems, stroke like symptoms and acute confusion (Brown & Hillam, 2004).

Multiinfarct dementia

Multiinfarct dementia (MID) is the most common type of vascular dementia and is secondary to two or more strokes. It arises from several small lesions or infarcts in the brain that lead to increased areas of brain damage causing symptoms of confusion, which gradually progress to dementia. Unlike Alzheimer's disease, mental decline in MID is likely to start more abruptly and symptoms tend to worsen in a stepwise manner following each attack. Brain damage also tends to occur in localised areas rather than being widespread as in Alzheimer's. Therefore, some mental abilities, or the patient's personality, may remain relatively unaffected, although short term memory loss is nearly always pronounced. Sufferers are more likely to be

aware of their condition and often anxious and/or depressed as a result (Bayer & Reban, 2004).

Small vessel disease

This is also known as subcortical vascular dementia or, in a severe form, Binswanger's disease, which is often associated with uncontrolled hypertension. Small vessel disease dementia is caused by damage to small blood vessels deep in the brain. The symptoms develop more gradually and are often accompanied by walking problems (Bayer & Reban, 2004).

Frontotemporal dementia

Frontotemporal dementia is characterised by degenerative atrophy and spongiform change of the frontal lobes and/or the temporal cortex situated laterally on each side of the brain. Presentation is typically before 65 years with about an 8-year survival span. Pick's disease is a type of frontotemporal dementia with widespread scarring, but without spongiform changes. Clinical presentation generally involves early behavioural problems, e.g. disinhibition, lack of hygiene, inappropriate sexual behaviour and repetitive performance of an action. Eating habits may also change; cramming sweet foods is not unusual. In addition, personality changes such as insensitive rudeness or the lack of emotional warmth can be very distressing for partners and carers. However memory is often preserved (Brown & Hillam, 2004).

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is a very rare dementia that results in the production of an abnormal prion protein in the brain causing progressive dementia and fatal brain disease. It usually has a long latency period, but once symptoms appear the condition tends to progress rapidly, often causing death within a matter of months (Cousens *et al.*, 1997).

Dementia with Lewy bodies

Often associated with Parkinson's disease, dementia with Lewy bodies is characterised by the presence of small spherical protein containing structures (Lewy bodies) in brain tissue. In Parkinson's, Lewy bodies are characteristically found localised in the brain stem; however, in dementia with Lewy bodies, the Lewy bodies are more widely distributed in the cells of the cortex and subcortex. Clinical features include fluctuating cognitive function, visual hallucinations and the spontaneous motor features of parkinsonism (Brown & Hillam, 2004) (see Chapter 7.6.1).

Other causes of dementia

These include:

- *Huntington's disease* – a genetically determined progressive neurodegenerative disorder resulting in movement disturbances, depression and dementia.
- *Down's syndrome* – dementia is more common in middle aged people with Down's syndrome than in the rest of the population (Janicki & Dalton, 2000).
- *Wernicke–Korsakoff syndrome* – caused by thiamine deficiency, usually as a result of alcohol abuse, and can lead to dementia type symptoms.
- *Pugilistic brain injury* – repeated blows to the head, e.g. from boxing, can cause brain damage, resulting in symptoms of dementia. The symptoms may not become apparent until 30 or 40 years after the end of the boxer's career. The number of fights and length of career seem to be more important than the number of knock outs (Bayer & Reban, 2004).

Diagnosis and medical management

Diagnosis of dementia should only be made after a comprehensive assessment, which should include a clinical cognitive assessment that is then repeated at intervals to assess levels of decline, e.g. Mini Mental State Examination (MMSE). A basic dementia screen should include biochemistry, thyroid function, vitamin B₁₂ and folate levels (NICE, 2006). Some subtypes of dementia have broadly agreed criteria for diagnosis based on clinical symptoms, e.g. dementia with Lewy bodies. Structural imaging, e.g. magnetic resonance imaging, should be used to exclude other possible cerebral pathologies and to help establish the subtype diagnosis (NICE, 2006).

Early diagnosis of dementia is important because in some cases it may be possible to prevent it worsening. It is particularly important that people with evidence of vascular dementia receive indicated treatment, e.g. anti-hypertensive medication, which may reduce the risk of further infarctive damage. Diet and lifestyle measures, e.g. not smoking, eating a healthy balanced diet, losing weight, exercising and reducing salt and alcohol intake are also important.

Medication

At present there is no cure for dementia. Drug treatments have been developed for Alzheimer's disease that can improve symptoms, or temporarily slow down their progression, in some people. There are two types of drugs used to treat Alzheimer's disease, cholinesterase inhibitors and glutamate blockers. Cholinesterase inhibitors increase acetylcholine concentrations, which increase communication between the nerve cells that use acetylcholine as a chemical messenger. This may in turn temporarily improve, or stabilise, the symptoms of Alzheimer's disease, particularly in the earlier stages. Cholinesterase inhibitors licensed in the UK are donepezil hydrochloride (Aricept), rivastigmine (Exelon) and galantamine (Reminyl). Glutamate is released in excessive amounts when brain cells are damaged by Alzheimer's disease, which causes brain cells to be damaged further. Memantine (Ebixa) can protect brain cells by blocking the release of excess glutamate.

The National Institute for Health and Care Excellence (NICE) amended its guidance in 2011 to recommend

donepezil, galantamine and rivastigmine as options for managing mild as well as moderate Alzheimer's disease. Memantine is now recommended as an option for managing moderate Alzheimer's disease for people who cannot take cholinesterase inhibitors and as an option for managing severe Alzheimer's disease. These drugs are well tolerated; however, the most frequent side effects include nausea and vomiting, diarrhoea, stomach cramps, headaches, fatigue and loss of appetite; such side effects are likely to have a negative effect on nutritional status.

Nutritional implications

The effects of dementia on food and fluid intake, and therefore nutritional status, are considerable. The behavioural, emotional and physical changes that take place as dementia progresses can all impact on eating habits and food and drink intake (Alzheimer's Society, 2007).

Dietary behaviour

This is dependent on the type of dementia and the individual; each person will experience dementia in a different way. However, a typical pattern is that in the initial stages the individual may experience difficulty in shopping, cooking and storing food; forgetting to eat or forgetting they have eaten, eating spoiled foods and changes in food choices may be noted. As the dementia advances, sufferers may find it more difficult to open their mouth and chew and may pool food in the mouth but not swallow. The ability to eat independently may be lost, non-foods may be eaten, patients may refuse food and become aphasic and therefore unable to express pain, e.g. dental pain, or to ask for food or fluids. They may encounter chewing and swallowing difficulties or become depressed.

As a result of these problems weight loss is common in patients with progressing dementia, which is nearly always a consequence of an inadequate energy intake rather than the disease itself (Prentice *et al.*, 1989). A more recent systematic review (Hanson *et al.*, 2011) found that high energy supplements and other oral feeding options, such as assisted feeding and modified foods, can help people with dementia to gain weight.

Increased energy requirements

In some cases the energy deficit may be exacerbated by increased energy requirements due to excessive walking or pacing up and down. A classic study by Rheume *et al.* (1987) showed that patients who wander required an additional energy intake to maintain their nutritional status. Pharmacological interventions for excessive pacing can result in a poor nutritional intake due to over sedation. Exercise and music therapy have been shown to be the most acceptable non-pharmacological interventions to reduce wandering in dementia (Robinson *et al.*, 2006).

Dehydration

Inadequate oral fluid intake and subsequent dehydration is a common problem and is implicated in many of the most common ailments of people with dementia, such as constipation, urinary tract infection, electrolyte imbalance and increased dizziness and confusion, leading to falls, all of which can have a negative effect on nutritional intake. The Royal College of Nursing (2007) Hydration Best Practice Toolkit provides practical advice for health-care staff in England and Wales on how to minimise the risk and potential harm that dehydration can cause.

Dysphagia

Dysphagia is a common problem in dementia and can be indicated by repeated chest infections, coughing at meal times or a prolonged oral stage (continuous chewing). Providing good nutrition for patients with dementia and dysphagia can be extremely challenging and requires a multidisciplinary approach. Patients require prompt assessment by a speech and language therapist who can advise on appropriate texture modifications of food and consistency of fluids with the aim of reducing risk of aspiration pneumonia (Kindell, 2002). Dysphagia can occur at the early stages of dementia (see Chapter 7.3).

Nutritional assessment

Patients with dementia are vulnerable to developing malnutrition and it is essential that an environment appropriate and validated nutritional screening tool be routinely used. Patients should be weighed at regular intervals. Calculation of nutritional requirements should include factors for stress or weight gain, and mobility and diet induced thermogenesis. (see Chapter 6.1 and 6.2). Food and fluid charts need to be accurately completed for patients identified as being high risk of malnutrition. However, if food and fluid charts are not available, assessment of food intake usually depends on a combination of obtaining information from relatives or care staff and observing actual practice at meal times. Note should be taken of any carers' reports of weight loss; loose fitting clothing may be an indicator of a problem with nutrient intake (Bayer & Reban, 2004).

Features that increase the likelihood of inadequate nutritional intake are:

- Sensory impairment, e.g. smell or taste.
- Poor or missing dentition.
- Constipation or loose stools.
- Food refusal due to depression, paranoia or confusion.
- Poor mental state and challenging behaviour.
- Physical difficulties in chewing or swallowing provided food.
- Inappropriate meal time environment and inability to eat independently.
- Medications resulting in side effects of dry mouth and altered taste or, in particular, heavy sedation, e.g. antidepressants and antipsychotics.

It is also important to check the nutritional adequacy of the food being offered. Texture modified food, e.g. fork mashable or puréed food, may need fortification in order to provide sufficient nutrition (see Chapter 6.3). The frequency with which food is offered and the time available for assisting people are important. In institutions there may be short intervals between meals and long gaps when nothing is offered, as well as limited time to encourage and assist patients to eat and drink.

Dietary management

A number of strategies can be employed to optimise nutritional intake. These will vary according to the individual circumstances and stage of the disease, and perhaps additional clinical problems, e.g. over sedation, diabetes or depression.

People who live alone in their own homes should be encouraged to:

- Engage with health and social care services and be reassured in regard to the benefits of accepting help, such as a package of care.
- Keep a store of foods that do not require cooking and can be opened easily, i.e. not canned or heavily packaged food. Suitable foods include bread, breakfast cereals, milk, cheese, sliced ham and bananas.
- Keep a good supply of cold drinks if preparation of hot drinks is a problem.
- Make use of meal delivery services and/or meals provided in day care or luncheon clubs.
- Be involved in food preparation for as long as possible and be aware of food fortification ideas.
- Sit with relatives or carers to promote the social side of eating and so that the relative or carer can act as an example or model for the confused or forgetful person.
- People with dementia, their relatives and carers, and the professionals who support them need access to reliable resources, e.g. Nutrition in the Community Settings (Welsh Assembly Government, 2011).

Guidance for care staff in institutions should emphasise the following:

- Importance of nutritional screening and the role of good nutrition in preventing weight loss, malnutrition and the prevention of pressure sores.
- Develop a high protein and energy menu that includes rich sources of fibre, calcium, folate and vitamins D, B₁₂ and B₆.
- Importance of being able to provide, when required, appealing and nutritionally good, texture modified meals, and be able to accurately thicken fluids to the recommended consistency.
- Develop a finger food menu for patients who are too distracted to sit through a meal.
- Need for specialist feeding aids, e.g. adaptive cutlery, deep lipped plates, non-slip place mats, wide neck and large handled mugs, and clothing protection where necessary.

- Benefit of investing in training, e.g. how to safely assist patients to eat or importance of hydration.
- Importance of adequate fluid consumption.
- Need to recognise individual variation in terms of nutrient needs and personal likes and dislikes.
- Benefits of nutritional supplements for those with inadequate nutritional intake and weight loss.
- The importance of a robust protected meal time policy and a calm and appropriate meal time environment.

Advice to carers should focus on the need to:

- Offer small nutritious meals and drinks at regular intervals. Not only does this help meet nutritional and fluid needs, but the routine of a regular meal pattern also provides comfort and reassurance to many people with dementia.
- Provide a variety of foods that the person likes and allow more time for the meal than is usual.
- Avoid assisting people to eat when they are not fully alert or if they are lying down or anxious.
- Help maintain the person's independence by providing foods they can manage themselves. Deep lipped plates, non-slip place mats, adapted utensils or finger foods may be helpful.
- Distracted or wandersome patients may do better with finger foods, e.g. chips, sandwiches, biscuits, etc. (avoid giving to patients with swallowing difficulties).
- Make the most of good times of the day (usually breakfast and lunchtime) to provide foods that are good sources of nutrients and energy.
- Provide regular fluids in a wide necked mug or cup; avoid filling to the brim to avoid spillages. Avoid giving drinks via straws or in spouted beakers as they are not dignified and may increase risk of aspiration as they direct fluids to the back of the mouth and decrease oral control. Fluids can also be given as soup, sauces or jelly (Kindell, 2002).

Meal time environment

Meal times should be given priority in the daily routine of people with dementia. The eating environment needs to be calm and relaxed. People with dementia should be advised that the meal time is about to start after being offered the opportunity to use the toilet and reminded or assisted with hand washing. In some cases people with dementia can help lay the table, which can be a good source of social contact and stimulation (Kindell, 2002). People with dementia may struggle to concentrate at meal times if there are other distractions; therefore, televisions should be switched off, as should loud music, but calm quiet music can help reduce agitation (Cohan-Mansfield *et al.*, 2009).

The Social Care Institute for Excellence (SCIE, 2011) recommends that people with dementia be allowed to sit and eat in a place where they feel comfortable. Carers should describe the food they are offering and ensure that the food is presented colourfully and attractively. The area in which a person with dementia eats should be bright and well lit so they can see the food easily. Images of food

can also be used for reminiscence activities; this can help stimulate discussion and interest in food and meal times by helping the person to reconnect with familiar foods from their past.

Eating assistance strategies

Relatives or carers may be able to provide advice on the level of support typically required. The following strategies may be helpful in overcoming poor dietary intake related to dementia:

- Involve the person with dementia with meal preparation for as long as possible, e.g. putting out napkins or cutlery; talking about food preferences can be a useful prompt.
- Overemphasising tidy eating habits should be avoided. Serving one familiar food at a time may help overcome confusion. Cutting food into smaller pieces (before the plate is taken to the patient) may be helpful (Bayer & Reban, 2004).
- If a person with dementia become distracted during the meal or passively sits in front of their meal without eating, gentle verbal prompts can be useful.
- Hand over hand assistance can be useful for people who are having difficulty coordinating cutlery, i.e. gently place the utensil in the person's hand and use your hand to guide them to start eating. Often once started, they will be able to carry on independently.
- Take into account individual food preferences but consider that due to taste changes people may prefer sweeter foods or foods with stronger flavours.
- Food should be presented attractively and be colourful; avoid serving white foods on a white plate. Take care that foods and drinks are not too hot.
- If self feeding is more erratic, specialist feeding aids, e.g. weighted cutlery, deep lipped plates and non-slip place mats, may help; eventually the person may need to be fed for at least part of their meal.
- Some people with dementia become sensitive to foods of mixed textures, e.g. minestrone or cornflakes in milk, and may spit them out; if so, a softer single texture food may be appropriate (Kindell, 2002).
- If a person walks away from an unfinished meal, be wary of assuming that the person has finished or dislikes the food. They may need some verbal prompts to come back to the table, or gesturing to the empty chair can show the person what is meant. If the person refuses to settle, they may benefit from finger foods (Kindell, 2002).
- Dementia sufferers with dysphagia should be positioned upright to reduce risk of aspiration; texture modified foods may need to be fortified in order to provide adequate nutrition and nutritional intake should be maximised when the desire to eat is higher.
- If fortifying foods and beverages proves insufficient, nutritional supplements will need to be prescribed. If a patient requires thickened fluids, consider using a prethickened supplement drink.

In the final stages of the illness, a multidisciplinary best interest meeting may be needed in order to make decisions concerning the use of enteral feeding or intravenous hydration for people who lack capacity to make this particular decision themselves. If known, the views of the patient must be considered as well as the opinions of relatives or carers. For more information, refer to the Mental Capacity Act (2005) (see Chapter 3.7). Each individual case should be reviewed on its individual merits.

Needs of carers

It is estimated that 600 000 people in the UK act as the primary carers for people with dementia (Alzheimer's Society, 2007). Caring can be an overwhelming experience and the costs of caring are significant. Many carers face financial hardship as they are often forced to give up work and pay high care bills from limited income or private savings. However, the needs of those who care for dementia sufferers in the domestic setting have been increasingly recognised. Under UK legislation, the Carers and Disabled Children Act (2000), carers aged 16 years or over who provide a regular and substantial amount of care for someone aged 18 years or over have the right to an assessment of their needs as a carer. In addition, the Carers (Equal Opportunities) Act (2005) places a duty on local authorities to ensure that all carers know that they are entitled to an assessment of their needs, which must consider their outside interests (work, study or leisure). Under the Employment Act (2007) carers have a statutory right to ask employers for flexible working conditions if they are caring for an adult who is a relative or lives at the same address.

Those carrying out the assessment should seek to identify any psychological distress and psychosocial impact on the carer. Care plans for carers should include tailored interventions and practical support, including access to respite and short break services that meets the needs of both the carer and the person with dementia (NICE, 2006).

Health professionals should work closely with the relatives/carers of someone with dementia because the latter:

- Know the persons best and are more likely to be able to identify or interpret any needs and problems.
- May be aware of relevant medical history, e.g. diabetes, gastrointestinal problems or dysphagia.
- Will be aware of the person's dietary preferences and recent body weight history.
- Have to implement any guidance given by health professionals.

When talking to relatives or carers, it is important to consider that caring for someone with dementia is extremely demanding, both physically and emotionally. Carers may feel:

- Unappreciated as that they are giving a lot for little return.

- Resentful that their lives are dominated by this situation.
- Guilty that they feel like this.
- Impatient and angry, which is often a sign of stress.
- Depressed and bereft at the loss of the person they once knew and whose company they will be unable to enjoy again.
- Isolated, particularly if they are trying to cope alone.
- Frightened of the difficulties ahead.

Carers need to be provided with information about what dementia is and the best way of caring for a person with dementia. This can increase their confidence, decrease levels of stress and improve the care they provide for the person with dementia (Alzheimer's Society, 2007). Information such as the comprehensive booklet entitled *Who Cares* (Department of Health, 2007) provides information and support for carers of people with dementia.

Drug–nutrient interactions

Donepezil, galantamine, rivastigmine and memantine are well tolerated; however, the most frequent side effects include nausea and vomiting, diarrhoea, stomach cramps and headaches, fatigue and loss of appetite.

Antipsychotic drugs may also be taken and may also impact on nutritional status (see Chapter 7.10.3).

7.10.3 Nutrition and mental health

Ursula Philpot

Key points

- Emerging evidence suggests that nutrition may have a role in mental health.
- The number of dietitians working in mental health is limited, but it is a growing area within the profession.
- Dietitians may be managed by non-dietetic personnel; therefore, they must be prepared to articulate their key skills and be clear about their professional boundaries, duties, roles and responsibilities.
- People with a severe mental illness are at greater risk of developing cancer, coronary heart disease, diabetes and obesity related illnesses than the general population.
- Some medications used to treat mental illness have side effects, including weight gain, hyperglycaemia and gastrointestinal problems.

Mental health is defined by the World Health Organization (WHO) as *'a state of wellbeing in which an individual realizes his or her own abilities, can cope with normal stresses of life, can work productively and is able to make a contribution to his or her community'*. Approximately one in four people in Britain has the diagnosis of a mental disorder or mental illness (McManus *et al.*, 2009). This is defined as a psychological or behavioural pattern associated with distress or a disability that is not a part of normal development or culture. Mental health disorders are experienced as problems with emotions (affect), behaviours, thoughts (cognitions) or perceptions. The disorders can significantly affect all areas of someone's life, from problems with day to day functioning through to those with relationships, work and quality of life. The most common mental health disorders in the UK are depression, eating disorders and anxiety disorders. The recognition and understanding of mental health conditions have changed over time, although there are still variations in the definition, assessment and classification of mental disorders. The ICD 10 Classification of Mental and Behavioural Disorders (World Health Organisation, 1992), and the DSM IV Classification of Mental Disorders (American Psychiatric Association, 1994) are widely accepted guidelines on diagnosis.

There are growing numbers of dietitians working in mental health settings in the UK, but the numbers per population varies greatly across regions. Common areas of employment include eating disorders, intensive care units, secure units, autism, older adults and dementia care, learning disabilities, forensic services and healthy living teams.

Causes of mental distress

There are many opinions about what causes mental distress. One belief is that personality is shaped by both life experiences and genetics. This means that some people may become more vulnerable to mental health problems than others through a combination of upbringing and life

events, combined with genetic factors. The following are a range of possible causes of mental distress.

Difficult family background

Growing up in an environment where feelings are not validated or spoken about, feeling uncared for or scared by a parent, or having been or being abused in some way can affect the development of children and leave them insecure and vulnerable to mental distress. However, being too overprotected as a child is also a risk factor.

Hidden feelings

If children are punished for getting angry, crying or laughing too loudly, they learn that they should not feel strong emotions. This leaves them feeling bad and out of control when emotions are experienced; thus leading to behaviours that try to suppress emotions, such as eating disorders, or drug or alcohol misuse.

Stressful life events

These may be traumatic events, such as the death of someone close, or longer term struggles, such as being the victim of some form of harassment or oppression.

Biochemistry

Biochemistry can affect mood, e.g. a stressful or frightening situation will trigger the body's fight or flight response and drive the body to produce adrenaline (epinephrine). If physical activity does not use all the adrenaline produced, the body remains tense and the mind stays over active.

Genetics

There is a genetic component to the risk factors for the development of disorders such as bipolar disorder, schizophrenia or eating disorders. This may be either direct or

through personality traits, such as perfectionism, which may have a genetic basis.

Common mental health disorders seen by dietitians

The most common mental health disorders that require dietetic input are:

- Schizophrenia.
- Depression.
- Alzheimer's disease.
- Obsessive compulsive disorder (OCD).
- Anxiety or panic and phobias.
- Drug and alcohol problems.
- Personality disorders.
- Eating disorders (see Chapter 7.10.1).
- Post traumatic stress disorder (PTSD).
- Learning disabilities (see Chapter 3.7).
- Bipolar disorder.

Schizophrenia

Schizophrenia is a mental illness that can severely interfere with abilities to perform everyday tasks and activities, caused by confusion and withdrawal. Symptoms can include hearing voices and seeing things that other people cannot.

Depression

Depression is the most common psychiatric illness and is increasing in prevalence worldwide (McManus *et al.*, 2009). Depression is characterised by dysphoric mood (feeling sad, hopeless, miserable or low) and sometimes mania caused by euphoric mood (elated, happy, excited, irritable or high). Depression is thought to result from an imbalance of the neurotransmitters that carry messages between brain cells. This can be disturbed by many factors, such as the effects of stress, trauma, relationship breakdown or hormonal changes, or as a side effect of some types of medication such as tranquillisers, steroids, antihypertensive and antihyperthyroid drugs. Genetic influences on brain function may make some people more susceptible to depression (Tsuang *et al.*, 2004).

Personality disorders

The term personality disorder refers to a diagnostic category of psychiatric disorders characterised by a chronic, inflexible and maladaptive pattern of relating to the world. This maladaptive pattern is evident in the way a person thinks, feels and behaves, which may lead to personal problems that induce extreme anxiety, distress and depression. The most noticeable feature of these disorders is their negative effect on interpersonal relationships. People diagnosed with personality disorder may also be very inflexible, i.e. they may have a narrow range of attitudes, behaviours and coping mechanisms that they cannot change easily or at all. They may not understand why they need to change, as they do not feel they have a

problem. Their behaviours can result in maladaptive coping skills, such as self harm, substance misuse and eating disorders.

People with personality disorders may find it difficult to:

- Make or keep relationships.
- Get on with people at work.
- Get on with friends and family.
- Keep out of trouble.
- Control their feelings or behaviour.

Disordered eating

Eating disorders are considered in Chapter 7.10.1. However, dietitians working in mental health settings will see a large number of service users with eating disorders not otherwise specified (EDNOS) and/or a range of disordered eating symptoms such as food restriction, binge eating, vomiting and laxative misuse. This may be part of a dual diagnosis with other disorders such as depression, OCD and personality disorders. In line with NICE (2006) guidance, EDNOS should be treated along the same lines as the eating disorder it most resembles. With all disordered eating, a psychologically based multidisciplinary team (MDT) approach is best practice. It is important to have an understanding of the psychological function of the eating behaviour in order to treat it successfully.

Treatment services in mental health

Mental health services are based in hospitals and the community. Psychotherapy (talking therapies) and psychiatric medication are two of the major treatment options, as are social interventions, peer support and self help. Patients are usually referred to as service users. The majority of service users enter treatment voluntarily, but for some it may be involuntary. Service users may be detained under the Mental Health Act according to specific sections; this is colloquially known as being sectioned. Some specialist services cannot be offered in a local mental health service. These are often provided on a regional basis, are known as out of area placements and are tertiary services. Examples include eating disorder, high secure, personality disorder, forensic and alcohol detoxification units. Treatment services are provided by various mental health professionals.

Psychiatrists

Psychiatrists are medically trained doctors specialising in mental health. They are responsible for arranging admission and discharge of service users for diagnosis and prescription of medication.

Clinical psychologists

Clinical psychologists assess and treat service users with a variety of psychological therapies. Dietitians and psychologists often work together, especially in the treatment of eating disorders. Psychologists can offer advice

on the different approaches to use to support dietary change.

Occupational therapists

Occupational therapists are often very experienced in working with groups and are involved in teaching life skills and activities, including shopping, cooking and budgeting. There is often close collaboration with dietitians and occupational therapists, e.g. when working on healthy lifestyle groups.

Pharmacists

The specialist pharmacist in psychiatry is a valuable resource for information on drugs used in psychiatric medicine, particularly in relation to side effects such as weight gain.

Psychiatric nurses

Psychiatric nurses offer support to people and the families of people who have mental health problems. They assess and develop care plans, give medication and some psychotherapy, either formally [via training in techniques such as cognitive behaviour therapy (CBT)] or informally.

Social workers

Social workers offer support for rehabilitation with regard to housing, benefits, and family work. They also assess the mental state of service users in order to determine whether sectioning under the Mental Health Act is appropriate.

Physiotherapists

Physiotherapists support service users to effect physical, cognitive and behavioural change through the use of exercise, relaxation therapy, stress management, electrical modalities and manual skills.

Counsellors or psychotherapists

These offer a range of talking therapies. Counsellors or psychotherapists are trained practitioners who work with people over the short or long term to help them bring about effective change or enhance their wellbeing.

Allied health professionals

Allied health professionals are often the minority professions within mental health settings, although numbers are growing. They may have more generic roles within mental health settings, e.g. occupational therapists as well as nursing staff will often act as a key workers for a clients with various disorders. However, because dietitians do not undertake compulsory placements in mental health settings as part of preregistration training, they are

not currently insured to undertake care coordinator or key worker roles in the same way.

As the number of dietitians is limited, they must carefully consider their duty of care to ensure they identify not only those service users most at risk, but also those most likely to benefit from dietetic input, i.e. ensuring they do the most good (or least harm) to the highest number of people within a case load population. This often involves working with carers and ward staff to ensure the basics, such as screening tools, staff training and the hospital menus, are right, rather than seeing a high number of direct clinical cases. A professional who is not a dietitian commonly manages dietitians; therefore an individual dietitian may represent their profession alone within the service. Dietitians must therefore be prepared to articulate their key skills to the team and be clear about their professional boundaries, duties, roles and responsibilities within the team.

Community mental health teams

Most service users with a mental health problem do not need to see a psychiatrist. The general practitioner (GP) is responsible for first line support, including assessment, medication and referrals to a counsellor or psychotherapist. However, if problems are more complicated or serious, the GP will refer the service user to a community mental health team (CMHT). This is a community based team made up of a MDT. Usually, one member of the MDT, such as a social worker or nurse, becomes the key worker for the service user.

Key worker

The key worker's role is to assess the service user's specific difficulties, discuss any plans for treatment and offer counselling, information and advice. The key worker is responsible for keeping in touch with other health professionals who are involved with the service user to ensure coordinated care. All treatments are documented in the care plan, which should list the key problem, what needs to be done and who should be doing what. The service user is always involved in putting together the care plan and will usually be offered a copy of this. Dietitians should ensure that dietetic care plans follow this example, fully involving the service user in joint care planning, and where possible, offering the service user a copy of all correspondence.

Care programme approach

If service users are going to be under the care of the CMHT or specialist services team for a long period, they may be put on the care programme approach (CPA). The key worker acts as the primary link between the client and the healthcare team, organising regular meetings and updates. The CPA is normally implemented by a MDT and aims to:

- Assess health and social needs.
- Draw up a care plan in conjunction with the service user and carers, together with health, local authority and voluntary sector workers.

- Monitor the quality and effectiveness of care.
- Review progress at regular intervals.

Common psychological treatments

Psychological therapies, sometimes referred to as talking treatments, counselling or psychotherapy, are a core treatment for mental illness. Psychological therapy encompasses a broad range of treatments, including talking therapies of different models and different forms of delivery, e.g. individual, family and group). The most appropriate treatment may vary according to the person's age, situation, diagnosis and personal preference. Therapy can either be used on its own or combined with medication. There is considerable evidence in support of the effectiveness of psychological therapies across a range of problems and settings. The National Institute for Health and Care Excellence (www.nice.org.uk) recommends psychological therapies for mild and moderate depression and anxiety, OCD, bipolar disorder, PTSD, eating disorders and schizophrenia. Therapy can help towards reducing distress, symptoms and risk of harm to self or others.

Dietitians need a broad understanding of these treatments to ensure they can work within the psychological approach taken by the team. For example, if a CBT model is used, then aligning dietetic treatment and education to use some CBT based techniques will ensure a consistent and evidenced based approach for the service user and team. Dietitians working within specific treatment teams and modalities will need further training in these specific psychological therapies (see Chapter 1.3).

Cognitive behavioural therapy

This therapy focuses on the here and now to identify maladaptive thinking (cognitions – ideas, mental images, beliefs and attitudes). It recognises that events in the past have shaped the way that an individual currently thinks and behaves, with a particular focus on thought patterns and behaviours learned in childhood. However, CBT does not dwell on the past, but aims to find solutions to change current thoughts and behaviours. Cognitive behavioural therapy has a strong evidence base for phobias, anxiety, depression, OCD and bulimia nervosa, for which it is often delivered within eight to 16 sessions.

Psychodynamic therapy

Psychodynamic therapy (or psychoanalytic psychotherapy) is the general name for therapeutic approaches that try to get the service user to bring to the surface their true feelings, so that they can experience them and understand them. This is often a longer term therapy delivered over a number of years.

Brief or solution focused therapy

This differs from other modes of therapy in that it focuses on a specific problem and provides a direct intervention for this. It is solution based rather than problem oriented.

It is less concerned with how a problem arose and more focused on the current factors sustaining it and preventing change.

Systemic and family therapy

This seeks to address how people operate in a family system and not at an individual level, as is usually the focus of other forms of therapy. It looks at people in relationships, dealing with the interactions of groups, their patterns and dynamics. It includes family therapy and marriage counselling.

Didactical behavioural therapy

This therapy is a type of CBT. Its main goal is to teach the service user skills to cope with stress, regulate emotions and improve relationships with others. Didactical behaviour therapy (DBT) is designed for use by people who have urges to harm themselves, such as those who self injure, or who have suicidal thoughts and feelings, but has also been adapted for other conditions where the service user exhibits self destructive behaviours, such as eating disorders and substance abuse.

Interpersonal therapy

This therapy has an evidence base for effective treatment of many psychological conditions, including depression and eating disorders. It is based on the principle that there is a relationship between the way people communicate and interact with others and their mental health.

Standards and policy

There is a large number of policy documents, guidelines and best practice guidance that need to be considered by dietitians working within mental health settings. These change frequently and may vary locally. Some current examples include:

- NICE guidance
 - Prevention, identification, assessment and management of overweight and obesity in adults and children (NICE, 2006).
 - Type 2 diabetes (NICE, 2008).
 - Prevention of cardiovascular disease (NICE, 2010).
- Care Quality Commission (QCC):
 - Standard 5: Meeting Nutritional Needs.
- National Patient Safety Agency (NPSA):
 - Ten High Impact Nursing Standards.
- Council of Europe Resolution:
 - Food and Nutritional Care in Hospitals.
- Essence of Care:
 - Benchmarks for Food and Drink; Best Practice Indicators.
- Patient Environmental Action Team (PEAT) Assessment Criteria.

In Scotland the Mental Health (Care and Treatment) Scotland Act (2003) and Food in Hospitals and Food Fluid

Nutrition Standards governed by Health Improvement Scotland (HIS), formerly known as Quality Improvement Scotland (QIS), are key.

Nutrition in mental health

Evidence from epidemiological studies suggests that nutrition may have an emerging role in mental health. For example, some epidemiological evidence suggests that sugar intake can be positively correlated with the incidence of depression (Weissman *et al.*, 1996; Westover & Marangell, 2002). Unipolar and bipolar depression have been inversely correlated with seafood consumption (Hibbeln, 1998; Noaghiul & Hibbeln, 2003). Peet (2004) suggested that recent increased consumption of processed foods, sugar, *trans*, saturated and n-6 fatty acids, and reductions in fibre, folate and n-3 fatty acids may be partly responsible for increases in mood disorders. The topic of food and mood is an area of emerging interest and with a growing evidence base. However, dietitians need to assert caution when interpreting studies that involve food and mood, as criticisms of papers in this area include low numbers of subjects, poor methodology and assumptions about cause and effect. No single food can cure mental health conditions, but some evidence about particular nutrients and their possible role in mental health are discussed below.

Nutrition supplementation

There is emerging evidence that certain nutritional supplements may play a role in the treatment of mental health conditions, especially considering the high incidence of poor dietary intakes in individuals with these conditions. Dietitians should ensure that those on inadequate diets receive adequate vitamin, mineral and n-3 supplementation if this is not achieved through diet.

Tryptophan

A Cochrane review (Shaw *et al.*, 2002) examined two double blind randomised controlled trials involving a total of 64 service users. They found that tryptophan was better than a placebo at alleviating depression, but the evidence was inadequate to make recommendations other than to ensure adequate protein intake.

Omega 3 Fatty acids

A meta analysis by Ross *et al.* (2007) found that trials of service users with major depressive disorder and bipolar disorder provided evidence that n-3 fatty acids reduce symptoms of depression, with suggestions that eicosapentaenoic acid (EPA) may be better than docosahexaenoic acid (DHA) for treatment of mood disorders. In a more recent systematic review, Appleton *et al.* (2010) concluded that although trial evidence of the effects of n-3 fatty acids on depressed mood has increased, it remains difficult to summarise the evidence because of considerable differences between trials. However, the evidence available does provide some support of a benefit in individuals with diagnosed depressive illness. Therefore, sup-

plementation of n-3, fatty acids, particularly EPA, should be considered.

Folate

A review by Taylor (2004) of three studies involving 151 service users concluded that folate may play a role as an adjunctive treatment for depression, but whether this applies only to those with existing folate deficiencies or to all is unclear. Further research is needed.

Zinc

There is evidence from epidemiological studies that low levels of zinc are associated with depression, but good quality clinical trials that explore the link between zinc supplementation and depression are sparse. A recent systematic review by Lai *et al.* (2012) found only four trials that met their inclusion criteria and they were unable to pool the results of these studies due to their substantial heterogeneity, i.e. the trials were too different from one another to be grouped together in a meta analysis. They found that in the studies that investigated treating depression with zinc supplementation and antidepressants, zinc significantly lowered depressive symptom scores of depressed service users. The authors concluded that the '*evidence suggests potential benefits of zinc supplementation as a stand-alone intervention or as an adjunct to conventional antidepressant drug therapy for depression. However, there are methodological limitations in existing studies and so further well designed, adequately powered research is required*'.

Carbohydrate

In a review of the evidence on carbohydrate and mood, Benton & Nabb (2003) suggested that in many individuals poor mood stimulates the eating of palatable high carbohydrate, high fat foods that stimulate the release of endorphins, which help to self regulate mood. Individual differences in the ability to control or respond to blood glucose levels leave some people vulnerable to bingeing.

Excess caffeine

Self medication through the misuse of high caffeine drinks and coffee is common, and contributes significant extra energy. Caffeine can cause insomnia, nervousness and restlessness, stomach irritation, nausea, and increased heart and respiration rate. Larger doses might cause headache, anxiety, agitation, chest pain and ringing in the ears, which can exacerbate conditions such as anxiety.

Physical health implications of mental illness

The main nutritional problems as a result of medication, disease state and lifestyle choice are cardiovascular disease (CVD), dyslipidaemia, high blood pressure, constipation, metabolic syndrome, type 2 diabetes and obesity. Common weight related health problems include raised lipids, raised blood glucose, raised blood pressure, diabetes, breathing difficulties, sleep apnoea, poor skin condition and constipation. People with serious mental

illness (SMI) such as schizophrenia and bipolar disorder have higher risks of certain physical conditions. For example, they have two to four times the rate of cardiovascular disease (CVD), two to four times the rate of respiratory diseases and five times the rate of type 2 diabetes than other people (Kupfer, 2005). The reason for this is unknown, but it is likely to be in due to a combination of medication, lifestyle and the disease state itself. A study measuring diet, exercise and obesity in community based men and women with schizophrenia found that none were consuming five or more portions of fruits or vegetables a day and their diets were high in fat and low in fibre compared to the general population, with more than one-third considered physically inactive (Brown *et al.*, 1999). McCreddie (2003) and Compton *et al.*, (2006) support these findings with data showing higher body weight, less physical activity and lower fibre and higher saturated fat intakes in sufferers of schizophrenia. Carbonated drink consumption is often excessive (Lien *et al.*, 2006).

Weight gain and serious mental illness

Weight gain can result as a side effect of medication and the adoption of an unhealthy lifestyle, such as insufficient physical activity and unhealthy dietary preferences, with excess calories consumed through high fat meal choices, excessive portions, snacks, carbonated drinks and takeaways (Brown *et al.*, 1999). The latter may be due to boredom as a result of low occupational activity, increased thirst as a side effect of medication or the perceived positive impact on mood by consumption of caffeine and sugar. Weight gain caused by boredom, especially when service users have long period of residential care and are on restricted access, can be challenging to change. Service users who are on restricted access cannot access foods other than those provided by the wards. Some service users on restricted access can go as far as the vending machines or the hospital shop, which generally promotes the purchasing of foods as part of a daily routine. Long stay service users report that they get bored with menus that remain the same on 3–4 week cycles and chose to order takeaways, especially if menus do not reflect service users' preferences for good quality meat, and spicy foods (Service User Led Audit Group, 2011).

Dieting or weight cycling is also related to depression, with repeated diet failure and episodes of binge eating affecting mood. The use of food as a coping strategy for emotion regulation has the potential to cause overweight or obesity in those experiencing negative mood. Depression also predicts attrition from weight loss programmes, as it can prevent people from engaging in the meal planning and physical activity necessary to lose weight (Markowitz *et al.*, 2008).

Lack of knowledge or skills around meal planning and cooking can also severely limit food choice. Occupational therapy support with improving skills and confidence in the life skills required for everyday living, such as cooking, ironing, cleaning, planning and budgeting, can improve these factors. Joint work between occupational therapists

and dietitians can considerably improve service users' occupational skills and healthy eating.

Weight loss

There is a risk of undernutrition in people with some forms of mental illness, particularly if chronic psychotic illness is associated with problems such as low income, poor housing, eating disorders or substance misuse. Malnutrition can also result as an effect of food phobia or paranoid episodes, where there is a belief that food is contaminated in some way. Some people presenting with deterioration in their mental illness may refuse to eat food available on the ward, perhaps from fear that the food is contaminated or poisoned. Usually food that is still packaged will be accepted, but their diet may remain limited and nutritionally unbalanced until medications have improved their condition.

Depressive illness often results in weight loss. This may be a result of taste changes leading to loss of appetite, low motivation for self care so that the patient does not bother to eat, or a preoccupation with other problems so that eating becomes a low priority event, or a combination of these. Similarly, people suffering with anxiety are often too preoccupied to eat or may complain of food getting stuck in their throat.

Unstable diabetes

Erratic meal patterns, binge eating, non-compliance with medication, excessive carbonated drink consumption and excessive sugar consumption are all common causes of unstable diabetes in mental health settings. A holistic care plan should involve the dietitian, the diabetes care team, key worker and the service user and carer.

Nutritional consequences of medication

A high majority of service users with SMI use medications long term. These types of medications are associated with weight gain, constipation, thirst and increased appetite. Increasing weight impacts on motivation and mobilisation, as well as increasing the risk of other health problems such as metabolic syndrome and CVD. Possible effects of commonly used psychotropic drugs on nutrition are shown in Table 7.10.5.

Psychotropic medication

Psychiatric medications used to treat mental disorders are called psychotropic or psychotherapeutic medications. These medications treat the symptoms of mental disorders. They cannot cure the disorder, but they make people feel better so they can function. Medications work differently for different people. Some people only need them for a short time, e.g. a person with depression may feel much better after taking a medication for a few months, and may never need it again. People with SMI may need to take medication for a much longer time. Psychotropic medication works by affecting the brain's neurotransmitters. Neurotransmitters are chemicals that

Table 7.10.5 Possible effects of commonly used psychotropic drugs on nutrition

Drug type	Examples	Licensed uses	Potential nutritional side effects
Antidepressants			
Tricyclics	Amitriptyline Imipramine Lofepramine Doxepin	Moderate to severe depression, particularly where sedation is required	Dry mouth, blood sugar changes, constipation or (rarely) diarrhoea, nausea and vomiting, epigastric distress, increased appetite and weight gain, SIADH leading to hyponatraemia, anorexia (rarely)
Selective serotonin reuptake inhibitors (SSRIs)*	Citalopram Fluoxetine Fluvoxamine Paroxetine Sertraline Escitalopram	Moderate to severe depression Bulimia nervosa Obsessive compulsive disorder Panic disorder Generalised anxiety disorder Post traumatic stress disorder Social phobia	Anorexia, nausea and vomiting, weight loss/gain, dry mouth, dyspepsia, diarrhoea, taste disturbances, abdominal pain SIADH
Monoamine oxidase inhibitors (MAOIs)	Isocarboxazid Phenelzine Tranylcypromine Moclobemide (reversible MAOI)	Moderate to severe depression Atypical depression Depression with phobic symptoms	Nausea and vomiting, dry mouth, constipation, increased appetite and weight gain, potentiation of action of insulin or oral hypoglycaemic with lowered blood glucose, hypertensive crisis if foods containing tyramine are ingested. NB: This is much less likely with the newer reversible inhibitors of monoamine oxidase (RIMA), such as moclobemide
Presynaptic alpha 2 antagonists	Mirtazapine	Moderate to severe depression	Weight gain, increased appetite
Selective inhibitors of noradrenaline (norepinephrine) reuptake	Reboxetine	Moderate to severe depression	Dry mouth, constipation, lack of appetite, nausea, lowering of plasma potassium concentration following prolonged administration in elderly people
Serotonin and noradrenaline (norepinephrine) reuptake inhibitors (SNRIs)	Venlafaxine Duloxetine	Moderate to severe depression	Constipation, abdominal pain, nausea, vomiting, dry mouth, anorexia, weight changes, diarrhoea, dyspepsia, taste disturbances, increase in serum cholesterol during long term treatment, SIADH
Antipsychotics			
Phenothiazines*	Chlorpromazine Fluphenazine Trifluoperazine	Psychoses Schizophrenia Mania Severe anxiety	Dry mouth, constipation, photosensitivity leading to sun avoidance and low vitamin D levels, appetite increase and weight gain, reduced response to hypoglycaemic agents causing elevated blood glucose
Butyrophenones	Haloperidol	Psychoses Mania Schizophrenia	Nausea, dyspepsia, loss of appetite (less effect on appetite than phenothiazines), dry mouth, constipation
Thioxanthines	Flupentixol Zuclopenthixol	Psychoses Schizophrenia	Increased appetite and weight gain (less commonly weight loss) May affect diabetic control
Substituted benzamides	Pimozide Sulpiride	Psychoses Schizophrenia	Nausea, dyspepsia, abdominal pain, constipation, dry mouth, changes in body weight, glycosuria
Atypical antipsychotics*	Clozapine Olanzapine Quetiapine Risperidone Amisulpride Aripiprazole Ziprasidone (not currently available in the UK)	Psychoses Schizophrenia Mania	Increased appetite and weight gain (likelihood of weight gain greatest with clozapine and then in decreasing order as listed), hyperglycaemia and/or development or exacerbation of diabetes, elevated triglyceride levels, constipation, dry mouth and hypersalivation, impairment of intestinal peristalsis, dysphagia
Hypnotics and anxiolytics			
Benzodiazepines	Diazepam Chlordiazepoxide Lorazepam	Short term anxiety Alcohol withdrawal	Nausea, vomiting, diarrhoea or constipation, appetite and weight changes, dry mouth, metallic taste, dysphagia. These symptoms have been reported both before and up to 6 weeks after withdrawal

Table 7.10.5 (Continued)

Drug type	Examples	Licensed uses	Potential nutritional side effects
Non-benzodiazepine hypnotics	Temazepam Nitrazepam	Short term sleep disturbance	As above
	Zopiclone Zolpidem Zaleplon	Short term sleep disturbance	Metallic taste changes, nausea, vomiting, dry mouth
Mood stabilisers			
Lithium salts	Lithium carbonate Lithium citrate	Treatment of mania and hypomania Prophylactic treatment of recurrent affective disorders	Early side effects: Nausea, metallic taste, increased thirst, polyuria, loose stools Later side effects: Weight gain, mild oedema, polyuria, metallic taste, possible hypothyroidism, hyperglycaemia, toxic effects (can result from sodium depletion), loss of appetite, vomiting, diarrhoea
Anticonvulsants			
Benzodiazepines	Clonazepam Clobazam	All forms of epileptic seizure	As for benzodiazepines
Barbiturates	Phenobarbitone Primidone (80% of its activity is phenobarbitone)	Grand mal and focal seizures	Decreased vitamin D levels, decreased folate levels, (rarely) gastrointestinal upsets
Other antiepileptics	Carbamazepine	Temporal lobe, tonic/clonic and partial seizures. (Mood regulation as an alternative to lithium) Neuropathic pain	Mimics action of ADH on kidney, causing water retention, nausea, loss of appetite, vomiting, diarrhoea or constipation (high dose), dry mouth, lowered plasma sodium levels
	Sodium valproate	All types of seizures (mania – valproic acid)	Nausea and vomiting, anorexia, gastric irritation or increased appetite and weight gain, diarrhoea
	Phenytoin	Tonic/clonic seizures Following head injury or surgery	Early side effects: Nausea and vomiting Later side effects: Decreased absorption of vitamin D leading to osteomalacia, increased turnover and decreased absorption of folic acid leading to megaloblastic anaemia, gum hyperplasia and soreness, tooth decay
	Lamotrigine	Partial seizures Primary and secondary generalised tonic/clonic seizures Myoclonic seizures Lennox–Gastaut syndrome	Nausea, vomiting, diarrhoea Possibility of interference with folate metabolism during long term therapy
	Gabapentin Pregabalin	Adjunctive treatment of partial seizures Neuropathic pain	Diarrhoea, dry mouth, dyspepsia, nausea and vomiting, weight gain Constipation, flatulence, blood glucose fluctuations in service users with diabetes
	Levetiracetam	Adjunctive treatment of partial seizures	Anorexia, diarrhoea, dyspepsia, nausea
	Topiramate	Generalised tonic/clonic seizures Partial seizures Adjunct in Lennox–Gastaut Migraine prophylaxis	Weight loss, nausea, anorexia, diarrhoea, dry mouth, taste perversion, metabolic acidosis (?)

*Not all drugs licensed for all indications.

SIADH, syndrome of inappropriate antidiuretic hormone secretion; ADH, antidiuretic hormone.

communicate information throughout the brain and the body, by relaying signals between nerve cells. There are three main types of neurotransmitters:

- Gamma amino butyric acid (GABA).
- Acetylcholine (ACh).
- Bioactive amines:
 - Noradrenaline (norepinephrine).
 - Adrenaline (epinephrine).
 - Dopamine.
 - Serotonin (5HT).
 - Histamine (H1).

The bioactive amines are monoamines, meaning they have a single amino acid group. Monoamines are metabolised by the enzyme monoamine oxidase (MAO) in the nerve synapses. This can result in low concentrations of the neurotransmitters that result in disease. Most people with psychosis (schizophrenia) have unnaturally high levels of dopamine; therefore, the treatment is to lower the monoamine (dopamine) levels. Most antipsychotics (neuroleptics) involve predominately blocking or lowering dopamine levels.

The antidepressant medication monoamine oxidase inhibitor (MAOI) inhibits the breakdown of noradrenaline and adrenaline. This leads to a build up in the synapse and thereby improves mood. These drugs have drug–nutrient interactions that service users must be aware of (Table 7.10.5). Newer antidepressants, selective serotonin reuptake inhibitors (SSRIs), e.g. Prozac, increase the amount of serotonin (and to some extent noradrenaline) in the synaptic gap, which correlates with an increase in mood.

Weight gain

The possible mechanisms for weight gain associated with this medication include:

- Blocking or lowering of ACh peripherally causes dry mouth and increased thirst. This may lead to an increase in the consumption of sugary drinks.
- Drugs that lower serotonin and histamine stimulate appetite and carbohydrate cravings. This may lead to an increase in total energy intake.
- Blocking dopamine, especially the D2 receptors, may increase appetite.
- Lithium may cause weight gain by fluid retention (due to its effect on sodium balance) and by reducing thyroxine levels (which results in a decreased metabolic rate and therefore a decreased energy output).

Therefore drugs that block ACh, serotonin and histamine will have the greatest effect on body weight. Drugs that blocks all three of these will provoke the greatest weight gain, e.g. clozapine, olanzapine and quetiapine.

Antidepressants

In a comprehensive review of antidepressants and weight gain, Zimmermann *et al.* (2003) showed that traditional tricyclic antidepressants, such as amitriptyline, clomipramine, imipramine and lofepramine, caused marked

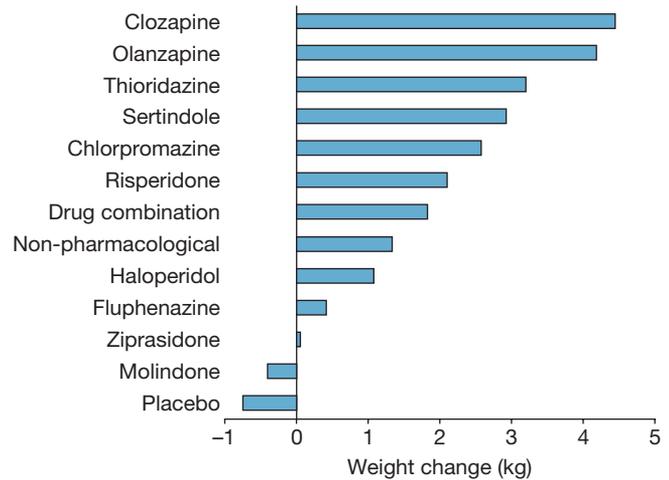

Figure 7.10.2 Effect of 10 weeks of treatment with antipsychotic medication on weight (source: Zimmerman *et al.* 2003. Reproduced with permission of Elsevier Publishing)

weight gain (Figure 7.10.2). The newer form of antidepressants (SSRIs), such as citalopram, paroxetine, fluoxetine and sertraline, may induce weight loss during the first few weeks and may prevent weight gain long term. They are commonly used to treat conditions such as bulimia, panic disorder, OCD and depression. Weight gain with mood stabilisers, such as lithium, can range from 5 to 15 kg over 1–2 years (Baptista, 1999).

Antipsychotic medication

Antipsychotic medications are an important treatment option for many individuals with schizophrenia. A study comparing the effects of older and newer antipsychotics for treating service users with schizophrenia showed that both newer and older types of antipsychotics were associated with weight gain and, of the newer antipsychotics, clozapine appeared to have the greatest potential to induce weight gain (Allison *et al.*, 2003) (Figure 7.10.2).

Parsons *et al.* (2009) and Norvik *et al.* (2009) reported that newer antipsychotic medications, such as olanzapine and quetiapine, also commonly cause dramatic and long term weight gain; with rapid gains of 30 kg over months and that continued over the 3 years of the study. Thakore (2005) found a three-fold increase in intra-abdominal fat stores and associated hypercholesterolaemia with antipsychotic drug use. These side effects can reduce compliance and increase risk of relapse. Whilst alternative medications may have less of an impact on weight, there may be a reluctance to change medications in those people whose mental health problem is well controlled. The concern is that there may be a relapse in control whilst the former drug is reduced and before introducing the new one, and for the consequences if the new drug is not as effective.

Constipation

Constipation is a common side effect of medication and can be severe and even fatal in some cases. Dehydration or an inappropriate diet can compound this.

Polydipsia and hyponatraemia

Polydipsia is associated with some disorders and types of drug treatment, and may result in water intoxication if renal function is impaired (Crammer, 1991). Some service users experience increased thirst sensation as a side effect of antipsychotic medication and consequently drink excessive amounts of fluid, putting themselves at risk of hyponatraemia. The consumption of large quantities of strong coffee or other caffeine rich drinks may make the situation worse. Treatment may necessitate withdrawal of antidepressants, but if continued use of antidepressants is unavoidable, sodium and fluid restriction may be necessary. Dehydration may exacerbate problems such as constipation or urinary incontinence secondary to urinary tract infections.

Additional nutritional problems for inpatient communities

Meal times

Many service users do not get up early and therefore start their day later. The evening meal is often fixed around 5 PM, which means that people are hungry again by 8–9 PM. Access to supper varies but is often limited to toast and cereals; this can promote the purchase of takeaways. Meals times can be a very stressful time for service users and there are many security issues for staff to deal with. There can be difficulties in managing paranoid service users in the same communal eating space as others, sometimes necessitating a staggered approach to meals, which requires different sittings in a short space of time.

Surveyed service users reported that they would prefer staff to sit and eat with them at meal times rather than be there just for observation; giving opportunity to build better relationships with staff and change culture at meal times, thus making them a more normalised and social event (Service User Led Audit Group, 2011). The (CQC) make protected meal times a measurable standard for all mental health trusts.

Takeaways

In the 2011 Service User Led Audit in the north of England, service users gave a number of reasons why takeaways were important to them. Hospital food was perceived as bland; therefore, takeaways were one way that people could have what they considered to be a 'decent meal'. Service users also viewed getting takeaways as a social experience that gives them some control over how and when they eat. It also provided an opportunity for people to eat together, often with staff and friends, in a way that normalised eating. This highlights the importance of service user input into food choice for the menus and dining arrangements. Takeaways in some hospitals have been successfully limited to Fridays or Saturdays and staff place the service users' orders. Hospitals have a duty of care to provide high quality food that meets service users' preferences, nutritional health needs and provides adequate choice (CQC Standard, Outcome 5).

The legal position

In the case of service users who are detained in long stay units, the law states that the hospital is considered the usual residence and therefore a home to service users. However, because of the nature of the residence, e.g. service users cannot access any alternative environment or food provisions, it is reasonable that there may be a case for restricting or adjusting environmental factors, including food type or amount, to support the goal of treating or preventing morbidity or mortality, e.g. to control blood sugars or to prevent weight gain and coronary heart disease in service users identified as high risk. Any restrictions that are placed on service users' food provision must be both justified and reasonable, e.g. not disproportionate to the goal of treatment. In order for this to be legal, there must be a transparent and meaningful consultation with the service users before any such restrictions are applied. All options should be explored in full, and careful consideration given to the type and severity of food restriction needed for treatment, which should be balanced against the service users' right to enjoy a normal diet. Therefore, dietitians should ensure all these steps are followed and all actions and discussions fully documented to ensure legal challenges from service users are avoided.

Management of nutritional issues

Nutrition screening

All service users admitted as inpatients should be screened for nutrition related problems, and those identified as high risk should have a nutritional care plan in place that is reviewed at regular intervals by an appropriately qualified professional (CQC, outcome 5). The Malnutrition Universal Screening Tool ('MUST') has not been validated for mental health settings, and is inappropriate for many of these as selective eating, food phobias or deliberate weight loss, and disordered eating are not easily identified. Therefore, a number of hospitals have adapted 'MUST' or developed their own screening tool, which has then been validated for use through measurements of specificity and sensitivity locally.

Service user led groups

These are often called nutrition steering groups, and may be attended by a nutrition link from each ward. These groups can help to educate and give opportunities to expand choices and experience through activities such as 'come dine with me' groups and themed food nights. Some trusts have catering groups or service user partnership groups, where service user representatives from each ward attend meetings to provide suggestions, comments, compliments, and feedback on menus and quality of the food. Service users also give suggestions for new menus; however, dietitians need to keep in mind the various policies around food in hospitals that each trust needs to adhere to.

Menu and snack choices

Other successful strategies include ensuring the menus are carefully planned to give healthy choices, e.g. all recipes including traditionally higher calorie choices, such as chips and curry, are given a healthy eating makeover aiming for high taste and lower fat. Foods such as snacks may be rated, e.g. red, amber and green (RAG rated), offering service users an informed choice. Stocking non-food items such as puzzle books and magazines in vending machines rather than food, stocking only caffeine and sugar free drinks and limiting shop sold items to small portion sizes are some ways in which hospitals have successfully started to promote healthier eating.

Weight management

A holistic care package should address the psychiatric features of SMI and any physical health consequences (NICE, 2009). A systemic review on interventions to control body weight in service users with schizophrenia suggested that, although weight loss may be difficult, positive effects are possible (Faulkner *et al.*, 2003). In addition, the authors also recommend a combined intervention of diet and exercise as a part of the behavioural modification programme for weight maintenance. The effect of an educational programme on weight gain induced by antipsychotics was examined in an intervention study (Littrell *et al.*, 2003). It was found that after the 6-month intervention, the intervention group did not gain weight (-0.06lb) compared with the control group, which gained 9.57lb. This was attributed to a difference in the knowledge about healthy eating habits and lifestyle changes acquired as a part of the educational programme.

Many service users do not find commercial or community based slimming groups useful due to the rapid pace of change expected, misunderstandings around the impact of the medication they are taking, and social and interpersonal difficulties experienced in group settings. In addition, the incidence of disordered eating is high (Hudson *et al.*, 2007). Therefore, many service users will not benefit from the traditional energy balance approach where the focus is on restricting energy, and educational approaches may inadvertently reinforce beliefs about good and bad foods. Instead the focus should be on regular meals and managing carbohydrate load through the day.

Research suggests that service users can successfully lose weight through targeted individualised plans supported by regular dietetic contact (Skouroliakou *et al.*, 2009) or more commonly through service user led weight management groups. A typical 8–10-week programme includes topics such as healthy eating principles, self esteem, activity, meal planning and demonstrations, activity scheduling, motivation, quizzes and evaluation (Chen *et al.*, 2009). Goals were set by the individual and the pace of change was slow, with focus on single changes such as changing to diet drinks and semi skimmed milk, using sweeteners in drinks, frying less and increasing

consumption of fruit or vegetables. Service users were self weighed at each session and peer support and suggestions offered. Results at 12 months were typically in the region of a 3-kg weight loss (Gabriele *et al.*, 2009; Chen *et al.*, 2009). Holt *et al.* (2009) also showed a consistent average weight loss of 0.34–0.07kg/week (average 3.0kg/12 months) over 8 years. Weight loss strongly correlated with the number of session attended, with 61 sessions being the average. Weight loss correlated with decreases in CVD risk factors such as blood pressure.

Promoting physical activity

It has been widely acknowledged that being more active contributes significantly to improved health and wellbeing, reducing the likelihood of developing heart disease and obesity, and mental health problems (MIND, 2007). In addition to the physical health benefits of exercise, an increase in physical activity has been linked to improvements in mental health. Collective evidence shows that exercise improves mental health and wellbeing, reduces depression, anxiety and negative symptoms, and improves self esteem and cognitive functioning (Callaghan, 2004). There is accumulating evidence to suggest that increased physical activity may also be an effective treatment for depression (Saxena *et al.*, 2005). It may also alleviate some of the negative symptoms of schizophrenia in addition to anxiety and depression (Faulkner & Biddle, 1999). There is now substantial evidence to support the need for physical activity interventions in service users with serious mental illness (Richardson *et al.*, 2005).

7.11

Immunology and immune disease

7.11.1 Nutrition and immunity

Elaine Gardner

Key points

- The immune system is a complex series of processes that interact as the body's defence system.
- Nutrients play a major role in the functioning of a healthy immune system.
- Any challenge to optimum nutritional status has an impact on the immune system.
- The immune system is linked to the pathogenesis of many everyday illnesses and diseases.
- Supplementation with nutrients may have a role in the treatment of illnesses and chronic diseases (through their impact on the immune system), as well as correcting deficiencies.

The immune system is complex and should be viewed as a range of tissues, cells and their products. This defence mechanism guards against invasion by foreign microorganisms and molecules, so protecting against illnesses and communicable diseases. A balance between destruction of foreign cells and avoidance of self destruction is necessary, and the body's ability to distinguish and identify cells and molecules that are part of its self and those that are non-self is fundamental. Further details of the structure and functioning of the immune system can be found in Sompayrac (2011).

Nutrients and the function of a healthy immune system

Adequate intakes are required for the immune system to develop and function correctly. A deficiency can negatively influence the body's defences and impair their ability to combat infections.

Energy and protein

Infection increases energy requirement due to an increase in the basal metabolic rate. There is an increased need for protein and energy for increased production of cytokines, B and T lymphocytes, macrophages and other

leucocytes and their products, e.g. immunoglobulins. If anorexia is present, and protein and energy demands are not met, fat is mobilised. Cytokine and other hormonal responses inhibit the efficient use of fats and the body relies on protein breakdown. The intake of macronutrients is crucial and influences the immune response. If requirements are not met, especially of methionine and cysteine, wasting will occur as mobilised amino acids are prioritised for the synthesis of proteins related to the immune response.

Arginine

Nitric oxide is synthesised from arginine and is important in immune systems since the inhibition of nitric oxide production increases the body's susceptibility to infectious agents. Nitric oxide production is induced in macrophages and supplementation of arginine benefits the immune response by increasing macrophage activity (Stechmiller *et al.*, 2005). It also plays a role in cell death in infected or tumour cells; it is suggested that this benefits wound healing by increasing collagen synthesis. In older people arginine supplements may enhance the immune response (Moriguti *et al.*, 2005). However, arginine supplementation during an inflammatory state could be detrimental due to the overwhelming production of nitric oxide (Calder, 2007).

Fatty acids

Fatty acids are important in the function of the immune system because they are structural components of cell membranes. The fluidity of membranes (which is affected by the chain length and saturation of incorporated fatty acids) is important for cell surface structures such as receptors, which are crucial in immune functioning. Polyunsaturated fatty acids (PUFAs) have a direct effect on the function of immune cells as they are converted to tissue hormones, e.g. prostaglandins. n-6 and n-3 PUFAs compete in prostaglandin formation, resulting in the production of different prostaglandins. n-3 PUFAs suppress the production of n-6 PUFA derived prostaglandin (Calder, 2006). Prostaglandins derived from n-6 PUFA appear to have strong regulatory functions for a variety of immune cells whose function is dependent on their concentration, with high level suppressing some immune cell functions (Galli & Calder, 2009). Diets rich in n-3 PUFAs tend to inhibit the immune response, whereas n-6 PUFA rich diets tend to promote immune responses, which lead to inflammation (Galli & Calder, 2009). This has implications in the treatment of patients with inflammatory conditions such as rheumatoid arthritis and ulcerative colitis.

Micronutrients

Tables 7.11.1 and 7.11.2 summarise the roles of micronutrients in the immune system. The tables should be viewed with caution as much of the evidence is derived from studies in low income countries, animals and *in vitro*. Micronutrients influence the effectiveness of the immune system and at least an adequate intake is required for the effective functioning of the body's defence mechanisms (Table 7.11.3).

Iron

Iron is essential for the growth, survival and replication of microorganisms and viruses. At the start of an infection, extracellular iron (and to a lesser extent zinc) shifts into the intercellular compartment; this shift is believed to make iron unavailable to some pathogens and so limits their potential growth (Weinberg, 2009). Supplementation with iron has the potential to increase pathogenic replication and its subsequent consequences. This has implications especially with regards to malaria infected children from developing countries, who are often anaemic, and pregnant women from these areas requiring iron containing supplements. Guidance on iron supplementation in malaria endemic areas can be found in a Cochrane review (Ojukwu *et al.*, 2009) and World Health Organization (WHO Secretariat, 2007) consultation document. There is no evidence to suggest that iron supplementation has adverse effects on infectious disease incidence or morbidity in the UK. There may, however, be possible adverse effects on individuals with HIV and children at risk of diarrhoea (SACN, 2010).

Antioxidants

The immune system is particularly at risk from oxidative stress, as many of the cells of the immune system produce reactive oxygen species during their normal functioning. Antioxidant defences have evolved to protect organisms against the damaging effects of free radicals. These defences include molecules that directly remove free radicals, e.g. vitamin E, beta-carotene, vitamin C, and antioxidant enzymes, e.g. glutathione and superoxide dismutase, which have trace metals components, e.g. manganese, copper, zinc and selenium. There is also an interaction between PUFAs and antioxidants, e.g. n-3 PUFAs and vitamin E.

The immune system and disease

Food allergy

The production of IgG or IgE antibodies in response to an allergen may be established before birth and in early childhood (through reprogramming of the immune response), and is dependent on the body's balance between types of T helper cells (Th1 or Th2 cells). Genes can increase or decrease susceptibility to allergies, and early exposure (or lack of exposure) to environmental factors, such as infectious diseases and microbial infections, may influence whether susceptible individuals become atopic (see Chapter 7.11.2).

Atherosclerosis

Atherosclerosis is an inflammatory disease of the arteries resulting in the deposition of plaques (Samson *et al.*, 2012). n-3 PUFAs may block the production of cytokines that promote inflammation and so inhibit the development of atherosclerosis. Vitamin E may help prevent oxidation of low density lipoproteins (Hansson & Hermansson, 2011) (see Chapter 7.14.1 and Chapter 7.14.2).

Autoimmune disease

Autoimmune disease occurs when there is a breakdown in the self preservation mechanism and a level of self destruction by the immune system. A genetic predisposition, lymphocytes with receptors that can recognise the self antigen and environmental factors, e.g. microbial infection, that lead to the breakdown of tolerance mechanisms, which are designed to eliminate self reactive lymphocytes, are all necessary for autoimmune disease to occur. Examples of autoimmune disease are type 1 diabetes mellitus, multiple sclerosis, coeliac disease, Crohn's disease and rheumatoid arthritis.

Cancer

Cancer cells arise when there is malfunction of systems that promote cell growth and those that protect against excessive cell growth in a cell. A weakened immune system can increase the risk of haematological and virus

Table 7.11.1 Vitamins and the immune system

Vitamin	Importance for the immune system	Effect of deficiency on immune system	Possible effects of supplementation
Retinol carotenoids	Differentiation of epithelial cells Development of lymphocytes ↑ Specific lymphocyte subgroups Enhances activity of NK cells Stimulates production of cytokines Activates phagocytic cells	↓ Physical barriers and impairs mucosal immunity ↓ Total number of lymphocytes ↓ Lymphocyte function Altered cytokine networks Altered antibody responses to antigens Impaired antibody production ↓ Phagocytic activity of neutrophils No alteration of neutrophil numbers (in absence of infection) ↓ Number and activity of NK cells Impaired growth, activation and function of B lymphocytes	May be beneficial for individuals with compromised immune systems Does not stimulate immune responses of healthy adults with adequate intakes In elderly, enhances NK cell activity, but no effect on T-cell mediated immunity <i>Conclusion: little value in well nourished populations</i>
Vitamin D	Immune system regulator (Lips, 2006) Stimulates production of antimicrobial peptides (including those in epithelial cells of the respiratory tract) Role in production of TNF	? ↑ Immune response to flu virus ? Predisposes children to respiratory infections ↑ Susceptibility to infections due to impaired localised innate immunity and defects in cellular immune response	↑ Subgroups of T cells in women at low doses ? ↓ Incidence of viral respiratory infections (Cannell <i>et al.</i> , 2006) <i>Conclusion: none confirmed</i>
Vitamin E	Powerful antioxidant ? Reduces prostaglandin synthesis ? Prevents oxidation of PUFA in cell membranes Effects on cytokine production	Impairs B and T cell immunity (Pekmezci, 2011) ↓ Lymphocyte proliferation responses ↑ Serum IgM concentrations, but impaired antibody production Impaired function of phagocytes	? Enhances immune functions (at doses higher than recommended levels) in elderly people (↑ antibody production; ↓ incidence of infections) ? Reduces exercise induced muscle damage and that associated with antiretroviral drugs <i>Conclusion: may improve immune status, particularly in elderly, but conflicting results on decreased respiratory tract infections</i>
Vitamin C	Stimulant of leucocyte functions, especially neutrophil and monocyte movement (important in phagocytosis and lymphocyte functions) Antioxidant protection at inflammatory sites, preventing oxidant mediated tissue damage ? Regulation of inflammatory response	Impaired lymphocyte proliferation of T cells Impaired inflammatory response Impaired function of phagocytes	Enhances neutrophil chemotaxis In response to infection, enhances T lymphocyte proliferation (↑ cytokine production, ↑ synthesis of immunoglobulins) <i>Conclusion: no consistent effect on incidence of colds, but possible modest effect in decreasing duration and severity</i>
Vitamin B ₆	Required for synthesis and metabolism of amino acids, and so for the formation of many immune cells and substances ↑ Production of interleukins	Modifies and impairs antibody production Modifies T cell activity Lymphocyte growth and maturation altered	Correction of deficiency rectifies effects on the immune status <i>Conclusion: no additional benefit to healthy adults</i>
Folate	Important in protein synthesis	Affects cell mediated immunity by reducing proportion of circulating T lymphocytes, leading to ↓ resistance to infections	? In elderly, improves immune function by altering age related ↓ in NK cell activity <i>Conclusion: possible protection against infections in elderly, but conflicting results with suggested mechanisms</i>
Vitamin B ₁₂	Interactions with folate mechanism Regulatory agent for cellular immunity	Alterations in immunoglobulin secretion and antibody response ↓ Number of lymphocytes Suppresses NK cell activity	Reverses deficiency effects <i>Conclusion: no additional benefit to healthy adults</i>

NK, natural killer; TNF, tumour necrosis factor; PUFA, polyunsaturated fatty acid.

Table 7.11.2 Minerals, trace elements and the immune system

Mineral/trace element	Importance for the immune system	Effect of deficiency on immune system	Possible effects of supplementation
Iron (Munoz <i>et al.</i> , 2007)	Proliferation of lymphocytes Part of iron metalloenzymes involved in oxidative processes	Intracellular killing of pathogens impaired Slight ↓ in macrophage cytotoxicity ↓ T lymphocyte count Absence of normal immune response to a particular antigen or allergen ↓ T cell function ↓ Innate immune response Altered balance between pro- and anti-inflammatory cytokines	May favour infectious pathogens by providing them with a supply of iron for growth and replication (SACN, 2010) ? Effect on morbidity and mortality from infections is uncertain <i>Conclusion: no evidence to suggest that in the UK this has adverse effects on infectious disease incidence or morbidity. Possibly adverse effects on individuals with HIV and children at risk of diarrhoea</i>
Zinc (Prasad, 2008; Prasad <i>et al.</i> , 2007; Ibs & Rink, 2004)	Cofactor for substances that modulate cytokine release and thus essential for highly proliferating cells Helps to maintain skin and mucosal membrane integrity Antiviral effect Regulates activation of acute phase response	↓ B and T lymphocyte proliferation and imbalance in T cell subpopulations Defects in cell mediated immunity demonstrated by a depression in delayed hypersensitivity responses ↑ Susceptibility to infections ↓ Number of mature T cells and ↑ in immature T cells Damages protective barrier of the skin, respiratory and gut linings and impaired wound healing Impairs innate immunity (impaired chemotaxis by neutrophils and macrophages, ↓ NK cell activity)	↑ Cellular components of innate immunity, antibody responses and number of cytotoxic cells ↓ Induced apoptosis of macrophages and T cells Reversal of T cell reduced responses when deficiency corrected High levels cause impairment in immunity (in phagocytic cell and lymphocyte function) <i>Conclusion: zinc has a major role in the immune system at all levels and deficiency manifests with increased susceptibility to infectious agents. Zinc supplementation may help reduce the incidence of infections, especially in the elderly</i>
Selenium (Beckett <i>et al.</i> , 2004)	Component of selenoproteins with some enzymes that exert antioxidant activity (involved in the removal of excess potentially damaging radicals) Essential for both cell-mediated and humoral immunity Stimulates lymphocytes and NK cells Interactions with vitamin E	Compromises neutrophil chemotaxis and macrophage function and subsequent killing of phagocytosed bacteria ↑ Oxidative damage in immune cell membranes ↓ Resistance to viruses Impaired antibody production ? ↑ Risk of developing some cancers	↑ Cytotoxic action against virus infected cells Eradication of Keshan disease Improved immune system function <i>Conclusion: correction of deficiency rectifies effects on the immune status. Possible role in cancer prevention and therapeutic effect on some inflammatory diseases</i>
Copper	Cofactor in copper dependent enzymes that are important in antioxidant defence (diminishes damage to lipids, proteins and DNA)	↓ Number of circulating neutrophils Affects synthesis and secretion of cytokines In animals, impairments in immune function (↓ thymus weight, ↓ production of antibodies, ↓ activity of NK cells, ↓ antimicrobial activity of phagocytes)	? Correction of deficiency rectifies effects on the immune status (phagocytic index returns to normal values) ? Immunosuppressive at high levels <i>Conclusion: further clinical trials needed.</i>
Magnesium	Component of enzymes and needed for normal functioning	↑ Thymus cell proliferation ↑ Levels of interleukins and TNF ↓ Levels acute phase proteins and complement Influences cytotoxicity of T cells and functioning of adhesion molecules	Conflicting results on improvement of asthma symptoms <i>Conclusion: additional studies warranted</i>
Manganese	Component of enzymes and needed for normal functioning Antioxidant activity	↓ Lymphocyte antioxidant enzyme activity In animals, ↓ antibody synthesis and secretion	? Antibody production improved, but only to certain level (in large amounts inhibition of production occurs) Can cause secondary iron deficiency leading to iron deficiency induced immune system abnormalities <i>Conclusion: none confirmed</i>

NK, natural killer; TNF, tumour necrosis factor.

Table 7.11.3 Summary of nutrient requirements for the functioning of the immune system (Maggini *et al.*, 2007)

Body's defence system	Nutrients required
Skin barrier function	Vitamins A, C and E Zinc
Synergistic working to support protective activities in immune cells (cellular immunity)	Vitamins A, B ₆ , B ₁₂ , C, D and E Folic acid Iron Zinc Copper Selenium Manganese Magnesium PUFA Methionine Cysteine
Antibody production	
B cell proliferation	Vitamin B ₆ Selenium Copper Zinc Glutamine
Promotion of humoral immunity	Vitamins A, D and E Arginine
Indirect action on protein synthesis and/or cell growth	Vitamin B ₁₂ Folic acid Magnesium Manganese

PUFA, polyunsaturated fatty acid.

associated cancers, but there is disagreement as to whether this applies to solid tumours. Macrophages and natural killer (NK) cells are able to destroy cancer cells that occur in the tissues, but require activation. Unless there is inflammation present, activation does not occur until a tumour becomes large and dying cancer cells activate the macrophages that enlist help from NK cells from the blood. Zinc, selenium, vitamins A and C and PUFAs have been postulated to be involved in ensuring a healthy immune system against cancer (Valdes-Ramos & Benites-Arciniega, 2007). A summary of the relationship between gut flora, immunity and colon cancer can be found in Greer & O'Keefe (2011).

Coeliac disease and gluten sensitivity

Coeliac disease derives from a mechanism that is triggered by the adaptive response of the immune system, whereas gluten sensitivity is connected to the action of the innate immune system and does not involve the function of the intestinal barrier (Sapone *et al.*, 2010; 2011) (see Chapter 7.4.7).

Critical illness and surgery

Following surgical trauma or during critical illness an excessive inflammatory response can be induced that can be followed by an immune suppressed state, which

increases susceptibility to infection. Some nutrients, including some amino acids, antioxidant vitamins and minerals, phytochemicals, long chain n-3 fatty acids and nucleotides may be able to influence the immune system (immunonutrition) by improving cell mediated responses. Research is being undertaken on their use in artificial nutritional regimens. Mizcock (2010) and Calder (2007) have reviewed individual nutrients and the rationale for their role in the immune system in critical illness.

Gut health

The gut associated lymphoid tissue secretes antibodies to inhibit the colonisation of pathogens and to prevent the entry of harmful antigens into the blood from the digestive tract. Indigenous bacteria also contribute to the protection at the mucosal surfaces by creating a barrier effect (colonisation resistance). When the balance of the organisms is disrupted, local immune systems may be impaired. Probiotics, prebiotics and synbiotics that rebalance gut bacteria may indirectly produce immune effects. The actions of probiotic bacteria depend on the strain, but they impact on the immune system by:

- Competing with pathogenic bacteria for receptors on the epithelial wall of the gut and for nutrients that are in limited supply.
- Counteracting the increase in gut permeability that occurs after exposure to viruses or foreign antigens.
- Stimulating the immune response to specific antigens.
- Enhancing phagocytosis.

The impact of probiotics on the immune system is reviewed by Rutherford-Markwick & Gill (2004) (see Chapter 5.2).

Soluble dietary fibre has an influence on the immune system. When it is fermented, short chain fatty acids are produced, which are involved in numerous physiological processes, including those directly relating to the intestinal immune function. Gut health and immunity has been reviewed by Scholz-Ahrens *et al.* (2007), Roy *et al.* (2006) and Wong *et al.* (2006).

HIV and AIDS

The human immunodeficiency virus 1 (HIV-1) slowly overwhelms and destroys the immune system, leading to profound immune suppression. It establishes an infection that can be latent and undetectable by the killer T cells for periods of time and then develops so the killer T cells or antibodies no longer recognise the virus (Sompayrac, 2011). As a result it has a high mutation rate and is successful because it preferentially infects and disables the immune system (particularly helper T cells, macrophages and dendritic cells) that would normally defend against it (see Chapter 11.3).

Undernutrition

In any infection, the nutritional status of the host critically determines the outcome of infection. Malnutrition

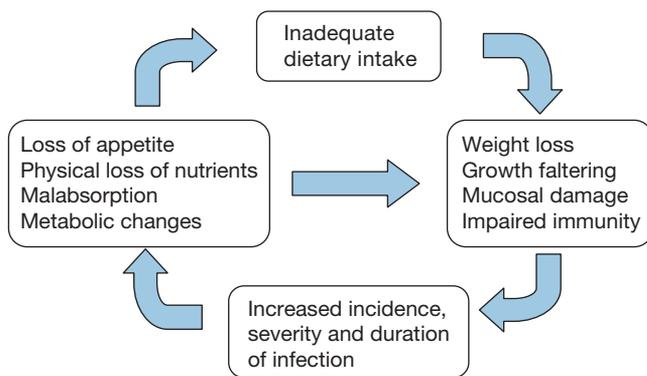

Figure 7.11.1 Cycle of undernutrition and infection [source: Tomkins & Watson 1989. Reproduced with permission of the UN Standing Committee on Nutrition (UNSCN)]

compromises immunity, which increases susceptibility to infection and disease. The general effects of undernutrition on the immune system are:

- Diminished T cell help in immune responses.
- Delayed antibody responses.
- Depressed mucosal antibody in response to mucosal infections.
- Impaired complement activation.
- Decreased lysozyme levels in leucocytes.
- Impaired activity of opsonin (a serum that attaches to bacteria to make them more attractive to phagocytes and thus more likely to be engulfed and destroyed).
- Thymic atrophy (the primary site of T cell development).

Infection has detrimental effects on nutritional status, which can lead to a perpetuating cycle of undernutrition and infection (Figure 7.11.1).

In low income countries, where protein energy malnutrition is more common, the impact of the undernutrition and infection cycle is devastating, resulting in growth retardation in children (and *in utero*) and increased rates of infections and parasite infestations, morbidity and mortality. A full review of the impact of this cycle on the immune system in low income countries can be found in Shetty (2010), Schaible & Kaufmann (2007) and Solomons (2007).

In high income countries, undernutrition is still seen within some societal groups, such as the elderly, who are at risk from the cycle of undernutrition and infection, which results in (subclinical) nutritional deficiencies, loss of weight, poor appetite, poor wound healing, as well as increased rates of infections (see Chapter 6.2).

The immune system in neonates

Cunningham-Rundles *et al.* (2009) reviewed the development of the neonatal immune response, particularly with regard to the effects of micronutrients, and concluded that nutrients mould the developing immune system and that, post birth, the interactions between dietary micro-

nutrients and microbial and environmental antigens define patterns of host defence in later life.

The immune system in the elderly

With ageing the immune system changes and the ability to respond to infections and develop immunity after vaccinations progressively deteriorate (immunosenescence). As a result, there is an increased susceptibility to infections, cancers and autoimmune diseases in the elderly. Innate immunity dysfunction may be due to increased production of proinflammatory cytokines (which may be linked to the development of diabetes, osteoporosis and atherosclerosis due to their inflammatory pathogenesis), a decline in phagocytic capacity and depressed NK cell cytotoxicity.

Changes in the adaptive immune system are two-fold. Humoral immunity is compromised due to the decreased production of immunoglobulin producing B lymphocytes and the loss of immunoglobulin diversity and affinity, leading to less well adapted antibody responses in older people. Age associated changes related to the thymus lead to a reduction in the functional size of the thymus that decreases T cell output and diversity, which may leave the elderly more susceptible to new pathogens.

A number of studies have looked at the effect of vitamin B₆, vitamin E, zinc and multi micronutrients supplementation, but the identification and levels of micronutrients necessary to slow down the immune ageing process are still to be determined. In those elderly that are undernourished, the decrease in immune functions is highly correlated with the intensity of the nutritional deficit and this causes a secondary immune deficiency (in addition to the primary deficiency caused by ageing *per se*). Refeeding may reverse secondary immune changes in the undernourished. Shetty (2010), Aw *et al.* (2007) and Lesourd (2006) have reviewed immune function in the elderly.

Exercise

Exercise has an impact on the immune system. Acute and chronic exercise alters the number and function of neutrophils, monocytes and NK cells of the innate immune system. Lymphocytosis is observed during and immediately after exercise, proportional to the exercise density and duration, with the number of T cells falling below pre-exercise levels during the early stages of recovery, before returning to resting values normally within 24 hours after the last bout of exercise. Acute bouts of moderate exercise have little impact on mucosal immunity, but there may be a link between moderate, regular exercise and a healthy immune system. However, prolonged exercise and intensive training provoke a response that has been linked to increased risk of upper tract respiratory infections during heavy training. This is linked to the elevated circulating stress hormones cortisol and adrenaline (epinephrine), which raise blood pressure and cholesterol levels and suppress the immune system. It is believed that the combined effects of small changes in the immune system may compromise resistance to minor

illnesses, especially in elite athletes (Walsh *et al.*, 2011b). The protective effect of exercise against chronic inflammation associated diseases, such as type 2 diabetes and cardiovascular disease, has been attributed to the anti-inflammatory effect of regular exercise. It has been suggested that this may be mediated via both the reduction of visceral fat mass and the establishment of an anti-inflammatory environment with each bout of exercise (Walsh *et al.*, 2011a). These authors concluded '*non-athletes, engaging in moderate physical activity programmes do not require nutritional supplements [to maintain immune function], and can obtain all needed nutrients from a healthy and balanced diet*'. The mechanisms and controversies related to exercise and immunology are reviewed by Walsh *et al.* (2011a,b) (see Chapter 4.3).

7.11.2 Food hypersensitivity

Isabel Skypala, Carina Venter and Tanya Wright

Key points

- Food hypersensitivity is an umbrella term referring to any reaction caused by food that is specific to an individual.
- It affects 8% of children and 3.7% of adults.
- Validated diagnostic tests exist for IgE mediated food allergy, lactose intolerance and coeliac disease; often diagnosis may only be achieved through strict and total exclusion of the suspect food, noting the effect on symptoms, followed by a period of reintroduction to see if symptoms are reproducible.
- Management is mainly through the exclusion of the culprit foods, the level of which depends on the type and severity of food hypersensitivity and the food involved.
- Food hypersensitivity can have deleterious effects on quality of life; it is therefore essential that the correct diagnosis is made.
- Children with food hypersensitivity need regular reassessment to determine potential resolution of the allergy, but also to check nutritional status, dietary compliance and coping strategies.

Data from hospital admissions suggest that there has been a substantial rise in the number of patients attending hospital for food allergic events (Gupta *et al.*, 2007). Correct diagnosis and management is vital in order to avoid severe or even fatal reactions to food and any nutritional consequences of unnecessary or unsupervised food avoidance, which will also affect quality of life. This chapter will cover the diagnosis and management of these adverse food reactions, usually termed food hypersensitivity (FHS) (Johansson *et al.*, 2004).

There is great disparity between perceived and actual prevalence; UK studies reported a 7.2% rate of parental reported food allergy compared with an actual rate of 4% in 12-month-old infants, and a 37% parentally reported rate in 3-year-old children compared with an actual rate of 6% (Venter *et al.*, 2007b). This pattern is repeated in adolescents; true allergy was found in only 1.0% of British 15-year olds and 1.7% of Danish young adults, despite a respective reported incidence of 18.7% and 19.6% (Pereira *et al.*, 2005; Osterballe *et al.*, 2009). The prevalence of self reported allergy amongst US adults was 9.1%, although only 5.3% had a doctor diagnosed food allergy (Vierk *et al.*, 2007).

Food allergy is most common in early childhood, with prevalence rates in infants and children varying from 2.3% in Denmark (Osterballe *et al.*, 2005) to 8% in the USA (Bock, 1987). The most recently reported prevalence in

the UK is 6% (Venter *et al.*, 2007b), with the study authors reporting that there was no significant difference between these data on the cumulative incidence of food allergy in children and those published by Bock in the USA 20 years previously. Adults generally have a lower prevalence of food allergy than children; reported prevalence, based on an oral food challenge, ranged from 1.8% in the UK (Young *et al.*, 1994), and 2.4–3.7% in Europe (Jansen *et al.*, 1994; Zuberbier *et al.*, 2004).

Diagnostic criteria and classification

Adverse food reactions and food hypersensitivity are umbrella terms referring to any untoward reaction following the ingestion of a food (or food additive). Adverse reactions to food can be divided into toxic and non-toxic reactions (Bruijnzeel-Koomen *et al.*, 1995). Toxic reactions are dose related and can affect any individual exposed to toxic compounds, which may be naturally occurring in foods or added during food preparation, e.g. scombroid fish poisoning or aflatoxins in peanuts.

The nomenclature of non-toxic reactions has been further defined by two European Academy of Allergy and Clinical Immunology (EAACI) task forces (Johansson *et al.*, 2001; 2004) as food hypersensitivity (Figure 7.11.2); published guidelines in the USA contain a similar classification (Boyce *et al.*, 2010). Where immunological

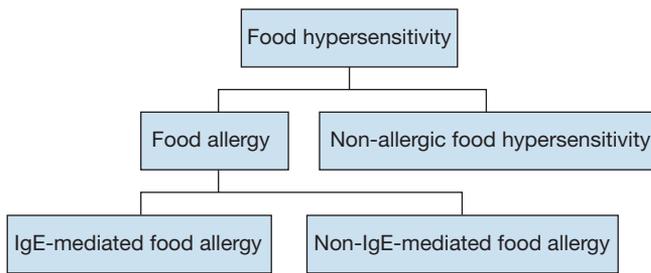

Figure 7.11.2 Proposed nomenclature for food hypersensitivity [European Academy of Allergy and Clinical Immunology Nomenclature Task Force Position Statement (Johansson *et al.*, 2004)]

mechanisms are involved, food hypersensitivity is defined as food allergy. The term immunoglobulin E (IgE) mediated food allergy is preferred when the involvement of food specific IgE antibodies has been demonstrated. Symptoms may be of rapid onset (IgE mediated, e.g. urticaria or anaphylaxis), but can also develop more slowly (non-IgE mediated, e.g. eczema, diarrhoea, vomiting and constipation) or may even be a mixture of both. Severe, generalised allergic reactions to food are classified as anaphylaxis. All other reactions, previously often referred to as food intolerance are classed as non-allergic or non-immune mediated food hypersensitivity. Such reactions may be due to non-immune mediated histamine release, pharmacological effects or enzyme deficiencies. They can be acute and severe (although rarely life threatening), but are more usually chronic and diffuse, and therefore often difficult to diagnose.

The main difference between food allergy and non-allergic FHS is that a protein interacting with the immune system causes food allergy, while non-allergic FHS is caused by other substances in food without immune system involvement. Both the European and US guidelines define coeliac disease as an immune mediated condition, and lactose intolerance as a non-immune mediated condition. The term food hypersensitivity will be used in this chapter according to the above EAACI definition (Figure 7.11.2).

Reactions to food may also be psychologically rather than physically based, i.e. they result from the emotional response to the thought of eating a particular food, and are termed food aversion. Food aversion is not classified as FHS and not discussed further in this chapter, but should always be considered when investigations of FHS are being made.

Food hypersensitivity mechanisms

Immune mediated food allergy

Food allergy results from a faulty and exaggerated response of the immune system following exposure to a foreign protein (allergen). The immune system can normally distinguish allergens that need to be destroyed, e.g. bacterial pathogens, from those that do not, e.g. food proteins, and can mount an appropriate response to protect the body from infection and damage. In addition,

the mucosal lining of the gastrointestinal tract provides a physical barrier to prevent large molecules such as proteins from entering the body.

Everyone is born with an innate immunity, but it is the cells of adaptive immunity that are involved in immune mediated FHS. The main protagonists are the T cell lymphocytes, which recognise and destroy allergens by producing cytotoxic substances or triggering inflammatory responses. When an allergen is encountered, naive T cells develop into either T helper 1 (Th1) or Th2 cells, depending on the presence of specific mediator proteins. The other cells involved in adaptive immunity are the B cell lymphocytes, which create antibodies (classes of immunoglobulin) to carry out further defensive reactions.

The immune system learns to do this in the early months of life, a process known as developing tolerance. If this learning process is faulty, an abnormal response to food proteins can occur, particularly to those that are encountered in early life when the immune system is still immature. Ingestion of the allergen triggers the production of inappropriately high titres of antibodies and/or altered T cell reactivity with consequent systemic effects.

IgE mediated food allergy

Food allergy is most common in atopic individuals. Atopy is defined as a predisposition to become sensitised and produce IgE antibodies to environmental proteins (Johansson *et al.*, 2004). It is clinically defined by a positive skin prick test and/or elevated allergen specific IgE to one or more common environmental allergens. IgE mediated allergy represents the clinical manifestation of an atopic predisposition and in addition to IgE mediated food allergy includes such disorders as asthma and rhinitis.

Classic IgE mediated food allergic reactions, such as those involved in peanut allergy, generally involve the production of Th2 cells. During the first exposure to a food allergen, Th2 cells stimulate B cells to switch from producing immunoglobulin M to immunoglobulin E (IgE), which is specific to that food protein. The IgE antibodies attach themselves to the surfaces of mast cells and blood basophils via a receptor (Maggi *et al.*, 1992; Sutton & Gould, 1993); a process known as sensitisation. The area on a food allergen that provokes the immune response is known as the epitope (Chapman *et al.*, 2006). Epitopes can be linear (sequential) or conformational. Linear epitopes are composed of short sequences of amino acids, most of which lie on the surface of the protein but which can also be hidden within the protein molecule, only becoming exposed when the protein is digested (thus being more likely to trigger delayed reactions). Conformational epitopes depend on the three dimensional structure of the protein because they are composed of amino acids from different parts of the protein sequence, brought together by folding. Due to their structural differences, linear epitopes are not usually affected by heat or proteolysis, whereas conformational epitope structures may be lost when a protein unfolds during cooking or digestion (Lin & Sampson, 2009). Those who experience a resolution of food allergy in

childhood or adolescence are more likely to be sensitised to conformational epitopes (Vila *et al.*, 2001; Jarvinen *et al.*, 2007). Epitopes from different food proteins can have a degree of amino acid sequence similarity, known as homology, which enables an IgE antibody specific to one allergen to bind with another structurally similar allergen epitope. Homologous epitopes are common in food allergy, and account for the cross reactivity between different foods and also between foods and pollens.

Many people may become sensitised to an allergen, but only a percentage will experience food allergic symptoms on subsequent exposure to that protein. Symptoms occur when the IgE antibody recognises the allergen and the allergen epitope attaches to the binding site of the antibody. Should the allergen succeed in binding to two IgE antibodies, cross linking them, the membrane of the mast cell perforates and preformed mediators, e.g. histamine and leucotrienes, are released. These mediators are responsible for classic IgE mediated food allergic symptoms; rapid onset sneeze, itch, red facial flush, hives and angioedema.

Non-IgE mediated food allergy

Non-IgE mediated allergy usually involves T cells (particularly the Th1 subset) and other inflammatory cells, e.g. macrophages and eosinophils. T cells become sensitised on initial exposure; subsequent contact with the allergen enables the epitope to combine with the sensitised T cells, which release cytokines, leading to chronic inflammation. Such reactions are usually delayed, although in some cases, patients may show a mixed pathology with both IgE mediated and cell mediated causes.

Figure 7.11.3 summarises the immune process involved in IgE and non-IgE mediated allergic reactions.

Non-allergic food hypersensitivity

Non-allergic food hypersensitivity encompasses a wide range of conditions, and therefore has a diverse set of triggers.

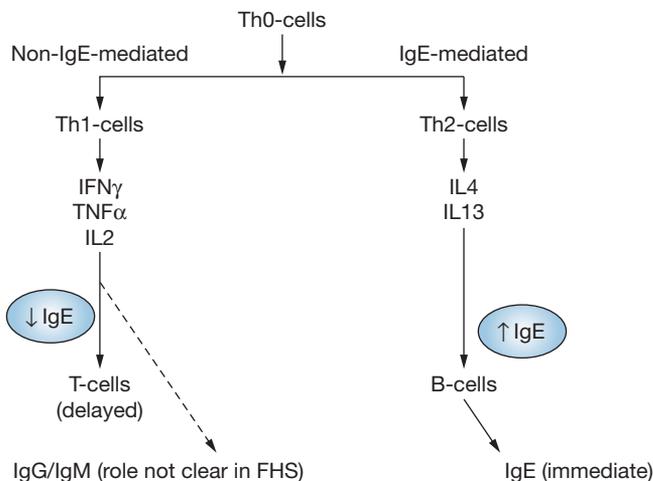

Figure 7.11.3 Food allergy – IgE and non-IgE mediated reactions

Th, T helper; IFN, interferon; TNF, tumour necrosis factor; IL, interleukin; FHS, food hypersensitivity

Mast cell activation

Mast cells can be directly activated by non-immunological mechanisms, with the subsequent release of histamine and other mediators provoking symptoms such as vomiting, diarrhoea and rashes. These symptoms can be severe and in some cases, hypotension and anaphylactoid reactions can occur. The main distinguishing feature from true allergy is that significant amounts of the offending food may be needed to cause a reaction, with symptom severity related to the amount ingested (in contrast to an immunologically mediated reaction where a massive effect can result from minute exposure). However, for practical purposes, this type of FHS is managed in the same way as food allergy. Shellfish and strawberries can both trigger such reactions.

Pharmacological reactions

Many foods and beverages contain substances that are pharmacologically active. Large intakes of, or undue sensitivity to, these substances can result in symptoms such as tremor, sweating, palpitations, headache or migraine, or psychological effects such as insomnia or anxiety. The most common triggers of pharmacological reactions are food additives and naturally occurring substances in foods, including biogenic amines, salicylates, caffeine, theobromines, benzoates, glutamates, nickel and alcohol.

Enzyme deficiencies

Partial or total deficiency of one or more enzymes in the digestive tract, e.g. lactase and disaccharidase deficiency, may result in symptoms of malabsorption when foods containing certain components are consumed.

Symptoms

Symptoms most commonly associated with FHS can broadly be divided into skin, gastrointestinal tract, respiratory system and systemic reactions (Table 7.11.4). These may occur within minutes, hours or days of ingestion.

IgE mediated food allergy

Symptoms suggestive of classic IgE mediated food allergy are acute, typical and may involve more than one organ. They may include one or more of the following: itching (pruritus), urticarial rash (hives), flushing, swelling, nausea, vomiting, abdominal pain, diarrhoea, asthma, rhinitis, tachycardia, hypotension, throat tightness, bronchospasm, shortness of breath, collapse and anaphylaxis. Anaphylaxis is a severe life threatening generalised or systemic hypersensitivity reaction that often includes multiple organ failure, hypotension and shock (Johansson *et al.*, 2001). In adults, mild oropharyngeal symptoms are the most common symptoms. They usually manifest as a condition known as oral allergy syndrome (OAS) (Amlot *et al.*, 1987), which is most often used as a diagnostic term for individuals with food allergy due to homologous epitopes in plant proteins that cause cross reactivity between pollen antibodies and plant food allergens

Table 7.11.4 Symptoms experienced with food hypersensitivity

Target organ	Symptoms
Skin	Pallor Erythema Pruritus Urticaria Angio-oedema Eczema Dermatitis herpetiformis
Gastrointestinal tract	Oral allergy syndrome Food protein enteropathy syndrome Gastro-oesophageal reflux Allergic eosinophilic gastroenteritis/oesophagitis Oral itch, throat itch, lip swelling Diarrhoea, nausea, vomiting Abdominal pain Enteropathy Proctocolitis Enterocolitis Coeliac disease Constipation
Respiratory tract	Heiner's syndrome Rhinorrhoea Asthma
Multisystem	Hypotension Anaphylaxis Exercised induced anaphylaxis
Controversial symptoms	Otitis media Hyperactivity Migraine/abdominal migraine Enuresis
Other	Irritability Listless with other symptoms

(Kondo & Urisu, 2009). The most common form of OAS involves pollen antibodies and is often called pollen food allergy or pollen food syndrome (PFS), to distinguish it from other forms of OAS (Holmann & Burks, 2008). It characteristically manifests in the form of mild to moderate pruritus of the palate, lips, tongue and throat, often accompanied by angio-oedema, numbness or tingling. The onset of IgE mediated food allergic symptoms are usually reported soon after ingesting the offending food, typically within 30 minutes of eating. Those with PFS usually report more rapid onset, most often on biting or chewing the foods (Skypala *et al.*, 2011).

Non IgE mediated food allergy

Both immediate and delayed onset reactions can occur in non-IgE mediated food allergy (Hill *et al.*, 1988). Symptoms may be more diffuse and often less easy to identify (or distinguish from non-allergic FHS). Non-IgE mediated food allergy commonly manifests in skin and gastrointestinal symptoms with mixed patterns of IgE and non-IgE mediated symptoms. There may be differences between children and adults. For example eosinophilic oesophagitis usually presents in children as abdominal pain and

vomiting, but in adolescents and adults, the most common presenting symptoms are dysphagia and food impaction (Noel *et al.*, 2004).

Non-allergic food hypersensitivity

Non-allergic FHS can manifest with similar symptoms to both IgE mediated or non-IgE mediated food allergy. Reactions are usually dose dependent and, although some reactions are delayed, others can occur immediately or within an hour of ingestion. Anaphylactic reactions are not seen with non-allergic FHS.

Triggers of food hypersensitivity reactions

Milk, eggs, peanuts, wheat, soya, tree nuts, fish and shellfish are all common childhood allergens (Bock, 1987). However, shellfish, fish, peanuts, tree nuts, fruit and vegetables are the usual triggers of adult onset IgE mediated FHS (Skypala, 2011). Milk is the food most commonly reported to provoke FHS reactions worldwide (Zuberbier *et al.*, 2004; Kanny *et al.*, 2001; Vierk *et al.*, 2007). More information on individual foods is detailed in the Management section.

Links to other conditions

Rhinitis

Allergic rhinitis is directly linked to food allergy due to the close homology between plant food proteins and pollen proteins. Schäfer *et al.* (2001) found that 73% of subjects reporting adverse food reactions also had allergic rhinitis. This may explain why PFS is the most prevalent food allergy in adults, affecting as it does people with concomitant seasonal allergic rhinitis (Katelaris, 2010). One-quarter of the UK population suffers from allergic rhinitis (Bauchau *et al.*, 2004), one-quarter of whom are likely to be allergic to tree pollen (Royal College of Physicians, 2003). It is known that two-thirds of those with tree pollen allergy are likely to have PFS (Skypala *et al.*, 2011). The incidence of reported allergic rhinitis has trebled in the last three decades in the UK (Gupta *et al.*, 2007). Ziska & Beggs (2012) suggest that climate change and increasing atmospheric carbon dioxide concentrations are likely to affect the severity and prevalence of allergic diseases linked to aeroallergen exposure in the future.

Asthma

Approximately 5.2 million people in the UK suffer from asthma, with about 20% being children (Asthma UK, 2004). Although IgE mediated reactions to foods can involve symptoms of both the upper and lower respiratory tract, asthma is not commonly exacerbated by FHS, except for occupational asthma in relation to food such as wheat flour (baker's asthma). There is a relationship between asthma, allergic rhinitis and food allergy in school age children (Penard-Morand *et al.*, 2005); and having a food allergy is independently associated with life

threatening asthma in children (Roberts *et al.*, 2003). Asthmatic adults, who have multiple food allergies or fish allergy, may have an increased risk of hospitalisation and use of oral steroids (Berns *et al.*, 2007). The association between asthma and food allergy persists into old age. Food allergic patients with asthma are more likely to suffer from fatal or near fatal food anaphylaxis. This highlights the need for all asthmatics with food allergy to have a robust food allergy management plan (Colver *et al.*, 2005).

Eczema

Eczema is associated with food allergy, allergic rhinitis and asthma (Burks, 2003). Many children with food allergy also have eczema, and many with adult onset food allergy had eczema as children. Eczema may be exacerbated by food allergic reactions within 2 hours of consuming the relevant food allergen, but more commonly the onset is delayed. It is considered that over 90% of atopic eczema in infants is caused by milk, egg, peanut and soya (Hill *et al.*, 2008), although egg is the most common offender. Other foods such as wheat, tree nuts and seafood may be responsible for reactions in older children and adults (Burks, 2003). However, it has also been shown that some eczematous reactions in those who have pollen food cross reactive allergy could be due to late phase reactions to cooked foods known to provoke symptoms when raw (Bohle *et al.*, 2006).

Gastrointestinal disease

Food hypersensitivity has been linked to a number of diseases of the gastrointestinal tract (see Chapters 7.4) (Lomer, 2009).

Migraine

A close association between migraine and allergic disease has been shown in a number of studies (Aamodt *et al.*, 2007), although it has been suggested that dietary restrictions are not beneficial in most migraine sufferers (Holzhammer & Wober, 2006). A summary of the effects of diet on migraine can be found in Luscombe & Thurgood (2009).

Hyperactivity and behavioural disorders

A meta analysis found a significant effect of artificial food colours on behaviour in hyperactive children (Schab & Trinh, 2004). A study investigating the effect of oral challenges with artificial food colourings and benzoates on hyperactivity in 3-year-old children found behaviour changes when assessed by parentally kept behaviour diaries (Bateman *et al.*, 2004). A follow-up study involving 3- and 8-year-old children taking two different additive mixes suggested that artificial colours or sodium benzoate preservative (or both) in the diet increased hyperactivity (McCann *et al.*, 2007).

Chronic disorders

People with chronic fatigue syndrome/myalgic encephalomyelitis (CFS/ME) often report experiencing FHS (NICE, 2007), although research evidence suggests that IgE mediated allergy is no more common in people with CFS/ME than in the normal population (Kowal-Krzysztof *et al.*, 2002) (see Chapter 7.6.5). Further information can be found in Luscombe & Thurgood (2009).

Disease consequences

Food hypersensitivity can have severe consequences; those diagnosed with food allergy may need to carry adrenaline (epinephrine) in case of a severe reaction that can happen unexpectedly at any time. Food accounts for 33–61% of all causes of anaphylaxis, with over a third of reactions treated as emergencies and most often due to peanuts, tree nuts, fish or shellfish (Pumphrey & Stanworth, 1996; Mullins, 2003). Although mortality is low and only 25% of all fatal anaphylaxis due to food, age range data for fatalities following anaphylaxis suggest that an increasing number of severe reactions to food are suffered by a greater number of younger people, including teenagers and children (Pumphrey, 2000). Morbidity is high and living with a food allergy has been shown to have a well defined effect on quality of life. Childhood food allergy has a significant impact on general health perception, emotional impact on the parent and limitation on family activities (Sicherer *et al.*, 2001b). Parents find shopping for foods for children on restricted diets very difficult, time consuming and confusing, particularly when products which would not be expected to contain nuts have a warning on the label (Food Standards Agency 2009). Results from validated health related quality of life (HRQL) questionnaires found that adolescents and adults with food allergy report more pain, poorer overall health, more limitations on social activity and less vitality when compared with the general population (Flokstra-de Blok *et al.*, 2010). Those who have reintroduced foods back into their diet following a negative oral food challenge report a general improvement in their social life (Eigemann *et al.*, 2006). The need to fit in with peers may lead some adolescents and young adults with food allergy to take risks, knowingly and purposefully ingesting potentially unsafe foods and not always carrying medication (Sampson *et al.*, 2006).

Prevention

Genotype, exposure to allergens and development of the immune response are involved in the development of allergic disease. Infants born to families with a history of atopy are more at risk of developing allergic diseases than those born to non-atopic families with genetic influences (Kjellman, 1977). Despite a large body of published research, the role that the maternal diet during pregnancy and breastfeeding plays in the development of allergic disease is still unknown; the same is true for feeding and weaning practices.

Maternal food intake in pregnancy

Maternal dietary intake has been extensively researched. The effect of dietary exclusion, or the intake of dietary fats, fruit and vegetables and fatty acids/fatty fish and fish oil supplements during pregnancy and lactation have all been studied. None of these studies has led to any recommendations of dietary changes during pregnancy in order to prevent allergic disease. Similarly, studies examining probiotic supplementation during pregnancy and/or the infant's first 6 months of life in high risk families have been inconclusive.

Vitamin D

Vitamin D has important effects on immune function (Cantorna *et al.*, 2004). Observational studies (Camargo *et al.*, 2007; Devereux *et al.*, 2007; Miyake *et al.*, 2010; Erkkola *et al.*, 2009) support the hypothesis that vitamin D intake in pregnancy may prevent the infant from developing wheeze, asthma and rhinitis in later childhood; the effect on eczema is not completely clear. However, Hypponen *et al.* (2004) reported that the prevalence of atopy, allergic rhinitis and asthma in adults was higher in those who had received vitamin D supplementation regularly during the first year of life. This paradox may be due to a threshold effect, with both low and high serum vitamin D levels affecting the development of allergic disease (Hypponen *et al.*, 2009). Supplementation during early life was provided at much higher levels than reported in the observational studies during pregnancy.

Antioxidant intake

High maternal dietary intakes of antioxidants, specifically vitamin E, during pregnancy were associated with a decreased response to allergens, which may influence the foetal immune system and affect the risk of childhood atopy (Devereux *et al.*, 2006). The strongest benefit appears to be from maternal vitamin E intake during pregnancy, which was associated with a reduction of wheeze/asthma at in offspring at the ages of 1, 2 and 5 years (Martindale *et al.*, 2005; Litonjua *et al.*, 2006).

Vitamin C could also have a pro-oxidant effect, which may have a negative impact on allergy risk. Thus, a low maternal intake of vitamin C coupled with a high intake of saturated fats during breastfeeding could increase the risk of infant allergies (Hoppu *et al.*, 2000). A higher concentration of vitamin C in the breast milk of atopic mothers was associated with a reduced risk of eczema and a positive skin prick test at 12 months; dietary intake rather than supplements determined the concentration of vitamin C in breast milk (Hoppu *et al.*, 2005).

Breastfeeding and maternal diet whilst breastfeeding

Two systematic reviews (Mimouni *et al.*, 2002; Gdalevich *et al.*, 2001) concluded that exclusive breastfeeding might have some protective effect on the development of allergic disease, which is greater when there is a family history of atopic disease. However, up to one-third of infants with a cow's milk allergy will develop it despite exclusive

breastfeeding, probably due to the cow's milk protein in breast milk. Therefore, whether breastfeeding protects against allergic disease needs further research.

Intervention studies in high risk infants

A number of randomised controlled trials in high risk infants have investigated the effect of different dietary allergy prevention programmes during pregnancy, breastfeeding or both. A review by the EAACI concluded that there is no evidence for maternal dietary intervention during pregnancy or lactation in the prevention of allergic disease (Muraro *et al.*, 2004). A systematic review showed that maternal allergen avoidance during pregnancy may be associated with a higher risk of preterm birth and a possible adverse effect on birth weight. Dietary interventions during lactation only did not show any adverse nutritional effects (Kramer *et al.*, 2006).

Use of infant formulae

In an attempt to avoid exposure to milk protein early in life, hydrolysed formulae (extensive or partial) have been investigated as replacement or supplement to breast milk. Studies (von Berg *et al.*, 2003; 2007; 2008) have compared standard cow's milk formula, extensively hydrolysed casein (eHF C), extensively hydrolysed whey (eHF W) and partially hydrolysed whey (pHF W). At 1 year, fewer allergic manifestations were found in the infants receiving eHF C than cow's milk formula, and also less eczema in pHF W and eHF C fed infants than those receiving cow's milk formula. Results from other studies suggest that protein hydrolysates reduce allergic manifestations during the high risk infant's first few years as either a replacement or supplement to breast milk. The nutritional adequacy of these formulae is sufficient for the needs of infants (Hernell & Lonnerdal, 2003), but could lead to insufficient weight gain (Isolauri *et al.*, 1998).

Reviews regarding dietary allergy prevention have been published by the American Academy of Pediatrics (Greer *et al.*, 2008), EAACI (Host *et al.*, 2008) and the European Society for Paediatric Allergology and Clinical Immunology Committee on Hypoallergenic Formulas and the European Society for Paediatric Gastroenterology, Hepatology and Nutrition Committee on Nutrition (Host *et al.*, 1999). The recommendations from these reviews are summarised in Table 7.11.5.

Infant weaning practices

The Department of Health (2009a) and other UK health departments state the introduction of complementary foods should start around 6 months of age. There are some foods that should be avoided before 6 months as they may cause allergies or make the baby ill, namely wheat based foods and other foods containing gluten, eggs, fish, liver, shellfish, nuts, peanut and peanut products, seeds, cow's milk and soft and unpasteurised cheeses. For high risk infants, the following information has been adapted from the British Dietetic Association's

Table 7.11.5 Allergy prevention advice

	AAP position statement	ESPACI/ESPGHAN (1999)	EAACI (2008)
Who is at risk?	If both parents or parent and sibling have documented allergic disease	If have one affected parent or one affected sibling	If have one first degree relative with documented allergic disease
Breastfeeding recommendations	Exclusive breastfeeding up to 6 months	Exclusive breastfeeding 4–6 months	Exclusive breastfeeding, preferably for 6 months but for at least 4 months
Alternatives if breastfeeding not possible or insufficient	Use an eHF, but a pHF could be considered	Use formula with proven reduced allergenicity	Use an eHF until 4 months of age. A pHF may have an effect, although it seems to be less effective than eHF

AAP, American Academy of Pediatrics; ESPACI, European Society of Pediatric Allergology and Clinical Immunology; ESPGHAN, European Society for Pediatric Gastroenterology, Hepatology and Nutrition; EAACI, European Academy of Allergology and Clinical Immunology; eHF, extensively hydrolysed formula; pHF, partially hydrolysed formula.

Food Allergy and Intolerance Specialist Group (2012) position statement on allergy prevention for high risk infants.

Time to wean

The introduction of complimentary food from about 6 months is desirable, but if weaning takes place earlier, it should never occur before 17 weeks (Agostoni *et al.*, 2008). By 6 months weaning should commence and the appropriate textures (Department of Health, 2009a; British Dietetic Association, 2013) and variety of flavours should be introduced to desensitise the child's palate (Mason *et al.*, 2005). Weaning should commence with what are traditionally considered to be low allergenic weaning foods such as rice, potatoes, root and green vegetables, apple, pear, banana and stone fruit given individually or in combination (Martindale *et al.*, 2005). The importance of continuing to breastfeed whilst solids are introduced is being further researched as some research has shown that continuing to breastfeed whilst solids are introduced reduces the risk of reactions to food (Ivarsson *et al.*, 2002; Poole *et al.*, 2006).

Introduction of allergenic foods

A European Union (EU) directive (2007) lists 14 foods or food additives identified as being the source of the majority of adverse food reactions. These are peanuts, tree nuts, sesame seed, mustard seed, cow's milk, eggs, fish, crustaceans, soya, wheat, celery, lupin, molluscs and sulphites. There is no need to delay the introduction of the foods on this list beyond 6 months (Zutavern *et al.*, 2008; Filipiak *et al.*, 2007). It is advisable to introduce these foods in categories, e.g. introduce wheat as one category by giving pasta, bread and other suitable wheat based products over a 2–3-day period (Maier *et al.*, 2008). Introduction should start with a small amount and no more than one new allergenic food at a time, and allow at least 3 days between each new food group in order to enable easy identification of any resulting reactions. The food categories include wheat, well cooked egg, cow's milk (as part of the diet rather than the sole source of nutrition), fish, shellfish and soya products, followed by the other major allergenic foods, should they form a part of the

family diet. Peanuts can be introduced into the diet of high risk infants after discussion with a GP, health visitor or medical specialist that it is safe to do so (Department of Health, 2009b).

Nutritional consequences

The avoidance of major food groups by patients with adverse reactions to foods, prior to diagnosis can have a deleterious effect on nutritional status (Fox *et al.*, 2004; Noimark & Cox, 2008). Children with FHS may be substantially affected by the removal of one or more food groups due to the requirements of normal growth and development. Flammarion *et al.* (2011) report that despite energy, protein and calcium intakes being similar, children with food allergy had weight for age and height for age Z scores lower than controls. Adults are most likely to be at nutritional risk if they are avoiding milk or wheat due to confirmed FHS or a self imposed elimination diet, or multiple foods due to OAS or of salicylates or vasoactive amines (des Roches *et al.*, 2006). Milk avoidance is especially common in patients with asthma (Wüthrich *et al.*, 2005); such individuals may be at greater risk of poor bone density if calcium intakes are not optimal, especially in those prescribed regular corticosteroids (Kershaw, 2009). Those who avoid one or more foods for some time prior to referral could be at greater risk of a suboptimal nutritional intake. Vieira *et al.* (2010) found that on referral the infants with suspected cow's milk allergy already had low weight for age and low height for age Z scores. Adults newly diagnosed with coeliac disease may present with nutritional deficiencies such as anaemia (low iron), vitamin B₁₂ or folate, and so should receive a nutritional assessment in order to determine any deficiency (McGough *et al.*, 2009). Deficiencies in micronutrients in the elderly, especially zinc, iron and vitamin D, may contribute to the development of allergies (Diesner *et al.*, 2011). There is a growing appreciation of the importance of vitamin D in the development of tolerance, immune system defences and epithelial barrier integrity. Vassallo & Camargo (2010) suggest that, concurrent with the increase in FHS, there is an epidemic of

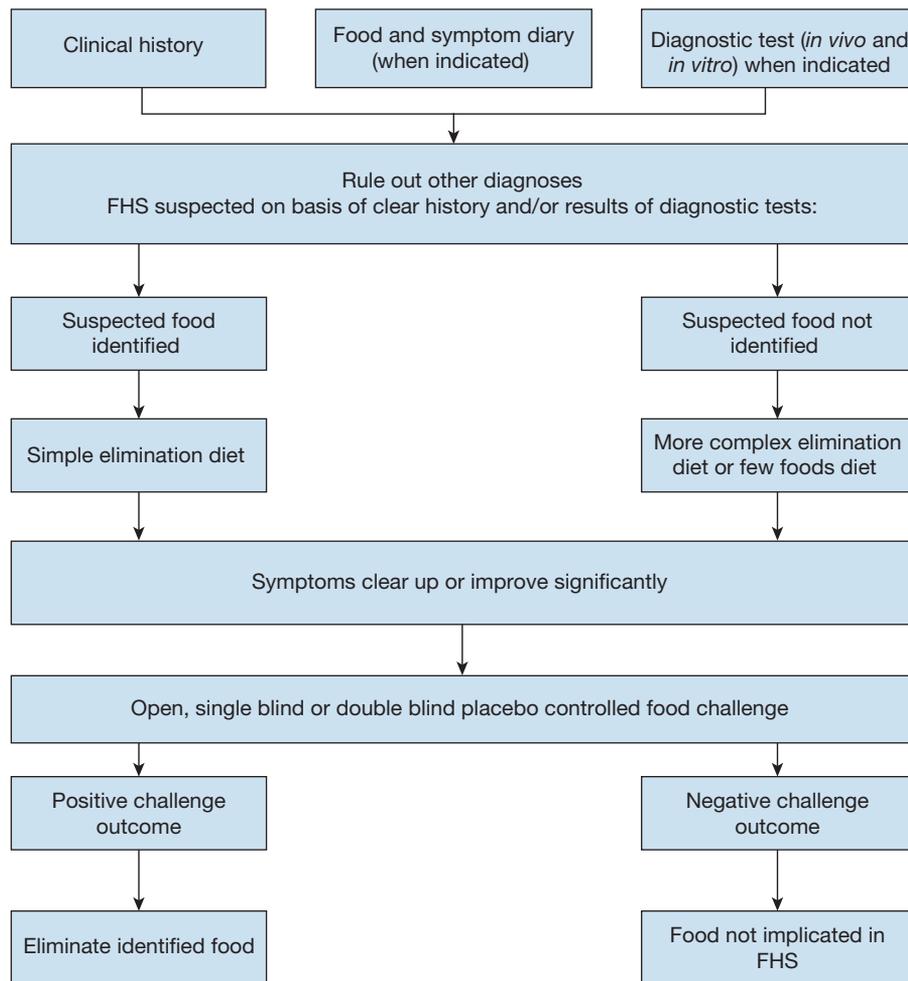

Figure 7.11.4 Algorithm for the diagnosis of food hypersensitivity (FHS) [adapted from Muraro *et al.* (2004)]

vitamin D deficiency caused by decreased sunlight/ultraviolet B (UVB) exposure.

Diagnosis

The first step in the diagnostic pathway is the ascertainment of the problem through the taking of an allergy focussed diet and clinical history, followed by appropriate tests, including the gold standard of the oral food challenge. The correct diagnosis of FHS is complex, and a definitive diagnosis may be difficult to achieve due to the paucity of validated tests and unavailability of oral food challenge facilities. Failure to diagnose FHS, due to negative test results, could risk further potentially severe or even fatal reactions or ongoing chronic disease. Alternatively, a diagnosis achieved on the basis of positive non-validated tests can result in unnecessary restrictions on lifestyle and possible disease from nutrient restriction. A robust diagnostic process is key since <50% of patients reporting reactions to foods are diagnosed with FHS (Seitz *et al.*, 2008). Venter *et al.* (2006a,b; Pereira *et al.*, 2005) have demonstrated that only 12–21% of children and adolescents reporting food allergy were diagnosed with food allergy confirmed by double blind placebo con-

trolled food challenge (DBPCFC). Diagnosis in children is now the subject of NICE (2012) guidance. The dietitian plays a key role in ensuring that a thorough clinical history and relevant tests have been undertaken, so that consideration may be given to the requirement for an elimination diet or supervised oral food challenge in order to confirm or refute a diagnosis. An algorithm of FHS diagnosis is shown in Figure 7.11.4.

Clinical history

Taking a detailed dietary and medical history, together with a physical examination, are essential first steps in the diagnosis of FHS. The information may vary depending on the age of the patient, but the following information should be elicited:

- Current daily dietary intake and pattern, including those foods currently being avoided and those included in the diet.
- Detailed history of any known food reactions, including food eaten, length of time between consumption and symptoms.
- Symptom type and affected organs.

- Suspected food triggers and the quantity likely to elicit a reaction.
- Other known allergies.
- Family history of allergy.

This information will enable the formation of a working diagnosis, inform decisions on diagnostic testing or food elimination and provide useful information for performing a food challenge should this be required. Cross reactions, inaccurate recollection of events and the involvement of multiple foods or the presence of cofactors can confound the clinical history. Therefore, as a supplement to taking a verbal history, diet and symptom diaries may help to identify problem foods, but their efficacy has not been formally assessed. There is little robust evidence to support the role of clinical history in FHS diagnosis, but its use is supported by experts in the field, provided it is not used as a sole diagnostic tool (Boyce *et al.*, 2010). However, validated diagnostic questionnaires have been shown to be effective in the diagnosis of some types of FHS such as OAS (Skypala *et al.*, 2011).

Diagnostic tests

An oral food challenge is considered the definitive test for those with a history of immediate adverse foods reactions in order to establish or exclude a diagnosis of food allergy. However, it is helpful to know whether the presence and level of specific IgE antibodies, bound to mast cells in the skin or circulating in the blood, correlate with clinical history to a sufficient degree to be diagnostic. A negative test suggests that the reaction is less likely to be IgE mediated, but it cannot rule out a diagnosis of FHS.

Skin prick tests

Skin prick tests (SPTs) measure specific IgEs attached to mast cells in the skin and provide an easy method to screen patients of all ages with suspected IgE mediated sensitivity to foods. The skin is pricked through a drop of food extract reagent and any resultant wheal measured against the results of a positive (histamine) and negative (saline or diluent) control. The positive control gives an indication of skin reactivity and the negative control can identify patients with dermatographism (skin reactions to any contact, including the prick with a lancet and not necessarily the allergen applied). In general, allergens eliciting a wheal of 3 mm or greater in diameter than the negative control are considered positive (Bindsvlev-Jensen *et al.*, 2004). However, some recommend the use of a cut-off of 2 mm in children, especially those younger than 6 months. Skin prick tests have a negative predictive value (NPV) of 95% or more (Sampson, 2004) and are therefore extremely useful in ruling out IgE mediated food allergy. However, since 5% of those with a negative test may have a food allergy, negative results should be verified by other tests such as specific IgE testing or an oral food challenge, especially if severe symptoms have been reported. The predictive value of a positive test is low; only 50–60% of those with positive tests will have a positive oral food challenge (Bock *et al.*, 1988). The reason for this is that

a positive test could indicate sensitisation to a food and needs to be of a convincing wheal size and linked to a positive clinical history for that food before it can be considered diagnostic.

Most SPTs are undertaken using purified allergen extracts; however, the allergen content of such extracts can be variable, making them unreliable for certain foods (Akkerdaas *et al.*, 2003). Fresh foods can be used in place of reagents, a procedure known as prick to prick testing (PPT), and may give a more accurate result (Rancé *et al.*, 1997), even though they lack standardisation.

Specific ige tests

Specific IgE tests quantify the level of circulating IgE antibodies specific to a particular food. As with SPTs, the presence of specific IgE in the blood indicates sensitisation but not necessarily clinical allergy. Specific IgE tests are often referred to as radio allergosorbant (RAST) tests, although the technology used now measures fluorescent enzyme labelled IgE (CAP RAST FEIA) and is usually called an immunoassay. Specific IgE is measured as kilo units of allergen per litre (kU_A/L; a test is classed as positive if the result is >0.34 kU_A/L. Some laboratories still grade results 0–6, where 0 is <0.34 kU_A/L. The negative predictive value of immunoassays are similar to those for SPTs, but negative tests need to be interpreted with the history as undetectable serum food specific IgE levels might occur in 10–25% of clinical reactions, depending on the food involved (Ives & Hourihane, 2002).

Guidelines suggest that SPTs and specific IgE estimation are interchangeable and either can be used to good effect with clinical history. However, a positive SPT may not always be confirmed by a corresponding positive serum specific IgE result; research suggests there is a correlation between the wheal size of SPTs and specific IgE levels in children but not in adults (Pongracic *et al.*, 2007). Skin prick tests are often a first line test due to their ease of use, low cost and immediate results. However, specific IgE blood tests may be more universally available, especially in primary care, and are useful for patients with severe eczema, those who have dermatographism or cannot discontinue antihistamines.

Several studies have examined the predictive value of SPT wheal diameters and specific IgE levels, but there is some variance in the results, which appears to suggest they may be specific to particular populations [see Venter *et al.* (2009) for further information]. Whilst SPTs and specific IgE tests are good first line tests for the diagnosis of IgE mediated food allergy, they are not useful in the diagnosis of delayed type/non-IgE mediated food allergy or non-allergic FHS due to the absence of the involvement of IgE antibodies in these conditions.

Diagnosis using individual allergens

A major advance in the diagnosis of FHS has been the sequencing of allergens and allergen epitopes, which has demonstrated that certain allergens or epitopes are linked to allergen severity and the likelihood of resolution (Vila *et al.*, 2001; Jarvinen *et al.*, 2007; Ando *et al.*, 2008). This technology can also aid diagnosis to foods

which currently have a poor positive predictive value, e.g. soya and wheat (Palosuo *et al.*, 1999; Ballmer-Webber *et al.*, 2007). They can also be used to differentiate between a primary allergy to peanuts or tree nuts and symptoms caused by cross reactions to tree and grass pollen in adults. Although early results are promising, this technology is not available to all practitioners involved in the diagnosis of FHS. It also does not overcome the common difficulty of sensitisation without clinical symptoms, which is widespread in populations and can make positive test results difficult to interpret (Ott *et al.*, 2008; Scala *et al.*, 2010; Ebo *et al.*, 2009).

Atopy patch tests

Atopy patch testing involves food allergens being applied to a healthy area of the patient's skin and the effects evaluated 48–72 hours later. Patch tests are usually used to determine the cause of delayed allergic reactions such as contact dermatitis, e.g. to nickel. It has been suggested that combining the patch test with specific IgE estimation improves the sensitivity and specificity of SPTs and specific IgE test, especially to foods with a poor PPV such as wheat (Niggemann & Beyer, 2005; Allen *et al.*, 2006). However, specialist evaluation is needed to distinguish between allergic reactions and simple irritant ones.

Other tests

Principal amongst the commercial tests are those measuring IgG antibodies. A European position paper published in 2008 stated that this test is not recommended as a diagnostic tool (Stapel *et al.*, 2008): a stance subsequently supported in the USA (Bock, 2010). Similarly, other tests including the leucocyte cytotoxic test, hair analysis, bioresonance diagnostics, auto homologous immune therapy, kinesiology, iridology, sublingual provocative food testing, homeopathic remedies and electro dermal testing (including electro acupuncture and Vega testing), are not valid diagnostic tests for any type of FHS (Niggemann & Grüber, 2004).

Diagnostic exclusion diets

For many patients diagnosis can only be made by means of a combination of clinical history and dietary investigations (diagnostic exclusion diets). A successful elimination diet will improve or resolve the symptoms. There are four types of diagnostic exclusion diets (Grimshaw, 2006).

Single exclusion diet

This excludes all sources of a single food, e.g. milk, as identified from the patient's dietary history.

Multiple food exclusion diet

This excludes a number of foods at the same time, most commonly milk and egg for eczema (Isolauri & Turjanmaa, 1996), and milk, egg and wheat for eosinophilic diseases (Spergel *et al.*, 2002). The major food allergens (peanuts, tree nuts, sesame seed, mustard seed, cow's milk, eggs, fish, shellfish, soya, wheat, celery, lupin, mol-

lusc and sulphites) (European Union, 2006) are usually the first foods to be avoided during a multiple food exclusion diet. The number and combination of foods avoided will depend on the symptoms, and often reflect clinical practices rather than research. Pork, bacon, liver and offal, maize/corn, citrus fruit, berries, potatoes, tomatoes, onions, herbs and spices, chocolate, food colours and food preservatives may also be excluded.

Few foods (oligoallergenic) diet

This includes only a few foods that are known to rarely cause allergic symptoms in the population and are not regularly eaten by the patient. It generally includes two meats (lamb and turkey), two starches (rice and corn), two fruits (pears and nectarines), two vegetables (sweet potato and butternut squash) and only water as a drink (Ventner, 2007). Sometimes a less restrictive few foods diet may be used, particularly if it will improve patient compliance (Table 7.11.6).

Elemental and protein hydrolysate formula diets

Amino acid based formulae are used in infants and young children; elemental feeds are used in older children and adults. These drinks can be used in infants and children in the diagnosis of a range of diseases. In adults these diets are often used in the diagnosis of severe allergic symptoms or in patients suffering from a range of reported food intolerances to establish if food consumption does play a role in their symptoms (Ventner, 2007).

For all exclusion diets, dietetic expertise is key in ensuring patients are educated regarding food avoidance, label reading, suitable alternatives and a healthy balanced diet, despite the dietary restrictions. Non-dietary sources of substances that can provoke reactions may also need to be excluded, but this is very individual and may not always be necessary. Patients should keep a food and symptom diary whilst on the diet in order to monitor both adherence to the dietary advice and any changes in symptoms.

Oral provocation tests

If symptoms improve, dietary exclusion needs to be followed by the reintroduction of the food either during a food challenge (hospital or home) or a reintroduction plan at home. Patients with a history of immediate symptoms or a positive SPT/specific IgE test should be challenged in a hospital setting. All other patients can undergo a food challenge at home or a food reintroduction plan but only if there is no risk of the patient developing immediate severe symptoms (Venter *et al.*, 2009; Allen *et al.*, 2009).

Many clinicians argue that a food challenge is risky and perhaps should not be performed; however, no fatal reactions during a food challenge have been reported in the USA since 1976 (Nowak-Wegrzyn *et al.*, 2009). Zijlstra *et al.* (2009) reported that the high anxiety levels shown by parents of children with suspected nut allergy were significantly reduced after challenge, even in the group with a positive outcome.

Table 7.11.6 Less restrictive few foods diet (Vikerstaff Joneja, 1998)**Meat and alternatives**

Lamb
Turkey
Chicken

Starchy foods

Rice (white), pudding rice, rice noodles, rice cakes – plain, Rice Krispies
Cornflour, corn flakes, maize flour, polenta – (not sweetcorn)
Potatoes (no skin) – cooked in any way as long as permitted margarines or oils are used in their preparation
'Kettles' potato chips, only lightly salted flavour
Oven chips or micro chips with no preservatives added

Fruit

Pears
Nectarines
Peaches
Mango
Fruit should be washed thoroughly and peeled before it is eaten
Tinned fruit in syrup or fruit sorbet made from the allowed fruit is acceptable, but make sure that no preservatives or colourings have been added

Vegetables

Carrots
Parsnip
Greens – only broccoli, marrows and courgettes
Swede
French beans
Squash
Sweet potatoes

Milk substitutes

Rice milk with added calcium

Fats and oils

Margarine made from vegetable oil, e.g. Pure, Granose vegetable margarine, Vitaquelle or Vitaseig
Supermarket's own brand of milk free/soya free margarines.
Soya margarines are not allowed
Any oil, e.g. sunflower, olive, rape seed, vegetable, will be suitable.

Flavourings

Sea salt and pepper in moderation
Herbs – mint, parsley, sage, thyme, basil, oregano, rosemary
We do not recommend using a lot of herbs, just a little bit of your favourites

Drinks

7-Up (non diet) limit to 1–2 cans/day
Water (filtered if possible)
Juices from allowed fruit but make sure that they do not contain any colourings or preservatives

Acceptable grains and flours

Potato flour, rice flour, cornflour, arrowroot, sago, tapioca, millet, buckwheat

Baking aids

Cream of tartar, sodium bicarbonate, pectin

Adding extra calories to food

Sugar, golden syrup

No other foods are allowed at all

This includes sweets, chewing gum, popcorn or corn snacks, fizzy drinks or squashes (and alcoholic drinks)
This also means no milk or any dairy products.
No vinegar or bottled sauces are allowed

Suitable gluten and wheat free products that may be purchased from your pharmacy

Ener-G Rice loaf
Ener-G Rice pasta
Glutano Gluten free pasta
Glutano Crispbread
Trufree Cake mix
Trufree Pastry mix
Dr. Schar Mix A – Cake mix
Dr. Schar Mix C – Flour mix for cooking

Basic instructions

- You will have started by following the *observation phase* for 7 days, recording foods and drinks normally taken and symptoms experienced on your normal diet.
- During the observation phase you will have time to plan and shop ahead. It will be necessary to have plenty of appropriate foods to hand.
- The menu is simple – without spices, butter or condiments.
- Do not start at Christmas or around birthdays.
- Use as many fresh food sources as possible.
- Frozen food is the next best alternative.
- You may initially feel worse, but your symptoms should improve within 3–4 days.

This diet should always be followed under the supervision of your dietitian

Foods will be reintroduced one at a time after a * day period
Please do not hesitate to contact the dietitian on: *

*Number of days and contact details to be supplied by local practitioners.

Box 7.11.1 Example of a one day open challenge procedure for immediate type symptoms (Venter *et al.*, 2009)

Cow's milk

For infants <6 months: use any cow's milk formula

All other children and adults: use skimmed cow's milk

Place 1 drop of cow's milk on lower oral mucosa of the patient

10 minutes' observation

If no reaction, proceed to:

0.5 mL of cow's milk to be drunk

15 minutes' observation

1 mL of cow's milk to be drunk

15 minutes' observation

2 mL of cow's milk to be drunk

15 minutes' observation

5 mL of cow's milk to be drunk

15 minutes' observation

10 mL of cow's milk to be drunk

15 minutes' observation

15 mL of cow's milk to be drunk

15 minutes' observation

25 mL of cow's milk to be drunk

15 minutes' observation

40 mL of cow's milk to be drunk

2 hours' observation

For adults and children:

100–200 mL of cow's milk to be drunk (can use cow's

milk formula for children <1 year) or 100–200 mL of yoghurt

2 hours' observation

Food challenges should be performed in the following circumstances (Nowak-Wegzyn *et al.*, 2009):

- Where there is a strong suspicion of allergy, but history or tests do not support the suspicion, or when no other tests are available.
- To demonstrate food tolerance when there is sensitisation to a food that has not been eaten before, cross reactivity is suspected or food processing might enable consumption, e.g. fruit and vegetables that may be tolerated in cooked form in the pollen food allergy syndrome. Also used to ascertain tolerance in cases where there is either no sensitisation to the food but the family is anxious about introducing it at home (usually when another sibling has an allergy or intolerance) or there has been resolution of delayed symptoms on avoidance of a number of allergens, i.e. there is a need to identify the culprit foods.
- To monitor sensitisation/therapy strategies, such as oral sublingual therapy or drug trials; and the management of food allergies or intolerances in cases where the SPT or specific IgE levels have reduced to such an extent that tolerance is highly possible or accidental ingestion of the allergen without any clinical reaction.
- To determine the tolerance level to a food.

Reasons for deferring a food challenge include the following (Nowak-Wegzyn *et al.*, 2009):

- High likelihood of reacting to the food as predicted by a food reaction history, such as a recent accidental ingestion provoking a reaction, increasing levels or high predictive levels of food specific IgE antibody and the patient's age.
- High risk of anaphylaxis, such as a recent convincing anaphylactic reaction to the food or unstable asthma.
- Medical conditions and medications that may interfere with treatment of allergic reactions, e.g. cardiovas-

cular disease, pregnancy or treatment with beta-blockers, and medical conditions that may preclude interpretation of the OFC, e.g. uncontrolled eczema and severe allergic rhinitis.

- Infant or young child is unlikely to cooperate with the challenge, unless special arrangements can be made to provide a longer time to complete the feeding and to provide an adequate observation period.

Food challenges

There are three types of food challenges:

Open food challenges

Both the patient and the clinician performing the challenge know the ingredients of the challenge food, e.g. peanut flapjack used for a peanut challenge (Box 7.11.1).

Single blind placebo controlled food challenges

The challenge, e.g. liquidised egg mixed with a fruit purée or compote, is administered without the patient knowing which dose is active and which is placebo, i.e. the patient is blind but the healthcare professional is not. This type of food challenge is particularly useful when dealing with highly anxious children or adults who have major concerns about ingesting the particular food.

Double blind placebo controlled food challenges

During this challenge neither the patient nor the investigator knows when the active or the placebo challenge is performed. This rules out measurement and reporting bias from the observer and the psychological effect from the patient.

The open food challenge is the challenge of choice in most cases when dealing with adults or children suffering from objective symptoms e.g. urticaria, angioedema etc.

(Venter *et al.*, 2007a). Blinded challenges are preferable when dealing with adults or children reporting subjective symptoms (abdominal pain, nausea, headache) or symptoms that are difficult to assess due to the nature of the disease, e.g. eczema.

For research purposes, a double blind placebo controlled food challenge (DBPCFC) is still the preferred method of choice (Bock *et al.*, 1988; Bindslev-Jensen *et al.*, 2004; Sampson *et al.*, 2012) as it is considered the gold standard for diagnosing FHS. This type of challenge is rarely used in clinical practice in the UK as it is costly and labour intensive. For a detailed discussion regarding oral food challenges in cases of chronic urticaria, recurrent angioedema and non-allergic asthma, see Reese *et al.* (2009).

Step wise approach in the planning of a food challenge

History

This should consider:

- Age and age of onset help determine how difficult it may be to perform the food challenge and also the possible food causing the symptoms.
- Food type, e.g. raw or cooked egg, and quantity causing symptoms (helps prevent false negative food challenges).
- Symptoms – speed of onset, type, duration and reproducibility of reactions.
- A thorough description of the most recent reaction – helps when designing challenges.
- Cofactors – whether a combination of foods, or the trigger food taken together with exercise, alcohol or drugs, is necessary to reproduce the reaction.
- List of tolerated foods – these could be used as a placebo or vehicle to mask the challenge food.

Factors to consider when planning a challenge

In any challenge, the food used should mimic the history as closely as possible.

Dose and time intervals for immediate symptoms

The total amount of food given in the challenge is generally based on a normal daily portion of food that is likely to be consumed by the patient and divided into 5–10 doses of increasing size. Some clinicians prefer to start the challenge with a labial rub of the lip (Rancé & Dutau, 1999), but that is not practice everywhere. There is no recommended starting dose that should be used for all patients or challenges, but it should be small enough to minimise the risk of severe reactions (Bindslev-Jensen *et al.*, 2004). The dose may be doubled every 15–30 minutes or increased logarithmically, as guided by the patient's history (Sampson *et al.*, 2012). The timing between each dose should be sufficient to allow symptoms to develop. Recent published guidelines on DBPCFC recommend a top blinded dose of 2g of food protein, although for some foods such as fish this may need to be higher (Sampson *et al.*, 2012). The food challenge should provide a final sufficient dose of the allergenic food to rule out food allergy, i.e. normal daily intake adjusted for

age (Bindslev-Jensen *et al.*, 2004). A challenge duration of at least 2 hours is needed.

Dose and time intervals for delayed symptoms

The dose of food given in the challenge is generally based on a normal daily portion of food that is likely to be consumed by the patient – as indicated by the patient history or based on age appropriate national food survey data (Bindslev-Jensen *et al.*, 2004). However, some studies have used gradually increasing dosages after day one of the challenge. A challenge period of 1–4 weeks may be required to reach the full daily dose or one that triggers symptoms (Majamaa *et al.*, 1999a,b).

In the UK, normal daily consumption can be calculated by reference to the National Diet and Nutritional Survey (see Chapter 4.2). Detailed information is discussed in Venter *et al.* (2009), which may be useful for dietitians.

Blinding/masking

When performing a DBPCFC, the challenge food should be sufficiently blinded so that the active and placebo challenges are identical regarding taste, appearance, smell, viscosity, texture, structure and volume (Bindslev-Jensen *et al.*, 2004; Vlieg-Boerstra *et al.*, 2004; Sampson *et al.*, 2012). This is less necessary when challenging young children. Cooking, canning and roasting can have different effects on the allergenicity of different foods and any form of processing used for the challenge food, particularly the fat content of the vehicle (Grimshaw *et al.*, 2003), could potentially influence the challenge outcome.

For validated recipes suitable for DBPCFC, see Vlieg-Boerstra *et al.* (2004), van Odijk *et al.* (2005), Palmer *et al.* (2005), Devenney *et al.* (2006) and Vassilopoulou *et al.* (2010).

Patient information prior to the food challenge

Patients should be well informed prior to the challenge/reintroduction at home regarding food avoidance, challenge procedure and which medications should not be used. Detailed information regarding this aspect of the food challenge can be found in Venter *et al.* (2009) and Ball (2005).

Safety procedures required to set up and carry out supervised food challenges

Both high and low risk food challenges have the potential to induce anaphylaxis and therefore should be medically supervised with a suitably trained nurse/dietitian providing the challenge doses according to a written protocol. The food challenge setting should be equipped with a crash trolley, emergency drugs and all other safety measures in place. Detailed information regarding this aspect of the food challenge can be found in Venter *et al.* (2009), Ball (2005) and Sampson *et al.* (2012).

Food reintroduction

Food reintroduction at home after a period of exclusion may be used in the diagnosis of non-IgE mediated food allergy or delayed non-allergic FHS. The main differences between a gradual food reintroduction plan and a home

Box 7.11.2 Instructions for standard reintroduction of food (Venter *et al.*, 2007a; Vickerstaff Joneja *et al.*, 2001)

Day 1

Breakfast

Eat a small quantity (quarter of your usual portion) of the test food

If no adverse reactions have been experienced, proceed as follows:

Wait 4 hours before eating the test food again

Lunch

Eat double the quantity of test food eaten in the morning, i.e. half your normal portion

If no adverse reactions have been experienced, proceed as follows:

Wait 4 hours before eating the test food again

Evening meal

Eat double the amount of food eaten at lunch time. This should be equal to your normal portion.

Days 2–4

Eat the amounts of the test food that you would normally, e.g. if you eat bread three times/day, you need to try it three times/day. However, if you test a particular cereal, which you normally would eat only once a day, then try it only once a day at breakfast

Any adverse reactions may be due to a delayed reaction to the foods you have eaten in the last 2–3 days

If there is no reaction after 3 days, discontinue testing this food and consider the food safe to eat from now on

See also Ball (2005)

food challenge are that the latter involves control over the food consumed with regard to portion size and blinding. The foods and amounts used for reintroduction regimens vary from centre to centre and are often adjusted for individual cases (Box 7.11.2).

Interpreting food challenge and food reintroduction outcome

During supervised food challenges the patient should be constantly monitored and all signs, symptoms and clinical observations should be recorded on a clinical observation chart. During home challenges or food reintroduction at home, patients or their carers should keep a strict food and symptoms diary.

Open food challenge/food reintroduction is considered negative in the absence of any subjective or objective clinical reaction. It is recommended that a challenge should be stopped and considered positive if a clear, clinical reaction is shown (Table 7.11.7). In the case of a questionable (subjective) reaction, a repeat dose can be given after waiting an additional 10–20 minutes to see if it elicits a more definitive allergic reaction (Niggemann, 2010). However, clinicians need to be prepared in case this extra dose precipitates a severe allergic reaction.

The more organ systems involved in a clinical reaction, the easier it is to make the decision of a positive challenge. It is recommended that a challenge can be considered positive if severe, reproducible or persisting symptoms are experienced (Niggemann, 2010). In children, a mood change (becoming very quiet), ear picking, tongue rubbing, e.g. scratching food out of the mouth, or neck scratching are often the precursors of a positive challenge (Table 7.11.8). The results of a food challenge/reintroduction could be falsely negative when diseases such as eczema, chronic urticaria or functional bowel disorders are in remission or falsely positive when they are active. Allergic reactions to inhalant allergens can also affect the challenge outcome.

False negative challenges could be caused by use of medication prior to challenge, too small challenge dose, too short a challenge period or observation time, or the absence of cofactors such as alcohol or exercise. False positive challenges could be caused by food eaten by mistake prior to the food challenge or cross contamination from too many food challenges on the ward. Other factors that can affect challenges include drugs, hormonal factors and concomitant illnesses (Werfel *et al.*, 2009).

For DBPCFCs, the challenge is considered negative if no symptoms are experienced during the active food challenge or if symptoms are experienced during the placebo phase of the DBPCFC. When symptoms are experienced during both the active and placebo phase of a DBPCFC, the challenge needs to be repeated. Symptoms developing only during the active phase of the challenges indicates a positive food challenge (Niggemann, 2010; Niggemann *et al.*, 2005; Niggemann & Beyer, 2007).

Management strategies after both positive and negative outcomes

Once the challenge and reintroduction of food is completed, sufficient after care should be provided for the patient or their carers to ensure that:

- *After a positive challenge* – the allergenic food is avoided, emergency medication is prescribed if needed and appropriate training is given to administer the medication, e.g. the use of adrenaline (epinephrine) auto injectors, and dietetic advice is given to ensure a balanced diet is maintained despite dietary restrictions.
- *After a negative challenge* – the challenge food is reintroduced into the diet and regularly consumed in order to prevent any nutritional deficiencies or re-sensitisation.

In some cases, i.e. some primary care settings, these tests may not be available or it may take a long time to obtain results. However, the history could give a good indication of the type and time of onset of symptoms, which should assist healthcare professionals to decide if symptoms are IgE or non-IgE mediated reactions, taking into account that eczema could initially present with delayed symptoms (Flinterman *et al.*, 2006), and then may turn into a presentation of immediate, more severe symptoms.

Table 7.11.7 Subjective and objective symptoms during food challenge (Niggemann, 2010)

Possible problems with interpretation	
Subjective symptoms	
Nausea	All difficult to interpret due to the subjective nature of the symptoms
Stinging/burning of tongue or mouth	
Itching	
Heart palpitations	
Sleeplessness	
Irritability	
Excitement	
General change of behaviour/sense of impending doom	Highly predictive of a positive challenge
Diarrhoea	Could be caused by stress
Abdominal pain and cramps	Could be caused by stress, but also a sign of impending anaphylaxis
Objective symptoms	
Flushing	Difficult to interpret if subsides very quickly
Urticaria	Could be contact urticaria if only around the mouth Generalised urticaria (in the absence of chronic urticaria) is almost always a sign of a positive challenge
Slight worsening of eczema	Difficult to interpret/could be contact related However, scored index increase of >15 points is very indicative of positive reactions – may need to wait 48 hours for assessment
Vomiting	Could be caused by food aversion – may need to ensure that vomiting occurs more than once and is severe in nature for a positive result
Cardiovascular symptoms – especially a drop in blood pressure	Almost always a sign of a positive challenge
Respiratory symptoms	Could be aero allergen related/generally uncontrolled symptoms However, stridor, wheeze, watery rhinitis, redness of eyes and nose, and tears are almost always signs of a positive reaction
Dyspnoea/difficulty breathing	Could be aero allergen related but is often a sign of a positive challenge

Table 7.11.8 Criteria for major and minor criteria for outcome of challenge

Major criteria	Minor criteria
≥3 hives	Eczematous pruritic rash (worsening to ≥10 SCORAD points)*
≥1 site of angio-oedema	1–2 hives
Wheezing	≥1 of sneezing, congestion or rhinorrhoea
Dyspnoea	Conjunctivitis
Stridor	≥1 of nausea, vomiting or diarrhoea for <20 minutes
Dysphonia	A change in behaviour, e.g. irritability, drowsiness, decreased activity, anxiety, distress
Aphonia	
Severe persistent abdominal symptoms for ≥30 minutes, e.g. abdominal pain/stillness, vomiting, nausea or diarrhoea	
Hypotension for age	

- Positive food challenge: presence of ≥1 major criteria or ≥2 minor criteria.
- Negative food challenge: absence of a major or minor criteria.

*Worsening of eczema alone is not a stopping criterion during the challenge. However, if a worsening of eczema to >10 SCORAD points is observed at the end of the active arm of the double blind placebo controlled food challenges (DBPCFC) with no worsening of eczema with the placebo challenge, the diagnosis of cow's milk allergy will be given.

Dietary management

At present, the only means of treatment is avoidance of the problem food, although a number of studies have examined the efficacy of food specific immunotherapy. This technique promotes tolerance to a food through the administration of daily oral doses of the food in increasing amounts until a maintenance dose is reached. It has been successfully used to treat some common food allergies, but cannot yet be recommended in routine practice (Fisher *et al.*, 2011).

Dietary avoidance issues

The dietary management of food hypersensitivity can be complex; unexpected ingredients are often present in a wide range of manufactured foods, and there may be poor comprehension of the dietary requirement and adherence issues. The restriction of food choices can increase the risk of overall dietary imbalance, especially if the problem food is a major contributor to nutrient intake. Help is required to determine the level of avoidance required, and to develop an individualised meal plan and advice on a whole range of lifestyle issues, such as shopping, eating at school or in the workplace,

socialising and eating out, holidays abroad and even on occasion on intimate issues such as kissing (Wright, 2006, Skypala & Venter, 2009). All children and adults with moderate to severe food allergy should also have an action plan for dietary management and drug prophylaxis. This has been shown to be effective in reducing the number of accidental exposures resulting in symptoms (Clark & Ewan, 2008; Ewan & Clark, 2005).

The patient's tolerance level or degree of avoidance required will mainly be determined by the type of FHS the patient is suffering from. Most people with IgE mediated food allergy need to completely avoid a trigger food – even in trace amounts. People with non-IgE mediated allergy or non-immune mediated FHS may be able to include small amounts of the food in their diet with no adverse effects. It is currently unknown whether allowing patients to eat small amounts of the trigger food if tolerated on a regular basis has an adverse effect on the development of tolerance or conversely induces further tolerance. Some patients will already be aware of their own tolerance levels; it is therefore important to ask open questions to establish whether or not this is the case.

From a nutritional view, avoidance of a single food or type of food, such as citrus fruit, will be of little significance if nutritionally similar foods, e.g. other fruit and vegetables, can be eaten instead. However, if food avoidance necessitates excluding a major food group, the nutritional impact will be considerable. Even if the food being excluded is not in itself nutritionally significant for most people, e.g. soya or nuts, it may be widely present in manufactured foods, resulting in a subsequent effect on overall dietary balance. Patients who exclude other foods because of, for example, cultural reasons, e.g. excluding nuts and milk in a vegetarian, or they are fussy eaters will also need special consideration if their usual staple foods are being excluded.

Some types of FHS resolve over time; both milk and egg allergies commonly remit in most people by the teenage years. Some forms of non-allergic FHS in adults may be transient, such as secondary lactose intolerance. The necessity for dietary exclusion should be reviewed at intervals so that dietary restrictions are not imposed for longer than necessary due to their major impact on diet and lifestyle.

Food labelling

European food labelling law

The Labelling Directive (2000/13/EC) and its later amendments is the only European Union legislation that refers to allergenic foods. It requires manufacturers to declare all ingredients present in prepackaged foods sold in the European Union, with a few exceptions. It has been amended a number of times (see Chapter 4.5). The most important amendments are listed here.

Directive 2003/89/EC

This lists allergenic foods that must always be labelled when present in a product (Commission Directive, 2003). These include:

- Cereals containing gluten, i.e. wheat, rye, barley, oats, spelt, kamut or their hybridised strains, and products thereof.
- Crustaceans and products thereof.
- Eggs and products thereof.
- Fish and products thereof.
- Peanuts and products thereof.
- Soyabean and products thereof.
- Milk and products thereof, including lactose.
- Nuts, i.e. almond (*Amygdalus communis L.*), hazelnut (*Corylus avellana*), walnut (*Juglans regia*), cashew (*Anacardium occidentale*), Pecan nut [*Carya illinoensis (Wangenb.) K. Koch*], Brazil nut (*Bertholletia excelsa*), pistachio nut (*Pistacia vera*), macadamia nut, Queensland nut (*Macadamia ternifolia*) and products thereof.
- Celery and products thereof.
- Mustard and products thereof.
- Sesame seeds and products thereof.
- Sulphur dioxide and sulphites at concentrations of >10 mg/kg or 10 mg/L expressed as SO₂.

All ingredients have to be clearly labelled so that the product from which they are derived is easily recognisable, e.g. milk cannot be listed as caseinate without the word milk being listed next to it.

Directive 2006/142/EC

This lists two further allergenic foods that must be labelled, namely lupin and products thereof, and molluscs and products thereof (Commission Directive, 2006).

Directive 2007/68/EC

This lists those products derived from these foods for which allergen labelling is not required.

The European Food Safety Authority (EFSA; www.efsa.europa.eu) provides more detailed information on food allergen labelling. In the UK the full directives are available from the Food Standards Agency (FSA) (www.food.gov.uk/safereating/allergyintol/label/).

May contain labelling

Manufacturers often use phrases such as 'may contain nut traces', 'made on a production line using soya or milk' or 'produced on a line handling egg' to show that there could be accidental traces of another food in a manufactured product from the production process. If the ingredient is purposeful, even if it is in a trace amount, it has to be listed in the ingredients list. However, there is no legal requirement to state on the label that a food might contain accidental traces of a food. This labelling is completely voluntary and therefore not legally binding, but many manufacturers choose to label their products in this way. Where labels contain this information, patients should be advised to still check the full ingredients listing and not just rely on the allergen advice panel for allergen identification.

Major food triggers

Milk

Cows' milk is a leading cause of food allergy, especially in infants and children. About 2.5% of children suffer from cow's milk allergy with rates ranging from 1.1–7.5% (Bock, 1987; Eggesbo *et al.*, 2001; Gerrard *et al.*, 1973; Hide & Guyer, 1983; Host & Halken, 1990; Schrandt *et al.*, 1993). Almost 90% of children will react to other mammalian milks (Bellioni-Businco *et al.*, 1999), such as goat's or sheep's milk. The prognosis of cow's milk allergy is good; remission rates vary, but about 90% of children will grow out of milk allergy by adulthood (Host, 1994; Skripak *et al.*, 2007).

IgE mediated milk allergy in adults is rare, and most adults who report symptoms to milk will not usually have specific IgE antibodies to milk (Zuberbier *et al.*, 2004). Lactose intolerance is the commonest form of non-immune mediated FHS involving milk, but patients also often cite milk as a cause of irritable bowel syndrome symptoms (Monsbakken *et al.*, 2006) and respiratory symptoms (Wüthrich *et al.*, 2005).

IgE mediated cow's milk allergy

IgE mediated cow's milk protein allergy is characterised by acute and rapid onset symptoms, including urticaria, angio-oedema, rhinitis, gastrointestinal upset, vomiting, respiratory distress or anaphylaxis. These reactions are commonly associated with a family history of atopy and usually develop early in infancy when the permeability of the gastrointestinal mucosa is greatest, and soon after exposure to cow's milk in the form of infant formula (Host & Halken 1990) or during early weaning with dairy foods. Symptoms can occasionally present in an exclusively breastfed infant because the mother is taking cow's milk (or derivatives) in her diet and the protein fractions pass through the breast milk causing symptoms in the infant. To determine whether this is the case, all traces of cow's milk and derivatives should be excluded from the mother's diet for approximately 2 weeks. If the symptoms resolve, then this diet should be adhered to for the duration of breastfeeding.

Non-IgE mediated cow's milk allergy

Non-IgE mediated cow's milk allergy is characterised by a delayed reaction following cow's milk protein ingestion. Symptoms typically occur within a few hours and sometimes after 2–3 days, and often include eczema, reflux, abdominal pains, constipation, diarrhoea, bloating and gas.

Non-immune mediated cow's milk hypersensitivity

The most common form of non-immune reactions to cow's milk is to the milk sugar lactose.

Milk avoidance carries a high risk of nutritional deficiencies (particularly energy and calcium), which can cause delayed growth in infants and children, but only if the diet is not managed well. For this reason, it is important that the need for milk exclusion is clearly established. The correct management of cow's milk allergy in breast-

fed infants is by complete avoidance of cow's milk protein from the infant's diet if weaned and sometimes in the breastfeeding mother's diet. In part or non-breastfed infants younger than 12 months, a nutritionally complete substitute formula is required. There are a number of available formulae for infants who cannot tolerate whole cow's milk protein or lactose and a dietitian should advise on the most suitable choice, as shown in Table 7.11.9.

Guidance when choosing a formula milk

The choice of formula milk will depend on the infant's requirements, taste preference, degree of hydrolysis required, indications for an amino acid formula, parental preference, clinician experience and many other clinical and non-clinical factors. There are European and world guidance (Fiocchi *et al.*, 2010), algorithms (Vandenplas *et al.*, 2007) and recommendations (Du Toit *et al.*, 2010) to enable the clinician to make the most suitable choice tailored to the individual infant's specific requirements. The clinician may need to prescribe an alternative formula if the infant refuses or reacts to the initial formula recommended. It is essential that infants tolerate sufficient volume of a nutritionally complete cow's milk substitute (Table 7.11.9) to meet their nutritional requirements for growth and development.

Goat's, sheep's and other mammalian milks should not be used as an alternative to cow's milk due to a high degree of cross reactivity resulting in poor tolerance. Furthermore, these milks have a low folate content and can be microbiologically unsafe (Department of Health, 1994). Non-prescribable, non-formula milks made from soya, rice, hemp, potato nut, coconut, pea or oat are not recommended for infants under 1 year old unless all other options have been exhausted and the alternative is no milk at all. When used in cooking they can increase the nutritional content of the diet because they encourage the consumption of a variety of other foods.

Due to inorganic arsenic being a natural component of rice milks, they are not recommended for children younger than 4.5 years (FSA, 2009). When they are used, daily intake should not exceed 200 mL. If used, any of these milks should be enriched with calcium. Products based on soya can be used after 6 months of age; these include soya yogurts, deserts, cream cheeses, hard cheeses and cream. These products can also be used on cereal and in cooking to make sauces, soups, scones, cakes and rice pudding to help to add variety, nutrition and taste to the diet. Oat cream is another useful product. These are available in supermarkets and health food stores or online. Once solid food is introduced into the diet, care has to be taken that it remains free of cow's milk protein, not only from obvious sources such as dairy products but also from its less obvious presence in many manufactured foods. Tables 7.11.10 and 7.11.11 give advice for general avoidance on the exclusion of cow's milk from the diet.

Reintroduction of milk

Cow's milk allergy is often transient and therefore is often challenged every 6–12 months until tolerance is

Table 7.11.9 Nutritionally complete milk substitutes for use in cow's milk hypersensitivity

Type of milk hypersensitivity	Product type*	Product name (manufacturer)
Used for IgE and non-IgE mediated cow's milk allergy	Soya based**	Infasoy (Cow & Gate) Wysoy (SMA)
	Do not use before 6 months unless no other choice, e.g. vegan or refusal of all other suitable formula	
	Casein based hydrolysed cow's milk	Nutramigen Lipil 1 and 2 (MJN) Pregestimil (with MCT oils) (MJN)
	Whey based hydrolysed cow's milk	Pepti Junior (Cow & Gate) Pepti 1 and 2 (Aptamil)
	Amino acid	Neocate LCP (SHS) Neocate Advance and Neocate Active if over 12 months (SHS) Nutramigen AA (MJN)
Lactose intolerance only	NB: <i>Some of the above products may also be suitable for lactose intolerance; check prescribing indications</i>	
	Usually contain whole cow's milk protein	Enfamil Lactofree (MJN) SMA LF (SMA)

*The choice of product depends on the age of the child, the level of sensitivity to milk and the presence of coexisting allergies. Check compositional details and prescribing indications for suitability. Choice may also be dictated by the infant's palate.

**Infants under the age of 6 months should not use a soya formula as the first choice due to their phyto-oestrogen content and the risk of becoming sensitised to soya. It can be used if other formulae are either not suitable, not acceptable or not tolerated by the infant, or if the mother is vegan. See www.bda.uk.com for the BDA Paediatric Group Position Statement on the use of soya protein for Infants.

Further details of products currently available and their prescribing indications can be found in the *British National Formulary (BNF)* or the *Monthly Index of Medical Specialities (MIMS)* or obtained directly from the manufacturers. Further information is also available to dietitians in the *Special Foods for Children* booklet compiled by the Dietetic Department, Children's Hospital, Birmingham. MCT, medium chain triglyceride.

Table 7.11.10 General guidance for milk exclusion

Exclude	Examples of foods to exclude	Notes
Cow's milk	Liquid whole, semi skimmed or skimmed milk Evaporated or condensed milk Dried full fat or skimmed milk powder Fresh and UHT	Goat's, sheep's and other mammalian milk should not be used as an alternative to cow's milk. They are also unsuitable for people requiring total exclusion of lactose or galactose
Dairy products	Butter Margarine or fat spreads containing milk derivatives Cheese and cheese spreads Yogurt Fromage frais Creme fraiche Cream Ice cream	Butter and some hard cheeses may be tolerated by people with mild lactose intolerance
Milk or milk derivatives in manufactured foods	May be described on ingredients lists as: milk, milk solids, non-fat milk solids, milk protein; skimmed milk, skimmed milk powder Casein or caseinates Whey; whey solids; buttermilk *Lactose, milk sugar, whey sugar, whey syrup sweetener. Within the European Union the presence of milk must be <i>clearly</i> labelled	Lactose in flavourings and medications may be a problem in some severely allergic patients

*It may not be necessary to exclude lactose and other milk sugars in all cases of cow's milk allergy but, for practical purposes, their presence is usually taken as indicative of the presence of milk, and foods containing them are excluded.

Table 7.11.11 Types of manufactured foods that may contain milk or milk derivatives

Food type	Foods to check
Cereals	Bread and rolls Breakfast cereals Cakes Biscuits and crackers Pizza Pasta (both fresh and tinned)
Fruit and vegetables	Vegetables canned in sauce Instant potato Baked beans Battered or breadcrumbed vegetables and potato products
Meat, fish and alternatives	Meat and fish products, e.g. beef burgers, fish fingers, sausages, ready meals
Other savoury items	Canned and packet soups Instant gravies Sauces/ketchups Crisps and savoury snack foods
Desserts	Instant desserts Dairy desserts Ice cream Custards
Confectionery	Chocolate Toffee Fudge Caramel
Fats and spreads	Margarines and fat spreads
Beverages	Instant drinking chocolate Malted milk drinks Coffee whiteners Pineapple and coconut juice drink

NB: This list is far from exhaustive and all food labels must be checked carefully and checked every time as ingredients do change.

Most of these products can also be milk free if you shop around or use 'free from lists' to locate them.

demonstrated. Most cow's milk allergy will resolve by the age of 5 years. If previous reactions have been severe, then reintroduction should only happen under medical supervision in a hospital setting. In practice, milk reintroduction sometimes happens inadvertently with the child already consuming foods containing small amounts of cow's milk. A clear dietary history can highlight if this has been the case.

If a child passes a milk challenge but then refuses milk and dairy foods due to anxiety or dislike of the taste, parents will need guidance on ways to incorporate hidden milk into the diet, such as in rice pudding, white sauce, scones, creamy soups, risotto, etc. In the rare cases where milk allergy persists into adulthood, a permanent exclusion of cow's milk is necessary.

Lactose intolerant disorders

Lactose intolerance results from an impaired ability to either absorb lactose or its component monosaccharides,

resulting in symptoms of malabsorption. If lactose needs to be excluded, food avoidance measures are almost the same as for exclusion of cow's milk protein (see earlier). The main differences with lactose exclusion regimens are that low lactose cow's milk products can often be included. Some foods are naturally very low in lactose, whereas others are manufactured specifically for this purpose. There are also formula milks available that are clinically free from lactose. If total and prolonged (or permanent) lactose exclusion is required, the diet will require careful management to ensure it is varied, nutritious and tastes good. The management of lactose intolerance is discussed in more detail in Chapters 7.4.6.

Congenital disorders of monosaccharide metabolism

Details of these disorders can be found in Chapter 3.8.6 and Chapter 7.8.

Peanuts and tree nuts

Peanuts and tree nuts are the most common foods to cause severe IgE mediated reactions. Between 1999 and 2006, 18 of the 44 deaths from food allergy were caused by tree nuts or peanuts (Pumphrey & Gowland, 2007). Food allergic patients who also have asthma are more likely to have severe reactions to foods, especially to peanuts (Sicherer *et al.*, 2001a). Peanut and tree nut allergies most commonly present in childhood; only 8–10% of cases are diagnosed in adolescence or adulthood (Mullins *et al.*, 2009; Ewan, 1996). Unlike milk and egg allergy, nut allergy rarely resolves. Over 90% of tree nut allergic and 80% of peanut allergic children will remain sensitised and symptomatic into their adult years (Skolnick *et al.*, 2001; Fleischer *et al.*, 2005). However, a proportion of tree nut allergy in adults will develop as a result of cross reacting allergic determinants in foods and pollens causing PFS (Skypala *et al.*, 2011).

It has been estimated that 0.5–1% of the population are likely to develop a peanut or tree nut allergy (Hourihane *et al.*, 1997a), with the prevalence of reported reactions ranging from 0% to 7.3% for any nut (Zuidmeer *et al.*, 2008). The prevalence has continued to rise in some countries; USA telephone survey data suggested that the prevalence had doubled every 5 years, rising from 0.4% in 1997 to 1.4% in 2008 (Sicherer *et al.*, 2010). This is mirrored in Australia (Mullins *et al.*, 2009), but differs from UK data from the 2001/2002 birth cohort showing a 1.2% prevalence compared with 1.4% in 1994/1996 (Venter *et al.*, 2010). Published data on the prevalence of peanut allergy solely in adults are sparse, although Vierk *et al.* (2007) reported that the doctor diagnosed prevalence of peanut allergy was 0.3% in US adults in 2007. The way peanuts are prepared can affect their allergenicity, which explains why peanut allergy is common in the USA, UK and Australia, but uncommon in China where peanuts are boiled rather than roasted (Maleki *et al.*, 2000). A large study in the UK is ongoing to determine whether early introduction of peanuts is more or less likely to provoke peanut allergy (Du Toit *et al.*, 2008). It

is for this reason that in 2009 the Department of Health revised its advice to pregnant and breastfeeding women about eating peanuts, and also about eating peanuts in the first few years of life (Department of Health, 2009b).

Peanut shares similar allergen epitopes with tree nuts, especially hazelnut, Brazil nut, almond and also some seeds (de Leon *et al.*, 2003). Peanut allergic individuals have a 25–40% risk of developing a coallergy to tree nuts (Sicherer & Sampson, 2000; Bock, 2007). Tree nut allergy prevalence is increasing, with US telephone survey data suggesting it is currently 1.1%, compared with 0.2% in 1997 (Sicherer *et al.*, 2010). Whereas walnut was the commonest tree nut provoking allergic reactions in this study, a UK study showed Brazil, almond and hazelnut to be the most common triggers of tree nut allergy (Ewan, 1996), with cashew nut allergy being predominant in Australia (Hill *et al.*, 1997). Cashew nut allergy can cause severe reactions (Davoren & Peake, 2005); children with a cashew nut allergy were more likely to experience anaphylaxis than case matched children with a peanut allergy (Clark *et al.*, 2007).

Peanut and tree nut allergic individuals are usually advised to avoid all nuts because of the risk of contamination; coexisting allergies to other nuts may not have been identified and are difficult to distinguish (Ferdman & Church, 2006). Adults with PFS to one nut may be able to tolerate other nuts on an individual basis, but the diagnosis of PFS must be confirmed to ensure no primary allergy to nuts exists. Avoidance can be problematic with many manufactured food products containing peanuts or nuts or derivatives (see European food law labelling section). In addition, they are used widely in both the food and cosmetic industries. Peanuts can sensitise via inhalation and the skin, as well as orally; therefore, exposure can also occur via peanut particles in the air or direct contact with peanut containing foods or some topical creams or ointments. In addition, peanut allergens are robust and cannot be removed from surfaces wiped with water alone or with antibacterial wipes (Perry *et al.*, 2004). It has been estimated that 5–12% of accidental exposures causing reaction are due to kissing (Eriksson *et al.*, 2003), possibly due to the longevity of some of the allergens involved (Maloney *et al.*, 2006). Up to 25% of patients may experience an accidental ingestion per year and 66% experience more than five accidental exposures in a lifetime (Sicherer *et al.*, 2001a); thus many nut allergic individuals carry adrenaline (epinephrine). Those that do so should know how and when to use it, and this information should be included in a regularly updated management plan. Most reactions occur when eating out, so stringent measures to reduce the risks should be taken to avoid this. For more information on eating out when suffering from a FHS, see Wright (2006).

Refined peanut oil is not allergenic (Hourihane *et al.*, 1997a,b), but other nut oils, e.g. walnut, hazelnut, almond and unrefined or cold pressed peanut oil, may contain traces of allergens and should be avoided. Unrefined peanut oil is most likely to be used in Thai, Chinese, Indonesian or Indian cuisine; other nuts oils may be used in salad dressings or garnishes. Food companies have to

declare both refined and unrefined peanut oil on food labels. Dietary sources of tree nuts and peanuts are summarised in Table 7.11.12. Peanut allergy sufferers have a greater risk of accidental exposure. Pumphrey & Gowland (2007) reported that 54% of recorded anaphylaxis fatalities between 1999 and 2006 occurred when eating restaurant or takeaway food. Thai, Indonesian, Asian and Chinese cuisines use peanuts and other nuts regularly in dishes. Chefs may often change ingredients or add additional items to dishes on an *ad hoc* basis.

Travelling with a peanut or tree nut allergy can be problematic. Many airlines stopped serving peanuts due to concerns about airborne peanut particles, but this is not universal and it is important that patients notify the airline of their concerns. Translation sheets for restaurants abroad, which give details of the problem, are useful as a list of food ingredients to look out for when travelling. Some brands of products that are nut free in the UK may not be nut free when produced and purchased in other countries (even if they have the same brand name), e.g. some infant formulae or vitamin D preparations may contain peanut. Learning the word for peanut or nuts in the relevant language, wearing medic alert identification and always carrying rescue medication are strongly recommended. Support groups, such as the Anaphylaxis Campaign and Allergy UK, can provide useful advice on all of these issues.

Soya and other legumes

After peanuts, soyabean allergy is the most common legume allergy worldwide (Bernhisel-Broadbent & Sampson, 1989), the prevalence being approximately 0.4%, although this depends on local eating habits and exposure (Zuidmeer *et al.*, 2008). Soya allergy is usually a transient allergy of infancy and childhood (Sicherer *et al.*, 2000). Savage *et al.* (2010) reported that 50% of their population had a resolution of their soya allergy by the age of 7 years. Only 6.5% of children with a peanut allergy are allergic to soya, although the majority of soya allergic children cannot tolerate peanuts (Bernhisel-Broadbent & Sampson, 1989). Although soya milk was thought to commonly affect children with cow's milk allergy, Zeiger *et al.* (1999) reported that only 14% of a cohort of cow's milk allergic patients were diagnosed allergic to soya. Soya allergy most commonly manifests in older children and adults due to cross reactions between homologous epitopes in soyabeans and birch pollen provoking reactions, which may be severe (Mittag *et al.*, 2004; Kleine-Tebbe *et al.*, 2002). It is possible that up to 30% of adults with a peanut allergy have cross reactivity to other legumes (Ballmer-Webber *et al.*, 2007), although this sensitisation may not be clinically relevant. Soya beans can provoke a range of symptoms including anaphylaxis; inhalation of soyabean dust can also provoke bronchospasm.

Soyabeans are ubiquitous, especially in processed foods, and commonly used as a binding agent, meat extender or replacement for meat in vegetarian dishes. Soya products can be divided up into whole bean products, hull products, protein products and oil products,

Table 7.11.12 Guidance for peanut and tree nut avoidance

Exclude	Examples	Notes
Peanuts and tree nuts	Peanut Brazil Walnut Hazelnut Almond Cashew Pistachio Pecans Macadamia	Some of these may be described as: Mixed nuts Ground nuts Monkey nuts Earth nuts Goober nuts Nutmeg, coconut, pine nut and palm nut are not classified as nuts
Spreads	Peanut butter and other nut spreads	Almond paste used in curries often contains peanuts
Sweets	Praline Noisette	Usually made from hazelnuts but mixed nuts can be used
Desserts and dessert topping	Marzipan Frangipan Amaretto products Macaroons Bakewell tarts Almond essence	Contain almonds but cheaper brands may contain peanut flour as an extender
Sweet paste or ice cream	Marron, e.g. marron glacé	Made from chestnuts but other nuts may be included
Sauces	Worcester sauce Satay sauce Korma sauce Pesto sauce	Contains walnuts Contains peanuts Contains almonds and sometimes peanut paste Made from pine nuts, but could contain other nuts
Hydrolysed vegetable protein	Hydrolysed vegetable protein	Usually from soya or wheat but can be derived from peanut, but this should be labelled clearly on prepacked manufactured foods in the European Union
Cheese	Nut containing or nut coated cheeses	Nut cheeses sold on deli counters can contaminate other products
Oils	Cold pressed gourmet oils, also called unrefined oils Peanut oil Arachis oil Groundnut oil Walnut oil Almond oil Hazelnut oil	Refined oils present in manufactured foods or sold as cooking oils are free from nut protein but still have to be declared on food labels
Manufactured foods containing traces of peanuts or nuts	This can include almost any food but particularly: Cakes, biscuits and pastries Ice cream, desserts and dessert toppings Chocolate bars Cereal bars and confectionery Savoury snack foods Breakfast cereals, especially muesli or nut mixtures Products containing hydrolysed vegetable protein Oriental/Asian food Sauces and salad dressings Mixed salads Wild rice	All manufactured foods should be considered a source of peanuts/nuts until it is known that this is not the case

and are therefore present in a huge range of products (Table 7.11.13). Refined soyabean oil and soya lecithin (E322) are safe for soya allergic patients to consume, although case reports suggest some individuals may still react to soya lecithin (Dueñas-Laita *et al.*, 2009; Awazuhara *et al.*, 1998; Palm *et al.*, 1999). The allergen associated with PFS reactions, Gly m 4, is unlikely to be present in products derived from roasted soyabeans or highly

fermented products such as miso or soya sauce, but is found in soya milk and dietary powders such as body building powders (Mittag *et al.*, 2004). Soya sauce is a highly fermented product containing high levels of histamine and can provoke oral symptoms in some people (Sugiura & Sugiura, 2010).

Allergy to other legumes such as chickpeas and lentils has not been extensively studied in the UK, although in

Table 7.11.13 Soya containing foods (L'Hocine & Boye, 2007)

Whole bean products	Soya sprouts, edamame, soya milk, tofu, miso, natto, yuba, tempeh, soya sauce, soya nuts, soyanut butter, soya cereals, soya cheese, soya milk, soya ice cream/yoghurt/desserts
Hull products	Bread, bakery products, snack bars
Protein products	Soya flour, protein concentrate, protein isolate, textured soya Baby foods, infant formulae, bread, biscuits, pancakes, pastry, crackers, snack foods, noodles, pizza, breakfast cereals, soya milk, ice cream, soya yoghurt and cheese, sausages, tinned meat and fish, soups and gravy, beef burgers, salad dressing, stock cubes, sauces
Oil products	Refined oil, lecithin Cooking oil, salad oil, margarine, salad dressing, mayonnaise, coffee whiteners, chocolate, sweets, pastry filling, cheese dips, emulsifying agents, dietary supplements and body building agents
Emerging products	Isoflavones, functional foods, medications

India and Spain they are a significant issue (Kumar *et al.*, 2010; Martínez San Ireneo *et al.*, 2008). Lupin is another legume not permitted for use in the UK, but it can be found in gluten free products and also in products containing wheat flour from other continental countries. Allergy to lupin has been reported (Peeters *et al.*, 2007), but the prevalence is low. Amongst those patients referred to specialist allergy services, the estimated prevalence of actual lupin allergy was only 0.3–0.8% (de Jong *et al.*, 2010).

Seeds

Sesame allergy was first reported in 1993 and is now one of the top 10 allergens in the UK and the most common seed allergy worldwide (Gangur *et al.*, 2005; Kägi & Wüthrich, 1993; Dias *et al.*, 2008). The reported prevalence in children ranges from 0.18% (Dalal *et al.*, 2002) to 0.42% (Sporik & Hill, 1996). However, data from the French national allergy data bank showed that around 2% of children and 5% of adults who reported reactions to foods were affected by sesame allergy (Lemerdy *et al.*, 2003). It only remits in about 20% of cases (Cohen *et al.*, 2007). Diagnosis can be difficult; a negative SPT and specific IgE tests to sesame occur in people who develop symptoms on oral food challenge, possibly due to the presence of allergens called oleosins, proteins found in oil bodies present in the seed (Leduc *et al.*, 2006). Other confounding factors for diagnosis are that white sesame seeds contain more protein than the black seeds (Fremont *et al.*, 2002), roasting or frying confers a reduction in allergenicity of the seeds as opposed to boiling (Lee *et al.*, 2009) and sesame oil appears to provoke the most severe reactions (Chiu & Haydik, 1991).

Table 7.11.14 Sesame products

Alternative names	Foods containing sesame	
Ajonjoli	Falafel	Halva
Benne/benne seed	Burger buns	Hummus
Gomasio	Bread sticks	Tahini
Gingelly	Pastries	Salad dressing
Sesamum indicum	Pretzels	Soups
Sim sim	Bagels	Sauces
Oleum	Biscuits	Noodles
Teel	Rice cakes	Samosa
Till	Crackers	Dips
	Sandwiches	Aqua Libra

Sesame cross reacts with tree nuts, peanuts, poppy seeds, kiwi and rye (Vocks *et al.*, 1993), with sensitisation linked to a high prevalence of sensitisation to tree nuts (Stutius *et al.*, 2010). Sesame and its derivatives can often be present under a variety of different names, as shown in Table 7.11.14. Unlike peanuts and tree nuts, restaurant staff may not be aware of which dishes contain sesame, a common ingredient in vegetarian dishes and also Thai, Indonesian, Japanese, Chinese, Middle Eastern, Greek and Turkish food. Sesame allergic patients also need to avoid sesame oil, which is a common addition to cooked food also and found in pharmaceutical products and cosmetics, listed using the Latin name *Sesamum indicum*.

The only other significant seed allergy is due to mustard seed, which affects an estimated 1.1% of children and 0.84% of adults, and may cause severe reactions in very small amounts (Morisset *et al.*, 2003). Mustard is a common ingredient in many preprepared foods and sauces, and needs to be considered if there are multiple reactions to foods that do not seem to have common food ingredients.

Fish and shellfish

Reactions to fish and shellfish can be induced both by IgE mediated mechanisms and non-allergic triggers, such as histamine or scombroid poisoning. Seafood is one of the most common causes of food allergy in adults; a telephone survey in the USA estimated the prevalence of seafood (fish, shellfish) as 2.3% (95% CI, 2–2.5%) for any seafood allergy, 2% for shellfish, 0.4% for fish and 0.2% for fish/shellfish (Sicherer *et al.*, 2004). The most frequently reported symptoms are oral itching and vomiting (Hebling *et al.*, 1996), but seafood often provokes severe food allergic reactions. Crustaceans are responsible for 10% of all cases of anaphylaxis to foods in France and 8% of fatal anaphylaxis in the UK (Moneret-Vautrin & Morisset, 2005; Pumphrey, 2000). Seafood allergy is thought to be lifelong (Daul *et al.*, 1990), although there have been no large studies on resolution.

Seafood contains highly cross reactive allergens that cause sensitisation or symptoms through consumption,

but also through inhalation due to aerosolisation during cooking (James & Crespo, 2007). Parvalbumin is the dominant allergen in finned fish (Hansen *et al.*, 1997), with beta-parvalbumin being the most potent (Griesmeier *et al.*, 2010). Crustaceans (prawns, shrimps, crayfish, crabs and lobsters) and molluscs (bivalves such as clams, oysters, mussels and scallops, and snails, octopus, squid and cuttlefish) also share a common allergenic protein called invertebrate tropomyosin. The presence of pan allergens means there is strong interspecies cross reactivity between fresh and salt water fish, and also between crustaceans and molluscs, but there is no cross reactivity between shellfish and vertebrate fish (Chapman *et al.*, 2006). However, IgE mediated allergy to one type of fish, mollusc or crustacean does not necessarily indicate avoidance of all fish, molluscs or crustaceans. Fish allergens may be denatured by extreme heat, such as that used in canning fish, but most fish allergic individuals will not tolerate fish cooked under normal conditions (Bernhisel-Broadbent *et al.*, 1992). In contrast, allergens from shellfish, which include crustaceans and molluscs, are not thermo labile and remain potent allergens after cooking. Lehrer *et al.* (2007) demonstrated shrimp allergenic activity in oil used to cook shrimp.

Most seafood is an obvious component of a meal; less obvious sources can include fish stock, Worcestershire sauce, caviar, aspic, buffet food, Asian cuisine, fish oil supplements and other health foods such as green lipped mussels. Seafood can also provoke adverse food reactions due to the presence of natural toxins, either present in live fish or scombroid poisoning where the toxin is produced in the flesh of caught fish. Scombroid poisoning produces symptoms of flushing, sweating, urticaria, gastrointestinal symptoms, palpitations and bronchospasm

within an hour of consumption, which in severe cases may be confused with anaphylaxis (Attaran & Probst, 2000). These symptoms are due to the bacterial breakdown of histidine into histamine; tuna, mackerel, skipjack, bonito, herring, sardines, marlin and anchovies all contain natural levels of histidine (Fritz & Baldwin, 2003).

Egg

Approximately 1.3–3.2% of children are reported to have egg allergy (Bock, 1987), which usually resolves in childhood (de Boissieu & Dupont, 2006), although the age at acquired tolerance varies in different population groups (Potamianou-Taprantzi *et al.*, 2002). Newly diagnosed egg allergy can occur in adults due to bird egg syndrome; hypersensitivity to bird allergens precipitating a cross reaction to the egg yolk allergen alpha livetin (Szépfalusi *et al.*, 1994). Asthma is a comorbidity associated with egg allergy (Tariq *et al.*, 2000).

Cooking reduces the allergenicity of eggs by 70% (Ford & Taylor, 1982), and the majority of egg allergic children are likely to be able to tolerate cooked egg (Kemp, 2007). Persistent egg allergy is associated with sensitisation to the linear epitopes of the egg allergen Gal d 1 (ovomucoid), which is not degraded by heat, unlike the other main egg allergen Gal d 2 (ovalbumin) (Jarvinen *et al.*, 2007). There may be a wide variation in the type of egg containing foods that those with an egg allergy can tolerate. Table 7.11.15 shows the type of foods that can be classified as containing well cooked egg, loosely cooked egg and raw egg. Egg can be a less obvious ingredient of foods such as pasta, biscuits, ice cream, egg glazes, sweets and desserts, so labels should always be carefully scrutinised for its presence.

Table 7.11.15 Classification of egg containing foods

Well cooked egg	Lightly cooked egg	Raw egg
Cakes	Scrambled egg	Fresh mayonnaise
Biscuits	Boiled egg	Fresh mousse and shop bought mousse that contains egg
Dried egg pasta	Fried egg	Fresh ice cream
Pancakes and Yorkshire pudding	Omelette	Sorbet
Egg in sausages, both vegetarian and meat varieties, and also in other processed meats such as burgers	Egg fried rice	Royal icing (both fresh and powdered icing sugar)
Prepared meat dishes	Meringues	Home made marzipan
Well cooked fresh egg pasta	Some marshmallows	Raw egg in cake mix and other dishes awaiting cooking (children of all ages love to taste or lick the spoon!)
Quorn	Lemon curd	Egg glaze on pastry
Sponges and sponge fingers	Quiche	Horseradish sauce
Chocolate bars that contain nougat or dried egg, e.g. Milky Way, Mars bar or Creme egg	Poached egg	Tartar sauce
Some soft centred chocolates	Pancakes	Cheese containing egg white in the form of lysozyme
Soft fruit chews	Egg in batter	Mayonnaise
Egg in some gravy granules	Egg in breadcrumbs, e.g. on fish fingers and chicken nuggets	Salad cream
Dried egg noodles	Hollandaise sauce	
Waffles	Quiche and flans (fruity and savoury)	
Commercial marzipan	Egg custard and egg custard tarts	
	Crème caramel	
	Crème brûlée	
	Real (egg) custard	
	Tempura batter	
	Yorkshire pudding – some patients who can eat well cooked egg can tolerate this, but it depends on how well cooked they are and if they contain any uncooked batter inside	

Lecithin used in food manufacture is more likely to be derived from soya than egg, but if this is not specified, the origin needs to be checked with the manufacturer. Even if derived from egg, most patients with an egg allergy will tolerate egg lecithin (E322), but reactions have been reported in the past (Palm *et al.*, 1999).

Fruit and vegetables

The most widespread group of foods provoking food allergic reactions in adolescents and adults is fruit, and to a lesser extent, vegetables (Osterballe *et al.*, 2009; Vierk *et al.*, 2007). These reactions are most frequently due to similarity or homology between plant food allergens and specific IgE antibodies of pollen, latex and plant foods provoking the characteristic symptoms of PFS (Amlot *et al.*, 1987). The prevalence of PFS varies according to pollen sensitisation rates, and the pollens involved, with up to two-thirds of those sensitised to birch tree pollen likely to develop PFS (Skypala *et al.*, 2011). The main trigger foods for PFS vary depending on the pollen involved, but most regularly include tree nuts, apples and stone fruit such as peaches and cherries (Table 7.11.16) (Katelaris, 2010). Celery is one of the most common foods to cause oral allergy syndrome in adults in European countries, but is not a major allergen in the UK. The allergy normally involves the celery root (celeriac) rather than the stalk of the plant and can result in anaphylaxis, often to small amounts (Vieths *et al.*, 2002). Unlike other PFS reactions, cooked celery and celery spice are as likely to cause a reaction in sensitive people as raw celery (Ballmer-Weber *et al.*, 2002). Another less prevalent manifestation of oral allergy syndrome is caused by antibodies to natural rubber latex (*Hevea brasiliensis*) cross reacting with various fruit and vegetables; 30–50% of those allergic to natural latex rubber will have associated hypersensitivity reactions to plant foods (Wagner & Breiteneder, 2002).

Symptoms of PFS are generally mild, probably because the allergens involved are extremely labile; however, fruit and vegetables can provoke severe reactions (Ross *et al.*,

2008). These reactions usually involve different allergens to those involved in PFS, including a group known as lipid transfer protein (LTP) allergens. Unlike the allergens involved in PFS, LTP allergens are resistant to proteolysis, pH change and thermal treatments, enabling them to be primary sensitisers (Fernández-Rivas *et al.*, 2006). However, like PFS, allergy involving LTP allergens is due to cross reactivity; those sensitised to peach LTP are more likely to have clinical cross reactivity to other foods containing LTP (Asero *et al.*, 2004). Sensitisation to these allergens is highly prevalent in southern Europe, with limited data showing that they could be relevant in Northern Europeans (Salcedo *et al.*, 2004; Flinterman *et al.*, 2008).

Wheat

Wheat allergy is usually a transient, but important, allergy of childhood, with a reported prevalence of 0.4% in children in the USA (Sicherer & Sampson, 2006; Venter *et al.*, 2006a; Pereira *et al.*, 2005). Almost all children with a wheat allergy achieve tolerance by adolescence (Keet *et al.*, 2009), but despite this 0.5–0.9% of adults report reactions to wheat (Schäfer *et al.*, 2001; Young *et al.*, 1994; Vierk *et al.*, 2007). In adults the most common manifestation is as a trigger of a condition known as food dependent, exercise induced anaphylaxis (FDEIA) (Beaudouin *et al.*, 2006; Dohi *et al.*, 1991). Those affected by this condition can tolerate wheat except when it is consumed within 2 hours of exercising. Anaphylaxis can be induced by exercise alone, but it is possible that 80% of all cases food could be a cofactor (Yang *et al.*, 2008). Shellfish, tomatoes, celery, peanuts, maize, soya, strawberries and cheese have also been implicated as triggers of FDEIA (Shadick *et al.*, 1999; Romano *et al.*, 2001).

Presenting symptoms to wheat are often cutaneous, such as atopic dermatitis and urticaria, but laryngeal oedema and anaphylaxis may occur as the first manifestation (Pourpak *et al.*, 2004). Non-IgE mediated symptoms may be chronic (diffuse gastrointestinal symptoms), with the role of T cells and their cytokines demonstrated in wheat related gastrointestinal symptoms (Latham *et al.*, 2003). The algorithm for food hypersensitivity classifies coeliac disease as a non-IgE mediated food allergy; and wheat is one of the cereals containing gluten (alcohol soluble prolamins) that can cause this condition (see Chapter 7.4.7). However, in adults wheat is most often reported to provoke gastrointestinal symptoms, most notably in those with irritable bowel disease, although the mechanism is unknown (Monsbakken *et al.*, 2006). Rice, maize, barley and oats can all provoke allergic reactions, but are not common triggers of FHS in the UK, although they should not be ruled out, especially as corn or barley may be minor ingredients in many foods. Although it is not a cereal, buckwheat is often used to replace flour; buckwheat noodles are a common cause of reactions in Korea (Yang *et al.*, 2008) and buckwheat in the form of galettes (pancakes) is becoming a common allergen in France and should be considered in cases of unexplained reactions.

Table 7.11.16 Cross reacting plant food allergens

Birch pollen	Apple, pear, cherry, peach, nectarine, apricot, plum, kiwi, hazelnut, other nuts, almond, celery, carrot, potato
Birch/mugwort	Celery, carrot, spices, sunflower seed, honey
Grass	Melon, watermelon, orange, tomato, potato, peanut, Swiss chard
Ragweed	Watermelon and other melons, banana, courgette, cucumber
Plane tree	Hazelnut, peach, apple, melon, kiwi, peanuts, maize, chickpea, lettuce, green beans
Latex	Avocado pear, chestnut, banana, passion fruit, kiwi fruit, papaya, mango, tomato, pepper, potato, celery

Wheat allergy (IgE mediated) may require total wheat exclusion. Partial exclusion may be sufficient in some non-IgE mediated food allergy or non-allergic food hypersensitivity forms of wheat hypersensitivity; the threshold of sensitivity varies and some people can obtain symptom relief by significant reduction of wheat intake. In the UK, wheat is a major component of most cereal foods and a common ingredient in many manufactured foods, ranging from sausages to ice cream. Wheat exclusion therefore has considerable impact on food choice and nutrient intake. In children, wheat may be an additional allergen excluded alongside milk and/or egg, which increases nutritional risks for calcium deficiency and makes the diet very limited unless a good range of substitutes are introduced. Additionally, a wheat free diet can result in a reduction of dietary fibre and B vitamins.

An excellent range of commercially produced wheat free (and gluten free) products, including bread, biscuits, pastries, pasta and ready meals are available. Some gluten free and wheat products are available on prescription. These are not prescribable for wheat FHS, but usually only for people with coeliac disease who can tolerate wheat starch as it is present in many proprietary gluten free foods. Gluten free products are not suitable for people with wheat allergy unless they are specifically labelled as wheat free. Dietary guidance for wheat exclusion is summarised in Table 7.11.17.

Other triggers

Food additives

Approximately 4.9% of the UK population cite food additives as a trigger of food allergy (Young *et al.*, 1994),

although the true prevalence ranges from 0.1% to 0.4% (Young *et al.*, 1987; Osterballe *et al.*, 2005). Problems are most commonly reported in children (Pereira *et al.*, 2005) and studies suggest artificial colours and the benzoate preservatives can increase hyperactivity in children (McCann *et al.*, 2007). In adults, those with chronic idiopathic urticaria or asthma seem to be more susceptible to reactions to food colours, benzoates and the metabisulphite preservatives (Di Lorenzo *et al.*, 2005). Although it is usually the azo dyes, in particular tartrazine (E102) and sunset yellow (E110), which are considered by the public to be the most likely to be implicated in adverse food reactions. A move towards the use of natural colourings has led to an increase in the use of carmine or cochineal, which being derived from insects can provoke IgE mediated food allergy. Of all the food additives, reactions to sulphites have been the best characterised and are the only food additives required by law to be declared on food labels (see Chapter 4.5). Sulphites are used universally to inhibit the enzymatic and non-enzymatic reactions that control browning (Taylor *et al.*, 2003). They are primarily added to wine, cider, vinegar, pectin, clear or light coloured fruit juices, lime and lemon juice and dried foods such as dried fruit and dried onions (E220–E228). Food hypersensitivity involving sulphites is more likely to affect asthmatic patients, especially those with steroid dependent asthma (Bush *et al.*, 1986). However, following the reduction in the levels of sulphite additives permitted to be added to foods by the US Food and Drug Administration, a significant drop in the number of adverse reactions reported to be linked with sulphite consumption was noted (Timbo *et al.*, 2004). Normal symptoms in sulphite sensitive individuals include the

Table 7.11.17 Dietary guidance for wheat exclusion

Cereal foods that must be excluded	Other foods that may need to be excluded	Cereal foods that can be included
All types of bread, including rolls, malt bread, chapatti, pitta, naan, paratha, croissants, soda bread and fancy breads Some gluten free breads Breakfast cereals unless derived solely from oat, rice and/or maize (corn) Cakes, biscuits and crackers Flour and all foods containing wheat, e.g. pastry, pies, batters, pancakes, sauces Bran Pasta Semolina, couscous Pizza Proprietary gluten free foods containing wheat starch Whole wheat or wheat grains Wheat flour Wheat starch (or modified starch) Wheat bran Wheat germ Wheat binder Wheat gluten Wheat thickener Cereal filler Rusk Breadcrumbs or bread	Manufactured foods containing any of the following ingredients: Modified starch (mostly from maize derived) Wheat germ oil Wheat thickener Raising agent containing wheat starch Hydrolysed wheat protein Spelt Oats* Rye* Barley* Triticale*	Rice and rice flour Corn (maize) and cornflour (polenta) Millet Arrowroot Buckwheat Sago and sago flour Tapioca Quinoa Proprietary gluten free, wheat free foods (NB: only prescribable for coeliac disease, not wheat intolerance <i>per se</i>)

*Some patients may have a cross sensitisation with these grains.

development of flushing, nasal and sinus symptoms, bronchospasm and occasional gastrointestinal upset, which usually develop 30–45 minutes after eating a high sulphite food, although they can develop much sooner than this. Like many other types of FHS, sulphite intolerance is dose dependent; whilst a small number of people are sensitive to small amounts, most report symptoms after consuming a dose of >20 mg (see Appendix A5).

Pharmacological food reactions

Reactions to biogenic amines, salicylates and other naturally occurring components of food are poorly researched and understood. It has been proposed that there is no relation between the oral ingestion of biogenic amines and FHS reactions (Jansen *et al.*, 2003). However, a more recent review concluded that histamine intolerance is probably underestimated (Maintz & Novak, 2007). Dietary histamine is degraded by the enzyme diamine oxidase, a lack of which may precipitate symptoms similar to those elicited by an IgE mediated food allergic reaction (Malone & Metcalfe, 1986). Like most pharmacological reactions, a histamine response is dose dependent; most people will react to a large dose but those who are especially sensitive may respond to levels as low as 2.5 mg (Malone & Metcalfe, 1986). Foods rich in biogenic amines include strong cheeses, especially Parmesan cheese and blue cheeses such as Roquefort, red wine, spinach, aubergines, yeast extract and scombroid fish such as tuna and mackerel (Fritz & Baldwin, 2003). Salicylates are signalling molecules usually present in plant foods in the form of salicylic acid. It is unknown whether naturally occurring salicylic acid in foods can provoke a response in individuals with a hypersensitivity to another form of salicylic acid, acetyl salicylate (aspirin). The efficacy of the avoidance of dietary salicylate has been refuted (Dahlén *et al.*, 1994), although others have suggested salicylate intolerance could be relevant in a percentage of people with a pre-existing intolerance to non-steroidal anti-inflammatory drugs who also have diseases of the lower gastrointestinal tract (Raithel *et al.*, 2005). The issue is compounded by the variance of the salicylate content of foods due to varietal differences and growing conditions (Baxter *et al.*, 2001). Dietary advice on salicylate avoidance is further complicated due to large discrepancies in the amounts of salicylate attributed by different studies to specific foods (Swain *et al.*, 1985; Venema *et al.*, 1996; Scotter *et al.*, 2007). The benefits of salicylate avoidance need to be weighed against the fact that a diet high in natural salicylates may be beneficial for the prevention of cancer and heart disease.

Other pharmacological reactions include those reported to dietary methylxanthines, such as caffeine in coffee, cola and chocolate, and theobromine in chocolate. These substances can provoke symptoms such as anxiety and disordered sleep in sensitive individuals (Mathew & Wilson, 1990; Pollak & Bright, 2003), although both coffee and cola drinks have also been reported to trigger urticaria and anaphylaxis (Infante *et al.*, 2003; Fernandez-Nieto *et al.*, 2002). Despite chocolate being the most commonly

reported food to provoke symptoms in the prevalence study of Young *et al.* (1994), allergy to chocolate bars is unlikely due to extensive processing of the cocoa beans (Zak & Keeney, 1976), although it has been proposed that the availability of chocolate containing pieces of roasted or raw cacao nut could lead to an increase in reported reactions (Chapman *et al.*, 2006).

Reactions to alcohol are most commonly due to a deficiency of the enzyme alcohol dehydrogenase, which predominantly affects people of Asian ethnicity (Agarwal *et al.*, 1981). However, alcoholic drinks can provoke FHS reactions or act as a cofactor in precipitating or exacerbating these reactions. The alcoholic drink most commonly reported to cause symptoms is red wine (Linneberg *et al.*, 2008). Rarely, but occasionally, these reactions are due to the pure alcohol itself (Ehlers *et al.*, 2002), but more common precipitants are the biogenic amines or added sodium metabisulphite (Fritz & Baldwin, 2003; Vally & Thompson, 2001). The LTP allergens in barley, wheat and grapes have also been reported to trigger severe IgE mediated allergic responses to beer and wine (Asero *et al.*, 2001; Herzinger *et al.*, 2004; Kalogeromitros *et al.*, 2005).

7.11.3 HIV and AIDS

Karen Klassen

Key points

- Good nutritional status is important for a healthy immune system.
- Human immunodeficiency virus (HIV) disease can present with a variety of nutritional problems.
- Nutritional interventions for people with HIV infection can include management of weight loss, micronutrient deficiencies, gastrointestinal complaints and metabolic diseases, such as dyslipidaemia, insulin resistance and osteoporosis.

The nutritional status of patients with human immunodeficiency virus (HIV) infection remains an important part of the medical management of HIV care worldwide. Both over- and under-nutrition can have important consequences for the health and wellbeing of patients. Although weight loss is much less common since effective antiretroviral therapy (ART) has been available, it is still highly prevalent, and even small amounts of unintentional weight loss may increase the risk of morbidity and mortality in this population. In juxtaposition to this is the rapidly increasing occurrence of obesity and metabolic complications. The combination of HIV infection, ART and lifestyle factors are contributing to the increased risk of cardiovascular disease and events, diabetes and osteoporosis. Nutrition intervention is the first line in the management for all these problems and is therefore crucial for both prevention and treatment in the HIV setting.

Some of the aims of dietetic intervention and nutritional care of patients with HIV infection are:

- Maintaining or achieving a healthy weight for the individual.
- Promoting a well balanced diet in order to optimise macro- and micro-nutrient status.
- Preventing or managing malnutrition and opportunistic infections.
- Preventing food borne illness.
- Improving and supporting quality of life.
- Increasing nutrition self management skills for people living with HIV disease and/or their carers.
- Decreasing hospitalisations, emergency room visits, morbidity and mortality, and cost of care.
- Decreasing or delaying invasive or expensive treatments by providing early, appropriate nutrition interventions.
- Improving tolerance and adherence to medications.
- Preventing or managing metabolic and morphological comorbidities.

The HIV virus was isolated and identified as responsible for acquired immune deficiency syndrome (AIDS) in 1983. HIV infection does not immediately cause AIDS; however, it grows in CD4 T cells, a subset of lymphocytes, and causes them to decrease in most instances, although

the rate of decline will vary among individuals. The first antiretroviral medicine for HIV was zidovudine (also known as AZT) and it became available in 1987. Since that time, the development and availability of other ART has been rapidly evolving.

In 2009, it was estimated that 33.3 million people around the world were living with HIV infection. Just over half of all adults living with HIV are women, and 2.6 million children are living with HIV, but a further 16.6 million have been orphaned due to AIDS. According to the Joint United Nations Programme on HIV/AIDS (UNAIDS, 2010), as of 2010, the overall growth of the global AIDS epidemic appears to have stabilised. It was thought to have peaked in 1999, and since then, the overall number of new infections has decreased. Although the rate of new HIV infections has decreased, sub Saharan Africa still bears an inordinate share of the global HIV burden, with 22.5 million (68% of the global total) people there living with HIV infection in 2009.

In the UK, as a direct result of reduced mortality and improved life expectancy with HIV (May *et al.*, 2011), the number of HIV positive people is increasing, and by 2012 it is estimated that 100 000 people will be living with HIV. By 2015, 50% of people living with HIV in the UK will be over the age of 50 years (Health Protection Agency, 2010). While this number is relatively low, it has increased substantially since the 1990s. New diagnoses among men who have sex with men (MSM) remains high. More than half (51%) of HIV diagnosed individuals accessing HIV care in 2009 were infected via heterosexual sex (12 290 men and 21 020 women), of whom 66% were black African and 21% were white (Table 7.11.18). Of those individuals who attended clinics for HIV care, 43% were MSM and 88% of these were white. A small proportion of individuals were infected through injecting drugs (2%, 1550) and mother to child transmission (2%, 1380).

Diagnosis and disease classification

Diagnosis of HIV is based on detecting anti-HIV antibodies in the serum. The enzyme linked immunoabsorbent antibody (ELISA) test, also known as enzyme immunoassay (EIA), was the first HIV test to be widely used; other HIV tests are now available. Most people will

Table 7.11.18 Ethnicity of HIV infected individuals seen for care in the UK

Ethnicity	2000	2009
White	66.5%	52.0%
Black Caribbean	2.5%	3.0%
Black African	23.3%	36.2%
Asian/Oriental	2.4%	3.0%
Other/mixed	6.4%	5.9%

develop detectable levels of antibodies within 3 months of acquiring HIV. If an HIV test is positive, the most common secondary tests are CD4 T cell count and viral load. The CD4 T cell count is a reliable indicator of the risk of acquiring opportunistic infections and is monitored over time. Viral load is the amount of virus in the peripheral blood and is used as a surrogate marker of viral replication rate. These are also used as markers to evaluate the effectiveness of ART. These markers are strongly associated with clinical response; however, they should be interpreted along with an individual's clinical condition (Gazzard *et al.*, 2008).

HIV disease staging and classification systems have been developed by the Centers for Disease Control (CDC) in the USA (Castro *et al.*, 1993) and the World Health Organization (WHO, 2007). These staging systems are used to track and monitor the HIV epidemic, as well as provide clinicians and patients with information about HIV disease stage and clinical management. The WHO system can be used in resource constrained settings, which may not have access to CD4 cell counts or other laboratory parameters. The CDC disease staging system was developed in 1986 and most recently revised in 1993, and it assesses the severity of HIV disease by CD4 cell count and the presence of specific HIV related conditions (Table 7.11.19).

Category B symptomatic conditions

These are symptomatic conditions occurring in an HIV infected adolescent or adult that meet at least one of the following criteria; including, but are not limited to, the following:

- Bacillary angiomatosis.
- Oropharyngeal candidiasis (thrush).
- Vulvovaginal candidiasis, persistent or resistant.
- Pelvic inflammatory disease (PID).
- Cervical dysplasia (moderate or severe) or cervical carcinoma *in situ*.
- Hairy leucoplakia, oral.
- Herpes zoster (shingles), involving two or more episodes or at least one dermatome.
- Idiopathic thrombocytopenic purpura.
- Constitutional symptoms, such as fever (>38.5°C) or diarrhoea lasting >1 month.
- Peripheral neuropathy.

Table 7.11.19 CDC classification system for HIV infected adults and adolescents

CD4 cell category	Clinical category		
	A Asymptomatic, acute HIV or PGL	B* Symptomatic conditions, not A or C	C# AIDS indicator conditions
≥500 cells/μL	A1	B1	C1
200–499 cells/μL	A2	B2	C2
<200 cells/μL	A3	B3	C3

Patients in shaded categories are considered to have AIDS. PGL persistent generalised lymphadenopathy; CDC, USA Centers for Disease Control.

Category C AIDS indicator conditions

- Bacterial pneumonia, recurrent (two or more episodes in 12 months).
- Candidiasis of the bronchi, trachea or lungs.
- Candidiasis, oesophageal.
- Cervical carcinoma, invasive, confirmed by biopsy.
- Coccidioidomycosis, disseminated or extrapulmonary.
- Cryptococcosis, extrapulmonary.
- Cryptosporidiosis, chronic intestinal (>1 month in duration).
- Cytomegalovirus disease (other than the liver, spleen or nodes).
- Encephalopathy, HIV related.
- Herpes simplex: chronic ulcers (>1 month in duration), or bronchitis, pneumonitis or esophagitis.
- Histoplasmosis, disseminated or extrapulmonary.
- Isosporiasis, chronic intestinal (>1 month duration).
- Kaposi sarcoma.
- Lymphoma, Burkitt's, immunoblastic or primary central nervous system.
- *Mycobacterium avium* complex (MAC) or *Mycobacterium kansasii*, disseminated or extrapulmonary.
- *Mycobacterium tuberculosis*, pulmonary or extrapulmonary.
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary.
- *Pneumocystis jiroveci* (formerly *carinii*) pneumonia (PCP).
- Progressive multifocal leucoencephalopathy (PML).
- *Salmonella* septicaemia, recurrent (non-typhoid).
- Toxoplasmosis of brain.
- Wasting syndrome caused by HIV (involuntary weight loss of >10% of baseline body weight) associated with either chronic diarrhoea (two or more loose stools/day for ≥1 month) or chronic weakness and documented fever for 1 month or longer.

Clinical investigation and management

There is no cure for HIV itself but treatment is available. Life expectancy in people treated for HIV infection has increased following the availability and widespread use of ART; however, it still appears to be shorter than that of the general population in the UK (May *et al.*, 2011). If treatment is started early and taken correctly, overall health and life expectancy are greatly improved. However, in the UK, half of adults are diagnosed with HIV at a late stage of infection (CD4 counts <350 cells/mm³ within 3 months of diagnosis). People diagnosed soon after infection may not need to start treatment straight away, depending on their clinical condition and/or CD4 cell counts. Treatment options have improved greatly over recent years; complex regimens with many side effects are being replaced with just one or two pills once or twice a day. Someone who is diagnosed now will have a different experience from someone who has been living with HIV for some time and gone through many different treatment options. Some people suffer side effects with ART, including nausea, diarrhoea, fatigue and headaches, especially in the first few weeks after starting treatment. Other side effects can include metabolic diseases (covered later in this chapter), peripheral neuropathy, lactic acidosis, pancreatitis, mitochondrial toxicity and hepatotoxicity. In some cases, treatment causes changes in body shape, depression and mental health issues. Other people find they are able to lead a very healthy life with HIV and may not suffer the same side effects. As well as managing medications and its side effects, social care, peer support and counselling are all important forms of support for people with HIV.

The British HIV Association has developed guidelines (Table 7.11.20) on treating HIV infection (Gazzard *et al.*, 2008), which provide the rationale for the treatment with antiretroviral drugs as follows:

Table 7.11.20 Recommendations for when to initiate therapy

Presentation	When to treat
Primary HIV infection	Treatment in clinical trial Or when there is neurological involvement Or when CD4 <200 cells/mL for >3 months Or AIDS defining illness
Established HIV infection	
CD4 <200 cells/mL	Treat
CD4 201–350 cells/mL	Treat as soon as possible when patient ready
CD4 351–500 cells/mL	Treat in specific situations with higher risk of clinical events – see text
CD4 >500 cells/mL	Consider enrolment into ‘when to start’ trial
AIDS diagnosis	Treat (except for tuberculosis when CD4 >350 cells/mL)

- Preservation of specific anti-HIV immune responses that would otherwise be lost, and which are associated with long term non-progression in untreated individuals.
- Reduction in morbidity associated with high viraemia and CD4 depletion during acute infection.
- Reduction in the risk of onward transmission of HIV.

There are currently seven different classes of antiretroviral drugs, each targeting the virus at different stages of its life cycle (Figure 7.11.5). The drug classes are:

- Nucleoside reverse transcriptase inhibitors (NsRTIs).
- Nucleotide reverse transcriptase inhibitor (NtRTI).
- Non-nucleoside reverse transcriptase inhibitors (NNRTIs).
- Protease inhibitors (PIs).
- Fusion inhibitor.
- CCR5 antagonist.
- Integrase inhibitor.

For further reading on the pharmacology and use of ART, see Chen *et al.* (2007).

Public health aspects and prevention

Transmission

The HIV virus is found in the blood and other body fluids, such as semen, vaginal fluid and breast milk; the virus does not survive for long outside the body. The most common form of transmission is through sexual contact, but it can also be transmitted through sharing needles and mother to child transmission via breastfeeding or during delivery.

Stigma

AIDS related stigma and discrimination refer to prejudice, negative attitudes, abuse and maltreatment directed at people living with HIV/AIDS (AVERT). Examples of this are being shunned by family, peers and the wider community; poor treatment in healthcare and education settings; an erosion of rights; and psychological damage. These can negatively affect the success of HIV testing and treatment.

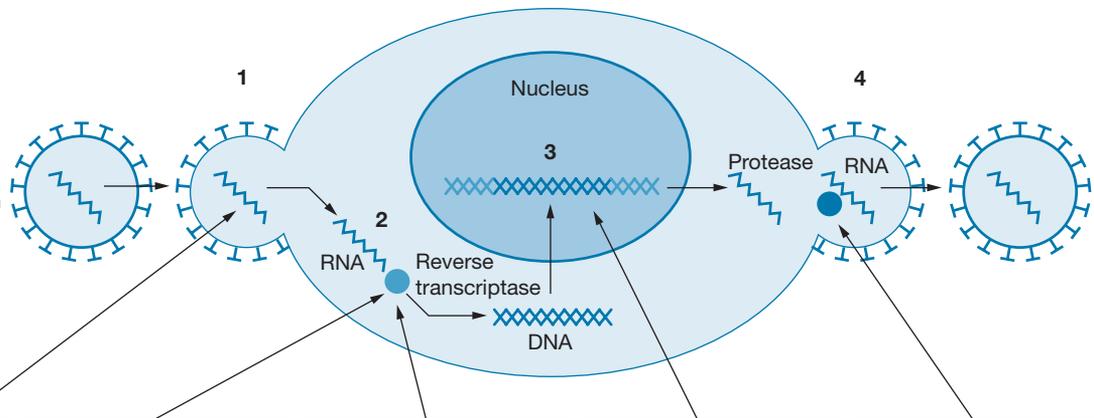

Although the awareness and understanding of HIV have improved in the UK over the past decade, stigma and discrimination still exist and can come from family, friends and healthcare workers. The National AIDS Trust surveyed HIV positive people and found that one in three reported had experienced discrimination in the UK. As a healthcare professional, it is essential to understand how HIV is transmitted, to use universal precautions with all patients [as it is estimated that one-quarter of people infected with HIV in the UK are unaware of their diagnosis (Health Protection Agency, 2010)] and to demonstrate non-judgemental attitudes towards all patients.

Nutritional assessment

Nutritional assessment of patients living with HIV infection may vary depending on the reason for referral and

Stages of HIV replication

1. HIV enters a CD4 cell.
2. HIV is a retrovirus, meaning that its genetic information is stored on single-stranded RNA instead of the double-stranded DNA found in most organisms.
3. HIV DNA enters the nucleus of the CD4 cell and inserts itself into the cell's DNA. HIV DNA then instructs the cell to make many copies of the original virus.
4. New virus particles are assembled and leave the cell, ready to infect other CD4 cells.

Fusion Inhibitors	Non-nucleoside reverse transcriptase inhibitors	Nucleoside/Nucleotide analogues	Integrase Inhibitors	Protease Inhibitors
Fusion inhibitors work outside the cell to prevent the first stage of HIV replication. They prevent HIV from entering the CD4 cell by blocking fusion of the outer membrane of the virus with the cell membrane.	Non-nucleoside reverse transcriptase inhibitors bind to reverse transcriptase and inhibit the enzyme. This stops HIV replication by preventing the conversion of RNA to DNA. These drugs are called "non-nucleoside" inhibitors because even though they work at the same stage as nucleoside analogues, they act in a completely different way.	The first effective class of antiretroviral drugs was the nucleoside analogues. They act as false substrates for reverse transcriptase, causing chain termination. The resulting DNA is incomplete and this prevents HIV replication. Nucleotides work in a similar way to nucleosides but they have a different chemical structure.	Blocking integration of HIV DNA into the cell nucleus is a promising target for anti-HIV drugs because this step is essential for viral replication. Integrase inhibitors are not yet clinically available.	Protease inhibitors work at the last stage of the viral replication cycle. They prevent HIV from being successfully assembled and released from the infected CD4 cell.

Figure 7.11.5 Actions of drugs that target HIV replication (source: Boehringer Ingelheim 2009. Reproduced with permission of Boehringer Ingelheim Pty Ltd, Germany)

the individual's clinical condition. This section will highlight aspects of nutritional assessment that are specific to working with patients with HIV.

Anthropometry and related tests

Routine nutritional assessment includes anthropometric measurements, and several HIV guidance documents recommend these at the time of starting ART and annually thereafter (Asboe *et al.*, 2011; Lundgren *et al.*, 2008). Using a variety of anthropometric measurements (Table 7.11.21) is helpful in order to adequately assess fat distribution changes and muscle mass loss. Fat free mass (FFM) and fat mass are generally lower in people with HIV (Fields-Gardner *et al.*, 2010). Studies evaluating anthropometry with gold standard measurements have found that anthropometry measurements correlated well with magnetic resonance imaging (MRI) (Scherzer *et al.*, 2008). Furthermore, they found that simple anthropometric measurements, such as mid arm muscle circumference and mid thigh muscle circumference, were associated with health risk indicators almost as strongly as MRI based measures.

In addition to anthropometric measurements, physical examination can provide additional evidence of nutritional status.

Signs of malnutrition can be:

- Easily plucked or falling out hair.
- Poor skin pallor or turgor, or dry, flaky, scaly skin.
- Scooped or cracking nails.
- Muscle wasting and weakness (can be visually determined by looking at the following muscles: temporalis, deltoids, biceps, quadriceps).
- Loss of fat stores can be easily seen by looking at the fat pads under the eyes and by pinching (lightly) the skin behind the triceps.

Biochemical and haematological tests

Biochemistry and haematology assessment will depend on the patient's clinical condition and varies widely as patients with HIV present with a variety of clinical needs (Table 7.11.22).

Clinical assessment

Clinical assessment will include:

- Current medications (including side effects) and medication history.
- Use of supplements, vitamins, herbs and over the counter medicines.

Table 7.11.21 Anthropometric and related assessments of individuals with HIV infection

Measurements	Indication of
Anthropometric	
Weight	Overall nutritional status; however, must be interpreted in individuals with caution and with a view to evaluating other aspects of body composition
Body mass index	Good marker of nutritional status in populations; can determine if overweight, obese or underweight; interpret with caution in individuals
Waist circumference	A good correlate of visceral fat and an indicator of metabolic syndrome
Mid upper arm circumference	Reflection of muscle and subcutaneous fat stores; can compare with reference values and evaluate changes over time
Triceps skinfold	Subcutaneous fat stores; can compare against reference values and serial changes in an individual
Mid arm muscle circumference	A good marker of lean body mass; useful in assessing changes in individuals
Hip circumference	On its own can reflect buttock muscle and fat stores and can be monitored serially in individuals
Waist to hip ratio	Use with reference values, but interpret in light of potential fat loss from lipodystrophy
Other skinfold measurements	Can be used to assess overall subcutaneous fat and estimate total body fat percentage
Other measurements	
Bioelectrical impedance analysis	Low phase angles have been shown to be of prognostic relevance in HIV infected patients (Kyle <i>et al.</i> , 2004); however, are not sensitive to detect changes in body shape, nor should be used to evaluate fat atrophy (Schwenk <i>et al.</i> , 2001). Can measure body cell mass, which is a component of some definitions of HIV related wasting (see Table 7.11.23)
Handgrip strength	A measure of muscle strength; correlates well with nutritional status; however interpret with caution as limited reference values, and consider factors such as mood, mobility and peripheral neuropathy

- Current medical status (opportunistic infections and comorbid conditions) and medical history.
- Blood pressure.
- Appetite, nausea, vomiting, early satiety, chewing and swallowing difficulties (note dentition).
- Bowel history (including frequency and consistency) and other changes in gastrointestinal function.
- Use risk calculators to calculate 10-year risk of cardiovascular disease (e.g. www.patient.co.uk/doctor/Primary-Cardiovascular-Risk-Calculator.htm) or 10-year risk of fracture (www.shef.ac.uk/FRAX/).

Dietary assessment

The dietary assessment should include:

- A record of dietary intake and food patterns:
 - Depending on the reason for referral, a variety of dietary history tools may be employed, e.g. 24-hour recall, food frequency questionnaire and usual intake pattern.
 - A recall of usual intake in 24 hours is also a good way to check medication adherence.
- Food allergies and intolerances.
- Other lifestyle factors should be included as a part of the dietary assessment:
 - Alcohol intake.
 - Smoking (history and frequency).
 - Substance abuse (history and frequency).
 - Eating out.
 - Erratic meal patterns.
- Nutritional knowledge.

Economic and social assessment

Patients living with HIV infection come from wide socio-economic and ethnic backgrounds, and individual assessment is crucial. Common characteristics to consider include:

- *Psychosocial factors* – depression, substance abuse, dementia and other psychiatric problems that may impede appetite or the ability to prepare meals.
 - *Educational factors* – consider basic understanding of bodily functions and key nutritional principles.
 - *Living environment* – homelessness, bed and breakfast rooms, access to a stove or refrigerator. Asking patients about their living environment and available cooking and food storage equipment is important for providing the appropriate nutritional advice.
 - *Financial factors* – poverty is a common problem and can be cyclical. Major drivers of poverty among people with HIV include:
 - Immigration system.
 - Insufficient benefits.
 - Poor physical or mental health.
 - Unemployment.
 - Inadequate housing.
 - Responsibility for children.
- The Terence Higgins Trust and National AIDS Trust (www.nat.org.uk/Media%20library/Files/Policy/2011/HIV&Poverty.pdf) provide support to many people with HIV living in poverty.
- *Functional status* – the ability to shop and prepare food. Other comorbidities and/or side effects, such as

Table 7.11.22 Laboratory markers used in patients with hiv infection

	Use to assess
Plasma markers	
Urea	Hydration status, renal function (usually measured in an inpatient setting)
Creatinine	Renal function (also useful to calculate estimated glomerular filtration rate) (Labarga <i>et al.</i> , 2010)
Potassium	Can be low in poor nutritional states and high in chronic renal disease
Phosphate	Measure of phosphate intake; however, hypophosphataemia is very common in people with HIV infection (Assadi, 2010) and needs to be interpreted in view of dietary intake, malabsorption, vitamin D deficiency and, importantly, tubular renal losses most commonly due to antiretroviral therapy and hyperparathyroidism. A fractional excretion of phosphate will help to determine the cause of hypophosphataemia
Liver function tests (LFTs)	Increased LFTs can be an indicator of liver function, especially considering the high prevalence of coinfection with hepatitis B and C; however, if only alkaline phosphatase is raised, it may be due to increased bone turnover and/or vitamin D deficiency
CD4 T cell count	See text
Viral load	See text
Albumin	Indicator of visceral protein status and related to inflammatory states, e.g. difficult to assess in cases of liver disease and acute infection. It is also an indicator of disease state and mortality. Can be low in malabsorption and states of protein loss
Vitamin B ₁₂ , folate	Low in macrocytic anaemia, can be related to low dietary intakes or other causes
Ferritin transferrin saturation, total iron binding capacity, etc.	Low in microcytic anaemic, can be related to low dietary intakes or other causes
Zinc, selenium	Need to be interpreted with caution in inflammatory states (see Micronutrients section)
Calcium	Plasma levels are bound to plasma proteins (such as albumin) and are tightly regulated, so are not a good reflector of dietary calcium intake
Vitamin D, parathyroid hormone (PTH)	Vitamin D deficiency is common in HIV as it is in many other individuals. Vitamin D deficiency or dietary calcium deficiency can result in secondary hyperparathyroidism
Other fat soluble vitamins	Can be useful to measure in patients with fat malabsorption
Hormones: testosterone, oestradiol, thyroid	Measured to rule out secondary causes of wasting and low bone mineral density
Fasting lipids (total cholesterol, HDL, LDL, triglycerides)	Use local reference values and national guidelines for target levels
Fasting glucose	Increased fasting or random glucose should warrant an oral glucose tolerance test to rule out diabetes, impaired glucose tolerance or impaired fasting glucose. It has been suggested that fasting insulin and glucose should be routinely measured, and HOMA-IR calculated, particularly in those at highest risk, such as those with metabolic syndrome, obesity, lipodystrophy or a longer exposure to antiretrovirals (Gianotti <i>et al.</i> , 2011).
Urine markers	
Protein: creatinine	Reflects renal protein loss and is more sensitive than a dipstick test. Should be measured annually in all patients on ART
Fractional excretion of phosphate (FePi)	$FePi = \frac{\text{urine phosphate} \times \text{serum creatinine} \times 100}{\text{serum phosphate} \times \text{urine creatinine}}$. This should be done fasting and can be used to determine whether hypophosphataemia is a result of renal losses or inadequate dietary intake/reduced gastrointestinal absorption
Faecal markers	
1-alpha antitrypsin	A protein synthesised in the liver that is neither actively secreted nor absorbed. Use with serum levels to determine clearance in order to help diagnose protein losing enteropathy if indicated (Umar & DiBaise, 2010)
Pancreatic elastase	Used to determine exocrine pancreatic function that may result in fat malabsorption and diarrhoea

peripheral neuropathy and severe weight loss, will affect energy levels and ability to prepare food and carry shopping bags. In addition to social services, some HIV charities can provide assistance and support to patients with these conditions.

- **Cultural factors** – dietary restrictions and habits. Becoming acquainted with food habits common in various cultures and religions will assist in providing appropriate nutritional advice. For example, some Somalian, Ethiopian and Eritrean patients may be

Orthodox Christian and may restrict meat during the Lenten season. For some, this will decrease ferritin stores and they may require iron supplementation during this time period. As well as religious restrictions, recent immigrants to the UK may find foods they are familiar with difficult to access. Knowledge of foods commonly consumed will enable the practitioner to advise on appropriate substitutes as well recipe modifications when necessary (see Chapter 3.5).

Energy and protein requirements

Energy requirements are likely to increase by 10% to maintain body weight and physical activity in asymptomatic HIV infected adults not on ART. During symptomatic HIV, and subsequently during AIDS, energy requirements increase by approximately 20–30% to maintain adult body weight (World Health Organization, 2003). Although studies of energy expenditure have not shown an increase in overall total energy expenditure (TEE) in patients with HIV related wasting, this may have been the result of individuals compensating by reducing activity related energy expenditure (AEE). Therefore, weight loss may have resulted from reduced dietary intake (Macallan *et al.*, 1995). Reviews of energy expenditure in HIV have concluded that it appears that resting energy expenditure (REE) is higher (but not always TEE) in HIV infected patients not on ART (Fields-Gardner *et al.*, 2010; Chang *et al.*, 2007), and a meta analysis confirmed this (Batterham, 2005). Factors associated with altered REE appear to be viral load, CD4, use of ART, body composition, hormones and proinflammatory cytokines, as well as other opportunistic infections.

Protein requirements have not been specifically addressed in studies of HIV adults. They may have higher requirements to maintain lean body mass, and general recommendations are 1.2–1.5 g/kg of body weight/day (Ockenga *et al.*, 2006). Protein requirements should take into consideration stage of HIV disease and presence of other infections or comorbidities.

Nutritional problems and their management

It is well known that nutritional deficiencies are commonly associated with an impaired immune response (see Chapter 7.11.1); therefore, malnutrition in patients living with HIV has serious consequences. Adults living with HIV can present with a variety of nutritional problems throughout the course of HIV infection. Furthermore, patients requiring dietetic intervention are often critically unwell, have multiple medical diagnoses and mental health issues, as well as issues surrounding confidentiality, stigma and ART adherence that require a specialist team approach. The complexity of these patients requires input from a specialist dietitian trained in the area of HIV, who plays an active role in the multidisciplinary team (MDT).

The different stages of HIV infection as well as opportunistic infections, comorbidities and metabolic side effects of antiretroviral therapy can all lead to various

nutritional problems. Ideally, all patients with HIV infection should have access to a registered dietitian for nutritional advice. Table 7.11.23 shows which patients with HIV in the inpatient and outpatient settings require a referral to an HIV specialist dietitian, and a summary of the possible outcomes from the referral.

Medication side effects

Side effects are most commonly seen in people who have recently started antiretroviral therapy; however, they can also occur due to the HIV infection itself, other opportunistic and comorbid conditions, or other medications. The most common side effects are:

- Nausea.
- Vomiting.
- Diarrhoea.
- Taste changes.
- Dry mouth.
- Flatulence.

Dietetic interventions for these side effects can be found in other chapters of this book.

Wasting and weight loss

Weight loss remains a problem for many people with HIV infection, even those on ART. In a longitudinal cohort of 466 patients followed from 1995 to 2005, the prevalence of wasting and weight loss was 38% (Tang *et al.*, 2005). Several studies have shown that weight or muscle mass loss, even a 5% loss of usual weight, increases the risk of mortality (Tang *et al.*, 2005; Scherzer *et al.*, 2011). Furthermore, HIV wasting disease is defined as an AIDS defining illness (Centers for Disease Control, 1987) that is common in states of severe immunodeficiency (Polsky *et al.*, 2001; Mangili *et al.*, 2006). Many clinicians and researchers in the area felt that the Centers for Disease Control definition of an AIDS defining illness did not fully capture all patients with HIV wasting; therefore, other definitions have been proposed (Table 7.11.24).

In cases of weight loss despite adequate highly active ART (HAART), special consideration has to be given to other factors such as depression, gastrointestinal disease, anorexia, self neglect, e.g. drug users, or dry mouth/lack of saliva caused by medication (Grinspoon *et al.*, 2003).

Aetiology

Weight loss can be due to one or a combination of several factors, depending on the patient's immune function and clinical condition (Figure 7.11.6):

- *Reduced food intake* – this can be due to a poor appetite, dysphagia or nausea.
- *Malabsorption* – can arise from other opportunistic infections, such as *Mycobacterium* spp., *Cryptosporidium*, pancreatic dysfunction or HIV enteropathy (Knox *et al.*, 2000).
- *Hypermetabolism* – resting energy expenditure (REE) is increased in patients not on ART and is positively correlated with viral load and C-reactive protein level

Table 7.11.23 Dietetic interventions and outcomes for treating nutritional problems in patients with HIV infection

Patients requiring a dietetic referral	Dietetic interventions and outcomes of referral
All patients with HIV	Healthy eating principles that ensure adequate nutrition and promote a healthy immune system to reduce infections and prevent development of metabolic comorbidities
Immunocompromised (e.g. CD4+ cell count <200 cells/mL)	Food and water safety counselling to reduce the risk of developing food and water borne illnesses
Pregnant women	Antenatal and postnatal nutrition and breastfeeding education (see Chapter 3.8.2) Improving micronutrient deficiency (including iron) and constipation
Poor dietary intake due to disease or side effects of treatment	Nutrition strategies for symptom management, e.g. anorexia, early satiety, swallowing problems, thrush, nausea and vomiting, diarrhoea, food intolerances Outcomes may be improved diarrhoea and improved dietary intake ensuring adequacy of macro- and micro-nutrients (prevention of weight loss and loss of lean body mass, which is known to increase mortality)
Patients taking antiretrovirals or other medications relating to opportunistic infections or comorbidities	Identifying food–medication interactions and strategies to ensure optimal medication efficacy and provide adherence support
Loss of >5% of usual weight	Alternative feeding methods, e.g. oral supplementation, tube feeding and parenteral nutrition Outcomes may be reduced risk of infections, mortality, hospital admissions (if an outpatient) and length of stay (if inpatient), and improve patient experience (quality of life and energy levels)
Dyslipidaemia and/or lipodystrophy and/or obesity and/or diabetes and/or insulin resistance	Strategies for treatment of body fat changes and altered metabolism (in collaboration with the clinician) include exercise, lipidlowering medications, dietary modifications, glycaemic control, hormonal normalisation and anabolic medications Outcomes may be prevention of cardiovascular disease events, reduced hospital admissions and improved quality of life (obesity related)
Bone disease (osteoporosis, osteopaenia, osteomalacia)	Assessment of dietary and lifestyle factors influencing bone mineral density (dietary protein, calcium, phosphorus and vitamin D; exercise, risk of falls, smoking, alcohol) and advice on altering these as needed Advising on vitamin D ± calcium supplementation Outcomes may include prevention of falls, fractures and hospital admissions
Allergies/intolerances or patients following special diets/taking excess supplementation	Evaluation of nutrition information, special diets, vitamin or mineral or other dietary supplementation, and other nutrition practices Prevention of toxic effects of hypervitaminosis, improved patient experience/wellbeing; ensuring nutritional adequacy, prevention of interactions with ART or other medications
Patients requiring weight loss or gain of lean body tissue	Additional activities and therapies that support good nutrition, e.g. physical exercise, medications for symptom management, chronic disease management, etc., including referral to appropriate exercise facilities See outcomes for dyslipidaemia
Alteration in bowel habit	Assessment of impact on quality of life and diet, dietary advice to improve symptoms (constipation/diarrhoea), discussion with patient about lifestyle factors; liaising with specialist gastroenterology team/dietitian, communication with GP if supplements or medicines are required Outcomes may be improved quality of life, prevention of nutritional deficiencies and enhanced medication absorption

ART, antiretroviral therapy.

Table 7.11.24 Definitions of HIV related wasting

CDC (Centers for Disease Control, 1987)	Consensus panel (Wanke <i>et al.</i> , 2004)	NFHL (Wanke <i>et al.</i> , 2000)
Involuntary weight loss of >10% of baseline body weight + either chronic diarrhoea or chronic weakness and documented fever in the absence of concurrent illness or condition	10% unintentional weight loss over 12 months Or 7.5% unintentional weight loss over 6 months Or 5% unintentional weight loss over 3 months Or in men: BCM <35% of total BW with BMI <27 kg/m ² Or in women: BCM <23% of total BW with BMI <27 kg/m ² In either men or women, regardless of BCM: BMI <20 kg/m ²	Unintentional loss of >10% of body weight Or BMI <20 kg/m ² Or Unintentional loss of >5% of body weight in 6 months and persisting for at least 1 year

BW, body weight; BMI, body mass index; BCM, body cell mass.

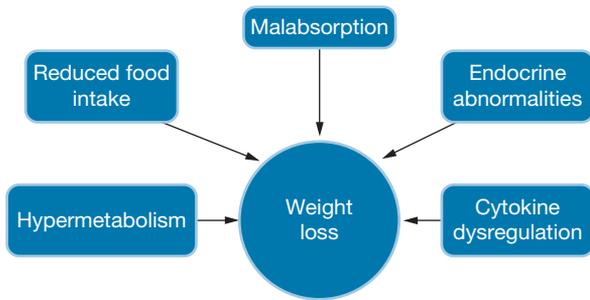

Figure 7.11.6 Potential causes of weight loss in HIV infected individuals

(Chang *et al.*, 2007). Opportunistic infections can also increase energy requirements.

- **Endocrine abnormalities** – altered regulation of anabolic and adipocyte hormones has also been implicated in causing increased REE. Altered regulation of other hormonal axes involved in energy homeostasis could potentially result from chronic immune activation.
- **Cytokine dysregulation** – increased REE is associated with catabolic cytokines interleukin (IL) 1b and tumour necrosis factor alpha (TNF α) abnormalities.

Dietetic treatment

The primary treatment for weight loss and HIV related wasting is treatment of the underlying condition that is leading to the weight loss. However, this is not always apparent and may take some time to diagnose. Therefore, to prevent further weight loss and to restore nutritional status, dietetic therapy is of paramount importance. Evaluating current dietary intake and calculating energy deficits is the first step in the nutritional management of someone who presents with weight loss. As hypermetabolism is one of the potential causes of weight loss, using indirect methods of measuring energy expenditure may help determine metabolic stress, which may be arising from opportunistic infections and other underlying conditions in addition to HIV disease itself. In the absence of objective measurements, anthropometric measurements should be closely monitored to determine effectiveness of nutritional intervention (see Chapter 6.1).

Several studies have shown that dietary counselling with oral nutritional supplements (providing 40–50 kcal/kg; 1.6g of protein/kg) achieved increases in dietary intake and lean body mass. When resistance exercise training was added, an even greater increase in physical functioning was achieved (Shevitz *et al.*, 2005; Rabeneck *et al.*, 1998). Another study evaluated resistance training and intramuscular testosterone injections in eugonadal men with AIDS wasting and these combined interventions increased muscle attenuation (Fairfield *et al.*, 2001). Other randomised controlled trials (RCTs) of nutritional supplements demonstrated an improvement in both energy and protein intake for patients given macronutrient supplements, compared with patients given placebos

or no supplements, but no uniform improvements in weight, fat mass or fat free mass were found (Grobler *et al.*, 2013). Most studies investigating the role of nutritional supplementation have not included HIV outcomes or mortality, although one trial found an increase in CD4+ cell counts associated with nutritional supplementation (Fields-Gardner *et al.*, 2010).

There is limited evidence regarding mode of artificial nutritional support. Enteral nutritional support is often used as supplementary intake in patients with HIV. For long term artificial nutritional support, gastrostomy feeding is feasible in HIV patients and should be considered as an option. Parenteral nutrition should be used only in patients who are unable to feed enterally (Ockenga *et al.*, 2006).

Diarrhoea and malabsorption are common causes of weight loss and poor nutritional status in patients with HIV. Furthermore, malabsorption in the absence of clinical symptoms has been found to be common in adults with HIV (Knox *et al.*, 2000). Medium chain triglycerides (MCTs) have been used in several studies in patients with HIV and diarrhoea. Use of MCTs results in fewer stools, decreased stool fat and weight, and increased weight gain and fat absorption (Wanke *et al.*, 1996). Several other nutritional interventions for diarrhoea in patients with HIV have been evaluated; however, these were all very small studies and from which conclusions could not be drawn. One study looking at vitamin A and beta-carotene supplements found that they decreased gut permeability and reduced the risk of severe watery diarrhoea. Other studies have looked at elemental diets, probiotics, pancreatic enzymes, calcium carbonate, glutamine and the BRAT diet [bananas, rice, apple sauce, weak tea and toast (American Dietetic Association Evidence Analysis Library, 2008)]. Other dietary strategies will depend on the cause and severity of diarrhoea.

Pharmacological agents used to treat HIV wasting have included megestrol acetate, oxandrolone and dronabinol (Grinspoon *et al.*, 2003).

Metabolic complications with nutritional consequences and/or causes

Metabolic complications in people living with HIV can arise from uncontrolled HIV replication, coinfections or as a side effect of some ART medicines. These complications include dyslipidaemias, altered glucose metabolism, bone problems, altered body fat metabolism characterised by changes in body composition, and lactic acidemia. The majority of antiretroviral medicines used to treat HIV interfere with viral genetic material. Many human metabolic processes are operationally similar to those of HIV viral replication, so it is not surprising that the side effects of ART include metabolic complications. As the population living with HIV ages, the prevalence of metabolic diseases will continue to increase. Helpful guidelines for the management of HIV related comorbidities are produced by the European Clinical AIDS Society (European AIDS Clinical Society).

Dyslipidaemia

Dyslipidaemia can occur from HIV infection or from ART. The following may occur in isolation or in combination, leading to an increased risk of cardiovascular disease:

- Hypertriglyceridaemia.
- Raised total or low density lipoprotein (LDL) cholesterol.
- Decreased high density lipoprotein (HDL) cholesterol.

Observational studies have reported that people living with HIV infection generally consume diets higher in total fat, saturated fat and dietary cholesterol, which has been related to dyslipidaemia (Shah *et al.*, 2005; Hadigan *et al.*, 2001).

Dietetic treatment

As there are several possible causes for dyslipidaemia in HIV infected individuals, evaluating the effect of dietary interventions is a complex task. Some studies have evaluated those with isolated dyslipidaemia, and others those with dyslipidaemia in the presence of lipodystrophy. Dietary advice has also varied between studies. Low fat dietary interventions have been investigated with various findings (Leyes *et al.*, 2008). In adults with HIV and dyslipidaemia, a retrospective review of dietary counselling found that total cholesterol decreased significantly by 13% (Woods *et al.*, 2009; Batterham *et al.*, 2003). Compliance with the dietary advice given was assessed in one trial; only 58 (36%) and 32 (45%) patients reported a good compliance with the prescribed diet at 3 and 6 months, and those with good compliance had a significant reduction in total cholesterol and triglyceride levels, as well as weight loss (Barrios *et al.*, 2002). n-3 Supplements have been shown in several trials to reduce triglycerides (De Truchis *et al.*, 2007), and when combined with dietary advice to reduce saturated fat, had an even greater effect and lowered the risk of lipohypertrophy (Woods *et al.*, 2009). Overall, there appears to be good evidence that a combination of exercise, low saturated fat, high fibre and decreased alcohol consumption all improved dyslipidaemia.

Altered glucose metabolism

Insulin resistance is the initial detectable step in the development of type 2 diabetes mellitus; in patients with HIV, it may be accompanied by abdominal adiposity, reduced limb fat and a buffalo hump. Traditional risk factors such as genetic predisposition, increased body mass index (BMI), smoking and increasing age, as well as HIV related factors such as mitochondrial dysfunction and elevated proinflammatory cytokines, all play a role in the development of diabetes mellitus (Paik & Kotler, 2011). Furthermore, patients on ART are more likely to develop glucose intolerance and diabetes mellitus than controls.

Care should be taken when using HbA_{1c} as a surrogate measure for glycaemic control in HIV patients as ART use may result in this measure underestimating glycaemia by up to 20%, particularly in patients using the nucleoside

reverse transcriptase inhibitors (NRTIs) such as abacavir (Kim *et al.*, 2009). The goals for diabetes mellitus treatment are the same as in uninfected individuals. The European AIDS Clinical Society and Paik & Kotler (2011) provide further information on management considerations.

Lipodystrophy (fat redistribution)

Lipodystrophy syndrome (LDS), also referred to as fat redistribution syndrome, describes body shape changes and metabolic disorders seen in some patients with HIV infection. Although the aetiology is likely multifactorial, most believe it occurs as a result of certain ART medications. Individual and viral factors such as duration of HIV disease, duration of ART, age, BMI, gender and ethnicity all seem to play a role in the development of lipodystrophy (Wohl & Brown, 2008). Limited evidence supports a relationship between low fibre or high glycaemic index (GI) and increased risk of fat deposition (Hendricks *et al.*, 2003).

Fat redistribution can occur in an individual in several ways:

- Lipodystrophy – the loss of subcutaneous fat tissue, most commonly in the legs, arms, buttocks and/or face.
- Fat accumulation (sometimes called lipohypertrophy) – the accumulation of adipose tissue in the intra-abdominal space (Figure 7.11.7), the dorsocervical

Figure 7.11.7 HIV infected woman with lipodystrophy [source: AIDS Images Library. Reproduced with permission of AIDS Image Library (www.aids-images.ch)]

regions (known commonly as the buffalo hump) and the breasts.

Dietetic management

There have been few RCTs studying lifestyle interventions in the treatment of lipodystrophy; therefore, much of the advice given in clinical practice is based on observational data and case series reports. There is no effective treatment for lipodystrophy using nutrition or lifestyle interventions. However, resistance exercises may improve the appearance of limbs by bulking up muscles to compensate for the loss of fat. Lipodystrophy is managed by switching ART regimens, and several other interventional treatments have been evaluated, but with limited effectiveness to date (Wohl & Brown, 2008). For facial fat tissue loss, polylactic acid has been reported to produce lasting changes in dermal thickness of the cheeks and is available for patients receiving care in the NHS in the UK (NICE, 2012).

Limited evidence from observational studies shows that a low fibre diet leads to an increased risk of developing lipohypertrophy (Hendricks *et al.*, 2003). A combination of diet and exercise in interventional trials has shown small improvements in abdominal girth and blood pressure, but limited effect on lipids (Engelson *et al.*, 2006; Driscoll *et al.*, 2004). Furthermore, a combination of both aerobic and resistance training appears to be the most beneficial exercise intervention in patients with HIV associated lipodystrophy (Yarasheski & Roubenoff, 2001).

Bone problems

Three main bone diseases have been described in the HIV setting:

- Osteopaenia and osteoporosis (decreased bone mineral density).

- Osteomalacia (softening of the bones or demineralisation from severe vitamin D or phosphate deficiency).
- Avascular necrosis.

The most commonly found and studied of these is reduced bone mineral density (BMD). Factors associated with low BMD in HIV infected patients are both traditional (i.e. well known in all populations to influence BMD) and HIV related:

- Low weight, BMI.
- Duration of HIV infection.
- Older age.
- Smoking.
- Non-black/white ethnicity.
- Corticosteroid exposure.
- Postmenopausal women.
- Viral load levels.
- ART exposure (most commonly, tenofovir and protease inhibitors).

Other risk factors also commonly found in patients with HIV include hypogonadism, vitamin D deficiency and secondary hyperparathyroidism, opiate use and various other medical conditions (McComsey *et al.*, 2010). Lifestyle factors influencing BMD include dietary calcium intake and exercise (North American Menopause Society, 2010). These have not been well explored in patients with HIV infection (see Chapter 7.9.1).

Micronutrient deficiencies

Micronutrient deficiencies are commonly seen in patients with HIV not on ART (Lanzillotti & Tang, 2005). They are also common in countries with poor overall nutritional status in the developing world. The micronutrients most commonly studied in patients with HIV are shown in Table 7.11.25.

Table 7.11.25 Observational studies of micronutrient deficiencies in relation to HIV disease

Micronutrient	Observational findings in HIV
Vitamin A	Low vitamin A levels have been associated with quicker progression of HIV disease and mortality in adults (Semba <i>et al.</i> , 1995, Tang <i>et al.</i> , 1993)
Vitamin D	Low vitamin D has been associated with HIV disease progression (Viard <i>et al.</i> , 2011; Mehta <i>et al.</i> , 2010). In the general population, vitamin D deficiency has been associated with cardiovascular disease, diabetes, immune functioning and mortality (Melamed <i>et al.</i> , 2008)
Zinc	Serum zinc levels have been linked to HIV disease progression, decreased CD4+ cell counts, and increased mortality (Baum <i>et al.</i> , 1997; 2003). An association was seen between people who took over the counter zinc supplements and a more rapid progression to AIDS and mortality (Tang <i>et al.</i> , 1993; 1996). This may be because adults with more advanced or symptomatic HIV disease are more likely to take more supplements (Bormann <i>et al.</i> , 2009)
Selenium	Low levels have been linked with progression of HIV disease (Baum <i>et al.</i> , 1997)
Calcium	Several studies have found that a high percentage of HIV infected individuals have inadequate dietary calcium intake (Arpadi <i>et al.</i> , 2009; Bonjoch <i>et al.</i> , 2010; Jacobson <i>et al.</i> , 2008). An increased dietary calcium intake has been associated with greater bone mineral density in HIV (McComsey <i>et al.</i> , 2007)
Iron	Iron deficiency is common, especially in women and in developing countries, and dietary iron appears to be a contributing factor (Castro & Goldani, 2009; Shet <i>et al.</i> , 2012)
Phosphate	Hypophosphataemia is commonly seen in patients with HIV regardless of ART use (Day <i>et al.</i> , 2005). It is thought that use of tenofovir contributes to renal tubular losses of phosphate; however, vitamin D deficiency, malabsorption and use of antacids can also be contributing factors (Assadi, 2010).

ART, antiretroviral therapy.

Table 7.11.26 Interventional studies of micronutrients in people living with HIV/AIDS

Micronutrient	Findings from randomised controlled trials (RCTs)
Vitamin A	No trials reviewed (Irlam <i>et al.</i> , 2010) showed a reduction in disease progression in adults with vitamin A supplementation. In children, vitamin A supplementation showed a reduction in mortality and moderate evidence for morbidity and growth benefits
Vitamin D	Limited RCTs have been done in adults or children. The doses used in trials thus far have been inadequate to achieve optimal repletion of vitamin D stores. One trial found that vitamin D ₃ supplementation decreased the risk of developing diabetes (Guaraldi <i>et al.</i> , 2011). No risks have been seen to date (Wejse <i>et al.</i> , 2009, Arpadi <i>et al.</i> , 2009)
Zinc	No benefit of zinc supplements have been seen in pregnant women, furthermore, zinc inhibits iron absorption so mitigates increases in haemoglobin levels, which are often low in pregnancy. In drug users in Florida, those who took the dietary reference intake (DRI) of zinc as a supplement, had a decrease in immunological failure (defined as CD4+ <200 cells/mm ³) and less diarrhoea, compared to those taking placebo (Baum <i>et al.</i> , 2010). In children, supplementation reduced risk and progression of diarrhoea in several studies (in Africa), but not prophylactically (Irlam <i>et al.</i> , 2010)
Selenium	Reduced diarrhoeal morbidity in pregnant women in Tanzania, and reduced viral load in two separate small trials in American adults (with high drop out rates) (Irlam <i>et al.</i> , 2010)
Calcium	Calcium with vitamin D supplements have been given in the control arm of several trials investigating the role of bisphosphonates in treating osteoporosis. These studies found that there was a trend for bone mineral density increases, albeit non-significantly, in those receiving calcium supplements only; however, this was significantly less than in those on bisphosphonates (Mondy <i>et al.</i> , 2005, McComsey <i>et al.</i> , 2007)
Iron and phosphate	To date, no RCTs have evaluated the influence of diet on iron or phosphate stores in patients with HIV infection. Iron supplements have been given in conjunction with multivitamins to women with hepatitis C (Semba <i>et al.</i> , 2007) and improved iron stores and anaemia. The results from this trial cannot be generalised to the HIV infected population as a whole due to the narrow inclusion criteria and short duration
Other	Multi micronutrient formulations have shown a reduction in mortality in patients with a CD4 of <100 cells/mm ³ in Thailand (Jiamton <i>et al.</i> , 2003), an increase in CD4 in the US (Kaiser <i>et al.</i> , 2006) and an improvement in benefits to mothers and offspring in Tanzania (Fawzi <i>et al.</i> , 2004)

It has been suggested that there has been a link with numerous micronutrient deficiencies in patients with HIV. However, trials of micronutrient supplements, especially individual supplements, in patients with HIV have not demonstrated consistent benefits. Micronutrient supplementation in clinical practice should be based on the individual's micronutrient levels in conjunction with available evidence from both the general and HIV specific population (Table 7.11.26).

Obesity

Exercise and dietary interventions have been investigated in HIV positive patients presenting with general obesity or metabolic syndrome. A randomised study of intensive lifestyle intervention, comprised of weekly one on one counselling sessions focusing on reducing saturated fats, increasing fibre and walking, evaluated 34 HIV positive subjects with metabolic syndrome. At 6 months, subjects assigned to the lifestyle intervention group showed a 2.6 cm decrease in waist circumference, as well as significant improvements in systolic blood pressure and HbA_{1c}, but not lipid levels, fasting glucose or insulin resistance (Engelson *et al.*, 2006; Fitch *et al.*, 2006). Dietary advice for the obese should be based on standard dietetic practice and tailored to the individual with HIV (see Chapter 7.13.2).

Food and water safety

General food safety advice may benefit all individuals with HIV; however, those who are severely immunocompromised, e.g. with a CD4+ cell count of <200 cells/mm³, may benefit from more targeted advice. Salmonellosis has been estimated to be nearly 20 times more common, and often five times more bacteraemic, in AIDS patients compared to patients without AIDS (Hayes *et al.*, 2003). Other microorganisms such as *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium*, *Salmonella*, *Sbigella*, *Listeria*, *Yersinia* and *Campylobacter* spp. have been identified as the cause of enteric infections in HIV infected patients and have also been recognised as causing food and water borne diseases. Preventative measures should include food and water safety advice.

Water safety advice is important as *Cryptosporidium* has been isolated from tap water. Cryptosporidiosis can be prevented by boiling tap water, using an appropriate filter or using sterile water. Bottled water or domestic water filters are not necessarily free from *Cryptosporidium* cysts, and therefore should not be recommended in place of boiled water or appropriate filters (Hunter & Nichols, 2002).

Drug–nutrient interactions

Some of the older antiretroviral drugs came with strict food requirements; however, new formulations and new

medicines mean that food requirements and timing are less of a concern today in the UK. With the exception of didanosine (ddI), all of the NRTIs/nucleotide reverse transcriptase inhibitors (NtRTIs) may be taken either with food or on an empty stomach. Many people find that taking NRTIs/NtRTIs with food helps reduce side effects such as nausea. It is advised to take efavirenz [an non-nucleoside reverse transcriptase inhibitor (NNRTI)] on an empty stomach to reduce side effects. Most protease inhibitors work better when taken with food; however, the new formulation of lopinavir/ritonavir and fosamprenavir have no food restrictions. Current information on antiretrovirals and food restrictions is available at www.aidsmap.com/resources/Antiretroviral-drugs-chart/page/1412453/.

Diabetes mellitus

Pam Dyson

Key points

- Diabetes is one of the most common non-communicable diseases, has high rates of both morbidity and mortality, and affects over 285 million people globally.
- There are two main types of diabetes; type 1 and type 2.
- Lifestyle interventions, including diet and physical activity, are fundamental to diabetes management, and evidence is accumulating for the most effective strategies.
- The key to successful management is tailoring lifestyle advice to the individual.

Diabetes mellitus (DM) is a metabolic disorder characterised by chronic hyperglycaemia resulting from defects in insulin secretion, insulin action or both (WHO, 2006). It is one of the most common non-communicable diseases worldwide, and is a leading cause of morbidity and premature death. The global prevalence of diabetes has been estimated by the International Diabetes Federation (IDF, 2009) at 285 million in 2010 (6.6% of world population) and is projected to increase to 439 million (7.8%) by 2030, of whom over 75% will live in lower and middle income countries. Diabetes UK, the leading charity for people with diabetes in the UK, has estimated that 2.8 million adults (4.3%) in the UK had a diagnosis of diabetes in 2010, based on data from the Qualities and Outcomes Framework (QOF) (NHS, 2010a). However, this may be an underestimate; an alternative study reported that the prevalence of diabetes in adults in the UK was already 3.1 million (7.4%) by 2010, and this was projected to rise to 4.6 million (9.5%) by 2030 (Holman *et al.*, 2011).

Diabetes is a disease with high rates of morbidity and mortality (Zimmet *et al.*, 2001). It is associated with macrovascular complications [cardiovascular disease (CVD), stroke, peripheral vascular disease] leading to heart attacks, hemiplegia and amputations, and microvascular complications [neuropathy, retinopathy, nephropathy] causing foot ulcers, blindness and kidney failure (EURO-DIAB IDDM Complications Study Group, 1994; Turner & Holman, 1995). Apart from the effects of diabetes in terms of health and quality of life, it imposes a financial burden on societies. In the UK in 2009, treatment of diabetes and its associated complications accounted for 10% of

the total NHS budget, approximately £9 billion (NHS, 2010b).

Historical perspective

The symptoms of diabetes were described in an Egyptian papyrus in approximately 1500 BC, and the disease was first given the name of *diabetes* (literally meaning a siphon) by the Greek physician Aretaeus, who lived and practised during the second century AD. Although described by other eminent physicians, including Avicenna (980–1037 AD) and Galen (129–210 AD), diabetes was largely unreported and untreated until the 18th century. Eventually, it was identified that the large volumes of urine associated with untreated diabetes contained sugar and the term *diabetes mellitus* was coined by Cullen to distinguish the condition from that of diabetes insipidus (Tattersall, 2009). The discovery of the presence of sugar in the urine led to the development of dietary treatments and two schools of thought developed; one insisting on dietary replacement of sugar lost in the urine (high carbohydrate) and the other on dietary restriction (low carbohydrate). Bouchardat reported improvements in symptoms as a result of severe food shortages during the Paris siege of 1870 and promoted dietary restriction. All physicians, including the Italian physician Catoni, whose dietary restrictions were so severe that he kept his patients under lock and key to ensure compliance, soon adopted this approach. Restricted diets were promoted by Allan in the US and relaxed only slightly with the introduction of insulin in 1921–1922, when Lawrence introduced the Lawrence line diet. Over the past century, the

development of new agents to treat diabetes, and growing evidence of the effect of dietary therapy has led to many changes in the nutritional recommendations for diabetes.

Diagnostic criteria and classification

Diagnostic criteria

The diagnostic criteria for diabetes have been developed and revised by the World Health Organization (WHO, 2006), and use the occurrence of diabetes specific complications to derive diagnostic cut-off points for diabetes. A diagnosis of diabetes can be made under any of the following circumstances:

- Fasting plasma glucose \geq 7.0 mmol/L (126 mg/dL) or greater.
- 2-hour glucose of 11.1 mmol/L (200 mg/dL) or greater after ingestion of a 75-g oral glucose load [oral glucose tolerance test (OGTT)].
- Glycated haemoglobin (HbA1c) of $>$ 48 mmol/mol (6.5%).

Glycaemia can be assessed by a simple blood test measuring levels of HbA1c. The WHO (2011) now recommends that this test may be used in the diagnosis of diabetes, provided that stringent quality assurance tests are in place and that assays are standardised to international reference values.

In addition, both impaired glucose tolerance (IGT) and increased fasting glucose (IFG) have been identified as risk factors for developing diabetes, and IGT is also a risk factor for CVD. The diagnostic criteria for IGT and IFG are:

- *IGT* – fasting plasma glucose of $<$ 7.0 mmol/L (126 mg/dL) and 2-hour plasma glucose of 7.8 mmol/L or greater and $<$ 11.1 mmol/L (140 and 200 mg/dL) after OGTT.
- *IFG* – fasting plasma glucose of 6.1–6.9 mmol/L (110–125 mg/dL) and (if measured) 2-hour glucose of $<$ 7.8 mmol/L (142 mg/dL).

Classification

There are two broad types of diabetes, namely type 1 and type 2.

Type 1 diabetes

Type 1 diabetes is an autoimmune disease characterised by destruction of the insulin producing cells of the pancreas. Its cause is unknown, although genetic factors and certain viruses may play a part. Type 1 diabetes usually presents in children and young adults, although it can be diagnosed at any age. Type 1 diabetes accounts for approximately 10–20% of diabetes and is treated with a combination of insulin replacement by injection or pump therapy and lifestyle modification.

Type 2 diabetes

Type 2 diabetes is most frequently diagnosed in middle aged or elderly people, and is caused by a combination

of impaired insulin secretion and resistance to the action of insulin. Type 2 diabetes has a strong genetic component, but is also associated with lifestyle factors; it is more common in societies with high levels of obesity and low levels of physical activity. Although type 2 diabetes is traditionally diagnosed in people over the age of 40 years, it is being increasingly diagnosed in obese children and adolescents, and as many as 1400 children may have type 2 diabetes in the UK (Lobstein & Leach, 2004). Approximately 86% of people with type 2 diabetes are overweight or obese (Haslam, 2011). Type 2 diabetes accounts for approximately 80–90% of diabetes and is treated with a combination of diet, physical activity, oral medications and, increasingly, injectable therapies including insulin.

Other types of diabetes

There are other types of diabetes that are neither type 1 nor type 2, namely:

- *Maturity onset diabetes of the young (MODY)* – a hereditary form of diabetes caused by gene mutations that affect insulin production.
- *Gestational diabetes* – caused by increased insulin demand during pregnancy. It may resolve after birth of the child, but carries an increased risk of type 2 diabetes in later life.
- *Secondary diabetes* – occurs after surgical removal of the pancreas, as a result of pancreatitis, or can be induced by drugs, usually high doses of steroids.

Disease processes

Diabetes is a condition in which the body is unable to utilise the glucose in the blood for energy due to complete or relative lack of insulin, insulin resistance (a condition where the body does not respond adequately to insulin) or a combination of both. Insulin is produced and secreted in the beta cells of the islets of Langerhans in the pancreas; type 1 diabetes is characterised by complete beta cell failure, leading to absolute insulin deficiency, and type 2 diabetes is characterised by progressive beta cell failure and is usually associated with peripheral insulin resistance. Complete or relative lack of insulin results in raised blood glucose levels and the diagnosis of diabetes.

Glucose is the body's primary energy source and is provided by foods containing carbohydrate. Carbohydrate is found in starchy foods such as bread, potatoes, rice and pasta; sugary foods such as sweets, chocolate and cakes; and as natural sugars in milk and fruit. After eating, any excess glucose is first stored in the liver and muscle as glycogen, which is released into the blood stream as blood glucose levels fall. Once glycogen stores are filled, further excess glucose is converted to fat and stored in adipose tissue.

Insulin is the hormone responsible for regulating blood glucose levels and is automatically released as blood glucose levels rise following carbohydrate intake. Insulin facilitates entry of glucose into muscle and adipose tissue

cells to be utilised as energy. Lack of insulin leads directly to increased blood glucose levels and the symptoms of diabetes, which are polyuria, polydipsia, fatigue, weight loss and increased susceptibility to infections.

Symptoms

Blood glucose levels above about 12mmol/L exceed the renal threshold and glucose begins to appear in the urine. The kidneys can only excrete glucose when it is accompanied by fluid, and this extra fluid causes excessive urine production (polyuria) leading to excessive thirst (polydipsia). Lack of insulin means that the body's cells are unable to utilise glucose for energy, and despite high circulating glucose levels, the body has to rely on its stores of fat for energy. The lack of available glucose causes fatigue and weight loss. In the absence of any insulin, people with type 1 diabetes rely entirely on fat and its byproducts, ketones, for energy. Small amounts of ketones can be used for energy, but large amounts cause acidity in the body and result in diabetic ketoacidosis (DKA), a life threatening condition.

Disease consequences

It is challenging to assess mortality and morbidity rates for people with diabetes as many countries do not have diabetes registers or a system of death certification. Where death certificates do exist, diabetes is often not noted as a cause of death and, as a result, available statistics frequently underestimate mortality.

Mortality

A statistical modelling approach used by the IDF (2009) estimated that in 2010, 4 million deaths in the 20–79 year age group (accounting for 6.8% of all deaths globally) were caused by diabetes. Diabetes is associated with premature mortality from a variety of causes including vascular disease, cancer, infectious diseases, intentional self harm, external causes and degenerative disorders (The Emerging Risk Factor Collaboration, 2011). Diabetes doubles the risk of vascular disease, which is the cause of death for nearly 60% of people with diabetes (The Emerging Risk Factor Collaboration, 2010), and people with diabetes are also 25% more likely to die of cancer. Hyperglycaemia is directly associated with risk of death, with levels of >5.6mmol/L linked with increased risk. On average, a 50-year-old adult with diabetes and without vascular disease, will die 6 years earlier than a counterpart without diabetes.

Morbidity

One of the most important features of diabetes is the association of sustained hyperglycaemia with long term tissue damage and, as a result, morbidity rates are high. Half of all people with type 2 diabetes have already developed a diabetes associated complication by the time of diagnosis (UKPDS Group, 1991).

Macrovascular disease

Macrovascular or CVD affects the large blood vessels and is the most common complication associated with DM. It is associated with premature mortality and poses a disproportionate risk for premenopausal women (Koerbel & Korytkowski, 2003) and ethnic minority groups with DM (Oldroyd *et al.*, 2005). Risk factors for CVD in people with diabetes include hyperglycaemia, hypertension, dyslipidaemia, overweight and obesity, tobacco use, high fat diet and physical inactivity. Management of CVD risk for people with diabetes is multifactorial and studies have shown significant benefits of risk factor control for both type 1 and 2 diabetes, with the exception of glycaemic control in those with type 2 diabetes where controversy remains (DCCT Study Group, 1993; UKPDS Group, 1998a,b). A review of recent studies that have failed to show a significant reduction in CVD events with intensive glycaemic control in people with type 2 diabetes concluded that individual targets for glycaemia may be appropriate, and that management of blood pressure and lipids, smoking cessation and healthy lifestyles are a priority for CVD risk management (Skyler *et al.*, 2009).

Microvascular disease

Microvascular disease affects the small blood vessels, especially in the eye, kidney and nerves. Diabetes is the most common cause of blindness in people of working age in the UK and is also the most common cause of lower limb amputations and end stage renal disease (ESRD) (Diabetes UK, 2010).

Diabetic retinopathy

This describes narrowing or blockage of the blood vessels at the back of the eye and is caused by high blood glucose levels, high blood pressure or a combination of both. It can be divided into early, reversible (background) retinopathy and the more developed stages that require treatment and may result in blindness. It affects 10–65% of people with diabetes globally (International Diabetes Federation, 2009) and the prevalence is related to the duration of diabetes. In the UK, it is estimated that 25% of people with diabetes will develop retinopathy after 5 years (NHS Choices, 2011).

Diabetic nephropathy

This affects the blood vessels in the kidney and the first sign is the presence of small amounts of protein in the urine (microalbuminuria). Microalbuminuria may be present for many years without progression, but can lead to increased protein loss and eventually ESRD requiring dialysis or transplant. Globally, between 5% and 30% of people with diabetes develop nephropathy and figures for the UK suggest that 30% of people with type 2 diabetes will develop kidney disease (Stratton *et al.*, 2000).

Diabetic neuropathy

Diabetic neuropathy describes the nerve damage associated with high blood glucose levels and can affect sensory

nerves (resulting in loss of sensation or increased pain sensation), autonomic nerves (leading to warmer, swollen feet or dry, cracked skin) and motor nerves (leading to muscle atrophy and deformities in the shape of the foot). Nerve damage is often associated with peripheral circulatory damage and can lead to foot ulcers, progressing to gangrene and requiring amputation. Peripheral neuropathy is estimated to affect between 15% and 55% of people with diabetes worldwide.

Sexual dysfunction

Erectile dysfunction and female sexual dysfunction are more common in people with diabetes. Erectile dysfunction affects between 35% and 90% of men with diabetes and is associated with increasing age, duration of diabetes, hyperglycaemia, hypertension, hyperlipidaemia, sedentary lifestyle and smoking (Malavige & Levy, 2009). Female sexual dysfunction was reported by 33% of women with diabetes in one study, but it does not appear to be associated with diabetes related factors (Nowosielski *et al.*, 2011).

Depression

People with diabetes appear to have a two-fold increased risk of depression (Anderson *et al.*, 2011), and this is true for both type 1 (Barnard *et al.*, 2006) and type 2 diabetes (Ali *et al.*, 2006). The presence of depression is associated with a reduced quality of life in people with diabetes (Schram *et al.*, 2009).

There is strong evidence that intensive glycaemic control and management of cardiovascular risk factors can reduce both morbidity and mortality associated with diabetes (DCCT Study Group, 1993; UKPDS Group, 1998a,b). There is also evidence that improvements in care have reduced the risk of complications for people with type 1 diabetes over the past 30 years. However, even those receiving intensive treatment still show relatively high levels of complications, with over one-fifth developing proliferative retinopathy and 9% developing nephropathy and CVD (Nathan *et al.*, 2009).

Public health aspects and prevention

There is no evidence for strategies to prevent type 1 diabetes as the aetiology remains unclear, but there is strong evidence from studies in different ethnic groups that type 2 diabetes can be prevented in high risk individuals by lifestyle and pharmacological interventions (Paulweber *et al.*, 2010). Lifestyle interventions show the greatest effect, with reductions of 28–59% in the risk of diabetes following implementation (Walker *et al.*, 2010), and evidence of a legacy effect with lower incidence of diabetes at 7–20 years after intervention (Knowler *et al.*, 2009; Li *et al.*, 2008; Lindstrom *et al.*, 2006). Evidence based European guidelines for diabetes prevention and Diabetes UK lifestyle specific guidelines have recently been published and are summarised below (Paulweber *et al.*, 2010; Dyson *et al.*, 2011).

Components of lifestyle interventions for type 2 diabetes prevention

Weight reduction

Weight reduction in overweight or obese individuals is the dominant factor for diabetes prevention, with weight losses of 5–7% significantly lowering risk; with a 16% reduction in risk is associated with each kilogram lost (Hamman *et al.*, 2006). Although the majority of studies have promoted reduced fat, high fibre diets with a moderate reduction in energy intake, there is emerging evidence that alternative dietary strategies, including the Mediterranean diet and low carbohydrate diets, are effective for weight loss and diabetes risk reduction (Walker *et al.*, 2010).

Physical activity

Increased physical activity reduces the risk of diabetes, and at least 30 minutes/day of moderate activity is recommended.

Diet

Studies have shown that diets high in fibre (≥ 15 g/1000 kcal), reduced in total fat ($\leq 35\%$ of total energy) and saturated and *trans* fat ($< 10\%$ of total energy) can induce weight loss and reduce risk. There are no randomised controlled trials of different dietary strategies to identify the most effective diet for type 2 diabetes prevention.

Despite the strong evidence from randomised controlled trials for the efficacy of diabetes prevention programmes, there is little evidence of translation into the area of public health and diabetes prevalence continues to rise around the world.

Nutritional assessment

Anthropometry

Body weight and body mass index (BMI) should be monitored regularly in people with diabetes, especially those with type 2 diabetes as they are prone to weight gain. Obesity increases the risk of diabetes related complications, especially CVD. Waist circumference predicts both type 2 diabetes and CVD (Yusuf *et al.*, 2004). Waist circumference cut-off points differ according to ethnicity and gender (see Appendix A7).

Biochemistry

Glycated haemoglobin (HbA_{1c}) measures long term glycaemic control (> 12 weeks) and should be measured at least once a year. It is now expressed in mmol/mol rather than as a percentage. A conversion table can be found in Appendix A9. Lipid profiles [serum total cholesterol, high density lipoprotein (HDL) and low density lipoprotein (LDL) cholesterol, and triglycerides levels) are measured to assess cardiovascular risk. Microalbuminuria is an indicator of early stage kidney disease; it should be measured annually. In addition, blood creatinine measurements can

be used to calculate estimated glomerular filtration rate, which provides an assessment of overall excretory kidney function.

Clinical examination

Blood pressure assesses cardiovascular risk and should be measured at regular intervals and at least once a year. Retinal screening involves dilation of the eyes and a retinal photograph, and is designed to measure diabetic eye disease. In the UK, there is a system in place to ensure that all people with diabetes have a retinal photograph annually. Foot examination assesses skin, blood and nerve supply to the legs and feet, and should be part of the annual review. Injection sites should be examined in people injecting medication to monitor for hyperlipotrophy – hard lumps under the skin caused by repeated injections into the same site, which affect insulin absorption.

Dietary assessment

There is some discussion about the usefulness of diet histories (including the most widely used 24-hour recall) in managing chronic diseases such as diabetes. Many dietitians feel that it is impossible to give people advice about a healthy diet for diabetes unless they have some idea of the individual's usual diet, but there is no evidence that taking a diet history improves diabetes control and strong evidence that up to 67% of people underreport intake, especially of snack foods; BMI is a strong determinant of underreporting (Poslusna *et al.*, 2009). Dietary assessment can be used to evaluate an individual's wishes and willingness to change in the following areas:

- Meal patterns and usual lifestyle – this is often called a typical day and gives additional information about work and physical activity.
- Likes and dislikes, including usual food choices, and attitudes and beliefs about different foods.
- Perceptions and beliefs about food related specifically to health.

Economic and social factors

Factors such as socioeconomic circumstances, ethnic group and occupation will have an effect on the individual's willingness and ability to manage their diabetes.

Clinical management

The aims of management of diabetes are to maintain blood glucose levels as near to the normal range as possible in order to minimise both the short term (hypoglycaemia and diabetic ketoacidosis) and long term (macrovascular and microvascular) complications associated with hyper- and hypoglycaemia.

Targets for glycaemic control

Internationally, it is generally agreed that for most people the target for HbA_{1c} level is 53 mmol/mol (7.0%) or less.

In the UK, targets for people with type 2 diabetes and people with type 1 diabetes and diabetes related complications are set lower at <48 mmol/mol (6.5%) (NICE, 2004; 2008a). Targets for self monitored blood glucose levels (SMBGs) in the UK are:

- *Children with type 1 diabetes* (NICE, 2004):
 - Before meals – 4–8 mmol/L.
 - 2 hours post prandial – <10 mmol/L.
- *Adults with type 1 diabetes* (NICE, 2004):
 - Before meals – 4–7 mmol/L.
 - 2 hours post prandial – <9 mmol/L.
- *Type 2 diabetes* (NICE, 2008a):
 - Before meals – 4–7 mmol/L.
 - 2 hours post prandial – <8.5 mmol/L.

Targets for risk reduction of comorbidities

Targets for risk factor reduction in the UK are:

- *Adults with type 1 diabetes* (NICE, 2004):
 - Blood pressure – <135/85 mmHg (in the high risk, aim for <130/80 mmHg).
 - LDL cholesterol – <2.6 mmol/L.
 - Triglycerides – 2.3 mmol/L.
- *Individuals with type 2 diabetes* (NICE, 2008a):
 - Blood pressure – <140/80 mmHg (in the high risk, aim for <130/80 mmHg).
 - No specific targets for lipid levels (aim for the lowest possible).

Pharmaceutical management

Type 1 diabetes

Type 1 diabetes is managed by insulin replacement; there are many different insulins available and the type, dose and regimen depends upon the lifestyle of the individual. Until the 1980s, insulin was only available by extraction and purification from the pancreas of cattle and pigs. This animal insulin is still in use but has been largely replaced by human insulin that is engineered genetically in laboratories. Newer analogue insulin has been introduced over the past few years in an attempt to replicate the action of naturally produced insulin in the body. Insulin can be divided into:

- *Rapid acting analogue insulin* with an onset of action within 5–10 minutes, peaking at 90 minutes and lasting for 3 hours. This type of insulin is commonly taken with meals and can be injected at the time of, or after, eating.
- *Short acting insulin* begins working within 30 minutes, peaks at 2 hours and lasts for 4–8 hours. Like rapid acting insulin, it is usually taken with meals, but is injected 20–30 minutes before eating.
- *Medium and long acting insulins* are usually taken once or twice a day and provide background insulin over 24 hours. They have an onset of action within 90 minutes, peak between 4 and 12 hours and last for 12–24 hours.

- Long acting analogue insulin is promoted as having a flat profile, with no peak action and lasts for 18–24 hours. It is usually taken once a day, often at bedtime.
- Mixed insulin consists of premixed short acting insulin with medium or long acting insulin and is usually taken twice a day, usually before breakfast and before the evening meal. It has an onset of action within 30 minutes, peaks at 2–8 hours and lasts for 16–20 hours.
- Mixed analogue insulin is a mixture of rapid acting and long acting analogue insulin with an onset of action within 5–10 minutes, peaking at 90 minutes and lasting for 16–10 hours.

The majority of people with type 1 diabetes in developed countries are encouraged to use multiple daily injection regimens (known as MDI or basal bolus), typically consisting of one injection of long acting insulin and three (or more) injections of rapid or short acting insulin with meals. This intensive insulin regimen has been shown to be associated with improved glycaemic control and allows for dietary flexibility (DCCT Study Group, 1993; DAFNE Study Group, 2002). The traditional regimen of mixed insulin injected twice daily, usually before breakfast and before the evening meal, is less common and is associated with increased hypoglycaemia in those who do not have regular meals.

Insulin is administered by syringe and needles, pen injection devices or pumps [continuous subcutaneous insulin infusion (CSII)]. Pump therapy consists of a portable pump that delivers rapid acting insulin through a cannula, providing background insulin and a bolus of insulin when food is eaten. Pump therapy is becoming more common; in the UK in 2010 approximately 4% (9750 people) of people with type 1 diabetes were using pump therapy, and guidance has been issued stating that pumps are suitable for those with disabling hypoglycaemia or who have failed to reach an HbA_{1c} of 69 mmol/mol or less despite MDI therapy (NICE, 2008b).

Type 2 diabetes

Type 2 diabetes is managed clinically with a combination of tablets and injectable therapies, including insulin. In the UK, algorithms have been produced recommending a treatment cascade for those with type 2 diabetes, beginning with a trial of lifestyle measures including structured education (NICE, 2008a). Medication includes:

- *Metformin* is recommended as a first line therapy. It belongs to the biguanide class of drugs and its main action is to increase insulin sensitivity and reduce hepatic gluconeogenesis. It does not cause weight gain or hypoglycaemia and may be associated with a reduced risk of CVD. Around 10% of patients do not respond to metformin and approximately 5–10% of patients a year will need another agent in addition. If maximum tolerated doses of metformin fail to achieve target glucose levels, a second agent is commonly added in.
- *Sulphonylureas* are the recommended second line agent and act directly on the pancreas to stimulate

insulin production. They are associated with a weight gain of approximately 3kg and can cause hypoglycaemia.

- *Metiglinides* are short acting agents that are used to control post prandial rises in glucose. They are taken before main meals and stimulate insulin production for that meal. Essentially, they may be viewed as a short acting sulphonylurea and have similar side effects.
- *Thiazolidinediones* (also known as glitazones) have been used only relatively recently since 1997. They are taken once daily, starting with a low dose, and take up to 3 months to have their maximum effect. Their action is to reduce insulin resistance and they produce a lowering of blood glucose levels comparable to metformin or sulphonylureas. Side effects include weight gain and fluid retention. Glitazones tend to be given as second or third line therapy, partly because of the 10–12 weeks it takes for them to have effect.
- *Acarbose* is an alpha glucosidase inhibitor that reduces the rate of carbohydrate digestion, thus controlling post prandial blood glucose rises. This agent has unpleasant side effects of flatulence, abdominal pain, bloating and diarrhoea. As its effect is moderate compared with the other agents available, it is rarely prescribed in the UK.
- *Incretin agonists* are injectable therapies that mimic the action of naturally produced gut hormones and act by stimulating glucose dependent insulin secretion from the pancreas, reducing glucagon secretion, inhibiting gastric emptying and thus promoting satiety and reducing weight. The most common side effects are nausea and vomiting.
- *Gliptins* prevent rapid degradation of the enzyme dipeptidyl peptidase 4 (DPP 4) and so increase concentrations of endogenous, naturally occurring incretin hormones. They are weight neutral and the most frequent side effect is nausea.

In addition to blood glucose management, people with diabetes frequently take agents to reduce blood pressure (antihypertensives) and blood lipid levels (statins), and may need further agents to treat any diabetes related complication.

Surgical treatment of diabetes

Bariatric surgery is increasingly used as a treatment for obesity in people with type 2 diabetes, with a recent IDF statement calling for surgery to be an accepted treatment option for people with type 2 diabetes and a BMI of 35 kg/m² or greater. Surgery can induce diabetes remission, with rates of 72% reported over 2-year follow-up (Dixon *et al.*, 2011) (see Chapter 7.13.3).

Other surgical procedures to treat type 1 diabetes include islet and pancreatic transplants. Both these procedures can restore endogenous insulin secretion, but are only available to a few people because of a shortage of donors and because immunosuppressive drugs have side effects that may outweigh the benefits.

Lifestyle management

Lifestyle therapy, including diet and physical activity, is an integral part of effective management of diabetes and has a vital role in helping people with diabetes achieve and maintain optimal glycaemic control and reduce the risk of long term tissue damage (Bantle *et al.*, 2008). There is evidence that intensive treatment of type 1 diabetes, especially with diet, improves outcomes (Delahanty, 1998) and that dietary change, weight loss and increased physical activity are of benefit to people with type 2 diabetes (Look Ahead Research Group, 2010; Pi-Sunyer *et al.*, 2007), although there are few well designed studies investigating the most effective approach (Nield *et al.*, 2007).

Physical activity

The benefits of increased physical activity for people with type 2 diabetes are clear and include improved glycaemic control and reductions in cardiovascular risk, including positive effects on lipids and blood pressure. Long term studies have shown that these benefits translate into a reduction in cardiovascular events and improvements in mortality and quality of life (Colberg *et al.*, 2010). Physical activity does not appear to have a direct effect on BMI in people with type 2 diabetes, although there is evidence of reduction in visceral adipose tissue (Thomas *et al.*, 2006).

The benefits of physical activity for people with type 1 diabetes are less clear. Although physical activity improves cardiovascular risk and may have a positive effect on quality of life, there is no evidence of improvement in glycaemic control in people with type 1 diabetes (Zinman *et al.*, 2003).

It is recommended that people with diabetes take at least 150 minutes of moderate activity each week. Physical activity guidelines are usually made in terms of daily activity, the most common recommendation being that moderate activity should be taken on at least 5 days each week for 30 minutes. Moderate activity is defined as any activity that raises the heart and breathing rate, but does not induce breathlessness, causes a feeling of warmth or promotes light sweating. For many people, brisk walking is sufficient.

Physical activity generally lowers blood glucose in people with diabetes and may increase the risk of hypoglycaemia in those taking insulin or sulphonylureas. For many people with type 2 diabetes not treated with insulin, the effects of physical activity are beneficial and do not require any adjustment to medication or dietary intake. People with type 1 diabetes require more active management to prevent hypoglycaemia. Management of activity can be facilitated by SMBG and may require adjustment of medication and/or increased carbohydrate intake.

Before activity people with diabetes treated with sulphonylureas or insulin are advised to test their blood glucose levels, aiming for levels within the range of 6–13 mmol/L. If levels are <6 mmol/L, an additional 15–30 g high glycaemic index (GI) carbohydrate should be taken. Examples of high GI carbohydrates include isotonic sports drinks, made up squash, bananas, jelly beans

and fruit pastilles. People with type 1 diabetes showing levels of >13 mmol/L should delay activity and test for the presence of ketones as they may be at increased risk of ketoacidosis.

During activity additional high GI carbohydrate may be necessary, depending upon the duration and intensity of exercise. As a rough guide, for any exercise session that lasts >60 minutes, 30–60 g/hour of high GI carbohydrate may be needed.

After prolonged or strenuous activity, the effect of exercise can be assessed by testing blood glucose levels. Consuming high GI carbohydrates within an hour of activity will replenish liver and muscle glycogen stores, and those with type 1 diabetes may need to reduce the post activity insulin dose.

Alcohol

Epidemiological studies have shown that moderate alcohol intake (1–3 units/day) in people with diabetes is associated with improved glycaemic control and reduced CVD and all cause mortality. The guidelines for alcohol intake for people with diabetes do not differ from those for the general population, but there are additional factors for consideration.

Hypoglycaemia is a well documented side effect of alcohol in people with type 1 diabetes, and can occur at relatively low levels of intake and up to 12 hours after ingestion. There is no evidence for the most effective treatment to prevent hypoglycaemia, but pragmatic advice includes recommending insulin dose adjustment, additional carbohydrate or a combination of the two according to individual need.

The amount of carbohydrate in alcoholic drinks can vary greatly with some (dry wines, spirits) containing little or no carbohydrate and some (sweet liqueurs, alcopops) containing significant amounts. Consumption of alcoholic drinks containing carbohydrate raises blood glucose levels and can cause hyperglycaemia. People treated with insulin may take extra to cover the carbohydrate in drinks, but this may exacerbate hypoglycaemia.

There are some medical conditions where alcohol is contraindicated, including hypertension, hypertriglyceridaemia, some neuropathies and retinopathy. As with the general population, alcohol should be avoided during pregnancy and when planning to drive.

Nutritional management

Aims of dietary treatment

Nutritional therapy is an integral part of diabetes self management and treatment. The aims of dietary treatment of diabetes are complementary to those of medical management and have been summarised by Diabetes UK as (Dyson *et al.*, 2011):

- Supporting self management to reduce the risk of type 2 diabetes and the comorbidities associated with diabetes.
- Promoting healthy lifestyles and quality of life.

- Providing flexibility and meeting the needs of all individuals, including those with comorbidities such as coeliac disease and cystic fibrosis (Lindstrom *et al.*, 2006).

Many countries have published nutritional recommendations for diabetes (Dyson *et al.*, 2011; Bantle *et al.*, 2008; Canadian Diabetes Association, 2008; Ha & Lean, 1998) and these have been subject to change over time as evidence emerges for effective dietary treatment of diabetes. Until recently, the majority of nutritional recommendations were based on the consensus of recognised experts in the field, but the recent guidelines from the American Diabetes Association (ADA) and Diabetes UK have moved towards evidence based recommendations. Recent recommendations have been made in terms of topic areas rather than nutrients and stress the importance of tailoring nutritional advice for each individual, taking into account personal and cultural preferences, beliefs, lifestyle and willingness and ability to change.

Education models

Structured education for people with diabetes in the UK is now recommended for all individuals at the time of diagnosis, with regular (at least annual) review (NICE, 2011). Nutritional management should be included as an integrated component of structured education, and there is strong evidence of clinical effectiveness, cost effectiveness and improved quality of life for both type 1 and type 2 diabetes (Dyson *et al.*, 2011). Structured education can be delivered in groups or to individuals. There are four key components to structured education:

- A structured, written curriculum, including philosophy and theoretical principles.
- Trained educators.
- Quality assurance.
- Audit and evaluation of both biomedical and quality of life outcomes.

More detailed criteria for education programmes include the recommendations that all programmes should be patient centred and incorporate individual assessment. They should be reliable, valid, relevant and comprehensive; theory driven and evidence based; flexible and able to cope with diversity and to utilise different teaching techniques; resource effective with supporting materials; written down (including philosophy, aims and objective, timetables and detailed content); and subject to robust audit and evaluation. Although these criteria apply more to structured education in groups, the principles can be applied to all education.

Education delivery

The traditional model of delivering education is the one to one interview between the healthcare professional and the person with diabetes, and is often based upon dietary histories and prescriptive advice. These didactic based approaches have been shown to produce modest improvements in outcomes, but patient education has been

shown to be more effective if it also has a behavioural element. Innovative approaches may be needed to deliver education to people with diabetes. Patients with chronic disease, including diabetes, state that they would like information in as many formats as possible and as early as possible after diagnosis, and a variety of techniques including picture charts, video techniques, computer packages, text messaging, email and phone applications can be used (Corben & Rosen, 2005).

Glycaemic control

Carbohydrate is the nutrient that has most effect on blood glucose levels after eating, and is a major nutritional consideration for people with diabetes. All carbohydrate foods are digested to glucose and appear in the blood between 10 minutes and 2 hours or more after eating, and both the amount and type will affect post prandial levels. There is no evidence for an optimal amount of carbohydrate for achieving and maintaining glycaemic control in people with diabetes, and for people with type 1 diabetes the emphasis is on matching insulin to carbohydrate on a meal by meal basis. This process is commonly called carbohydrate counting and insulin adjustment. It requires those with type 1 diabetes to calculate the amount of carbohydrate in each meal and snack, and to inject a matching amount of insulin. There is no evidence supporting the use of carbohydrate counting for people with type 2 diabetes. People with type 1 diabetes treated with fixed doses of insulin, and those with type 2 diabetes are advised to monitor carbohydrate intake by a variety of means, including exchanges, portions or experience based estimation.

Carbohydrate assessment

Carbohydrate awareness is the process of identifying carbohydrate containing foods and is the first step in the process of carbohydrate estimation. Carbohydrate awareness can be facilitated with a variety of teaching aids, including food lists, picture charts, food photographs and food models.

Carbohydrate budgets or portions can be facilitated by a variety of strategies. Traditionally, carbohydrate was restricted in people with diabetes by the use of the exchange system (one exchange contained 10g of carbohydrate, e.g. $\frac{2}{3}$ slice bread, $\frac{1}{3}$ pint milk, two plain biscuits), where diets were prescribed with a limited allowance of exchanges at each meal or snack. The modern use of budgets or portions encourages consistent amounts of carbohydrate at each specific meal from day to day, but does not necessarily prescribe a limited amount of carbohydrate. Teaching aids for promoting consistent portion sizes include using household measurements (spoonfuls, cupfuls and units), visual estimation with reference to food photographs, comparing portion size to hand size, e.g. a fist sized portion of starchy food such as rice, potato or pasta, and exchanges lists.

Carbohydrate counting, used by people with type 1 diabetes, is the most accurate method of carbohydrate

assessment. The amount of carbohydrate in individual meals and snacks is usually calculated to the nearest 5–10g, or expressed as carbohydrate portions (CPs), with each portion containing 10g carbohydrate. Strategies include the use of household measures, exchange or portion lists and visual estimation using food photographs or phone applications. Nutritional labels on packaged foods can provide useful information. It can be helpful to weigh individual foods such as breakfast cereals, rice and pasta where there is no recognised portion size, and food tables are then necessary for carbohydrate calculation.

Type of carbohydrate

The most significant predictor of post prandial blood glucose levels is the amount of carbohydrate eaten, but the type of carbohydrate does have some effect. Relevant concepts are those of GI, sugar and dietary fibre. The GI has been widely promoted for dietary management of diabetes and both the ADA and Diabetes UK recommend a low GI diet. Low GI diets can significantly improve glycaemic control and reduce hypoglycaemia in people with diabetes (Thomas & Elliott, 2009). The GI is a scale that ranks carbohydrate foods by how much they raise blood glucose levels compared with a reference food (usually white bread or glucose). High GI foods cause large fluctuations in glucose and insulin levels, and low GI foods cause smaller fluctuations. It is measured in the laboratory by feeding samples of food containing 50g of carbohydrate to volunteers and testing blood glucose levels at 15-minute intervals for 2–3 hours. The results are plotted on a graph and the area under the curve (AUC) is compared with a reference food using the formula:

$$\frac{\text{AUC for test food}}{\text{AUC for reference food}} \times 100 = \text{GI value for test food}$$

The GI of the test food is then expressed as a number compared with the reference food. The average results from 10 volunteers are required for each food tested. Table 7.12.1 shows GI ranking by derived values and Table 7.12.2 examples of low, medium and high GI foods. The disadvantages of low GI diets in practice are that this strategy may reinstate a prescriptive approach to dietary advice, other factors may affect the GI of foods, e.g. adding organic acids such as lemon juice or vinegar to a food lowers its GI, and it takes little account of the amount of carbohydrate eaten. This last point is addressed by the concept of glycaemic load (GL).

The GL reflects the amount and quality of carbohydrate eaten and can be expressed by the formula:

$$\frac{\text{GI}}{100} \times \text{Net carbohydrate} \\ (\text{total carbohydrate} - \text{dietary fibre}) = \text{GL}$$

Recommendations for the GL of foods and a guideline total daily value are shown in Table 7.12.3.

Table 7.12.1 Glycaemic index values and ranking

Glycaemic index value	Glycaemic ranking
0–55	Low
56–69	Medium
70 or more	High

Table 7.12.2 Examples of low, medium and high glycaemic index (GI) foods

Food	Low GI (<55)	Medium GI (56–69)	High GI (>70)
Bread	Multigrain, stone ground wholemeal, granary and rye		All other wholemeal, brown and white bread, including French and naan bread
Breakfast cereals	High bran cereal, muesli and porridge made with stone ground oats	Other bran cereals, including bran flakes and those with dried fruit	All other corn and wheat based cereals, including wholewheat and sugar coated cereals
Potatoes	Sweet potatoes, yams	New potatoes	Old potatoes – boiled, mashed, baked, roast and chips
Pasta and rice	<i>Al dente</i> pasta and egg noodles	Basmati rice, rice noodles	White and brown rice, rice pasta
Vegetables	Pulses, peas, beans and legumes		
Fruit	Apples, pears, stone fruit (peaches, plums, cherries), citrus fruit (oranges, tangerines) and berries	Tropical fruit (bananas, pineapples, mangoes)	
Dairy products	Full fat, semi skimmed and skimmed milk, yogurt	Ice cream	
Cakes and biscuits	Plain sponge cake, fruit and malt breads	Plain biscuits, crackers	Doughnuts, scones
Savoury snacks	Maize or corn chips	Crisps	Extruded potato snacks, pretzels

Table 7.12.3 Recommendations for low, medium and high glycaemic load (GL)

GL ranking	GL value	Daily GL
Low	10 or less	79 or less
Medium	11–19	80–119
High	20 or more	120 or more

Although GL is a tool for assessing the overall effect of carbohydrates on blood glucose levels, it is complicated to use in practice and is not recommended as a management strategy for people with diabetes.

Sugar was traditionally restricted in people with diabetes as it was commonly assumed that the sugar (sucrose) content of food related directly to blood glucose levels. Traditionally, table sugar (sucrose) has been restricted for people with diabetes and the original nutritional recommendations from the British Diabetic Association (now known as Diabetes UK) in 1992 stated that no more than 25 g of sucrose should be consumed daily. In terms of glycaemic control, sucrose has no more effect on blood glucose levels than isocaloric amounts of starchy carbohydrate and most recommendations do not now impose a rigid restriction on sugar. Apart from sucrose and glycaemic control, there has been some recent research showing that high intakes of sugar sweetened beverages are associated with the development of obesity, type 2 diabetes and CVD (Malik *et al.*, 2010), and that the general advice for healthy eating (<10% of total energy from sugar) should be applied to all individuals.

Dietary fibre is promoted for its cardioprotective effects, but there is little evidence for its effect on glycaemic control in people with diabetes. Some studies report improved glycaemic control, but these use large amounts of fibre (40–50 g/day) with little evidence supporting smaller amounts. The recommendation for the general population for fibre should be applied to people with diabetes (Franz *et al.*, 2010).

Diabetes complications

Cardiovascular disease

People with diabetes have a two-fold increased risk of CVD and it is the leading cause of death (The Emerging Risk Factor Collaboration, 2010). As these people are at high risk, nutrition recommendations are similar to those for people with established heart disease. The aims of nutritional guidelines for CVD are to reduce risk by improving blood lipid profiles and reducing blood pressure by dietary factors such as fat, plant stannols and sterols, salt, dietary fibre and alcohol.

Fat

High fat intakes, especially of saturated fat, are associated with increased lipid levels and risk of heart disease, and current recommendations from both the ADA and Diabetes UK are that people with diabetes reduce saturated

fat and replace this with unsaturated fat, particularly monounsaturated fat. There is no strong evidence to support a specific amount of fat in the diet; current guidelines reflect this and have not formulated recommendations for exact proportions of energy derived from fat, but do recommend individual flexibility. There is little evidence for guidelines about *trans* fat intake in people with diabetes, and the guidelines for the general population should be adopted (see Chapter 4.2).

High intakes of oily fish (salmon, trout, herring, mackerel and sardines) are associated with reduced rates of CVD and should be consumed at least twice weekly. There remains controversy about the use of fish oil supplements for people with diabetes, with some evidence of reduction in triglyceride levels in those with hypertriglyceridaemia. Diabetes UK recommends that fish oil supplementation may have therapeutic benefits for this subgroup.

Plant stanols and sterols

Studies have shown that plant sterols and stanols included in manufactured foods such as margarine, yogurt and yogurt drinks can significantly lower cholesterol levels by at least 10% (Thompson & Grundy, 2005). These products can be recommended, but they are only effective at doses of 2 g/day or greater, and they are more expensive than regular products.

Salt

Salt intakes are significantly associated with blood pressure, and studies show that salt reduction lowers blood pressure. The daily average intake of salt in the UK is 8.6 g/day, and most guidelines recommend reductions to 5–6 g/day, effectively reducing consumption by a third. Reductions in salt intake can be achieved by avoiding or reducing salt used in cooking or added at the table, and by avoiding obviously salty foods such as savoury snacks, but the majority of salt (75%) in the western diet comes from processed foods, and effective salt reduction will require intervention from the food industry.

Dietary fibre

Although there is contradictory evidence for dietary fibre in terms of glycaemic control, high intakes of fibre and especially soluble fibre are associated with reductions in total cholesterol and LDL cholesterol levels. Guidelines for people with diabetes recommend adopting the dietary reference values (DRVs) for the general population.

Physical activity, alcohol and weight management

These are all key factors for cardiovascular risk reduction and are discussed fully elsewhere.

Dietary strategies

Dietary strategies to reduce CVD combine some of the individual elements associated with risk reduction, and include the Mediterranean and DASH (Dietary Approaches to Stop Hypertension) diets. These diets recommend reducing saturated fat and substituting fish and olive oil for red meat and butter, and increasing vegetable, fruit

and wholegrain intake. The combined effects of these diets have a greater effect on blood pressure than those achieved by the individual components, and significantly reduce cardiovascular risk (see Chapter 7.14.4).

Microvascular disease

The most important predictor of both development and progression of microvascular disease is glycaemic control. All nutritional strategies to maintain or improve blood glucose levels in people with diabetes can be applied to those with microvascular disease. There is very little good quality evidence for specific nutritional management of diabetes related microvascular disease apart from that of glycaemic control.

Hypoglycaemia

People with diabetes treated with insulin, sulphonylureas or metiglinides are at risk of hypoglycaemia and this risk increases with duration of diabetes. Hypoglycaemia is defined as a blood glucose level of <4 mmol/L, and people with diabetes can be advised to 'make 4 the floor', meaning they should treat any level below 4 mmol/L as soon as possible. People without diabetes do not experience hypoglycaemia due to a homeostatic response as blood glucose levels fall; glucose stored in the liver is released into the blood stream by the action of the counter regulatory hormones glucagon, adrenaline (epinephrine) and cortisol. Although this process does occur in people with diabetes, it may be over ridden by the presence of excess insulin and there is evidence of attenuated hormonal response related to duration of diabetes. The causes of hypoglycaemia include:

- Missing or delaying a meal or snack.
- Eating less carbohydrate than normal.
- Increased physical activity or exercise.
- Drinking alcohol.
- Taking excessive amounts of insulin or tablets.

The first symptoms of hypoglycaemia are caused by adrenaline (epinephrine) release and include sweating, shaking, increased heart rate, hunger or nausea, anxiety, irritability, tiredness and headache. As hypoglycaemia progresses, lack of glucose to the brain can cause confusion, lack of coordination, slurred speech, drowsiness and aggression, and eventually convulsions and coma. Hypoglycaemia is rarely fatal, although deaths have been reported following excessive alcohol consumption.

Treatment of hypoglycaemia aims to raise blood glucose levels to the normal range as quickly as possible, avoiding over treating and associated hyperglycaemia and preventing reoccurrence of hypoglycaemia. Glucose is the preferred treatment for hypoglycaemia and advice for treatment follows the rule of 15:

- 15–20g of glucose taken as soon as possible.
- If glucose levels do not rise above 4 mmol/L after 15 minutes, repeat treatment.
- A follow-up snack containing 15–20g of carbohydrate may be necessary to reduce the risk of further hypoglycaemia.

Isolated incidences of hypoglycaemia should follow the above guidelines, but repeated hypoglycaemic episodes need further investigation, as prevention is better than cure. Advice for prevention involves identifying the cause and taking steps to prevent reoccurrence by adjusting insulin dose or carbohydrate intake. General advice includes avoiding missing meals, always carrying glucose, testing blood glucose levels before driving and avoiding drinking alcohol on an empty stomach.

Hypoglycaemia unawareness is a condition in which people no longer recognise the symptoms of hypoglycaemia. It is more prevalent in people with type 1 diabetes and is associated with duration of diabetes and intensive management. Symptoms may be restored after a period of maintaining glucose at higher levels and this should be done under medical supervision.

Other nutritional considerations

Protein

In the past, recommendations for protein for people with diabetes have advised that protein intakes should be restricted to the lower end of normal intake as there were concerns about the effect of high protein intake on kidney function and the development of nephropathy. There is insufficient evidence to support protein restriction to prevent the development of diabetic nephropathy, and a systematic review has concluded that there is little evidence to support protein restriction as a management strategy for established diabetic kidney disease (Robertson *et al.*, 2007). Current guidelines recommend that protein intakes for the general population should be adopted for people with diabetes.

Vitamins and minerals

Recent research has investigated the role of vitamin D in diabetes and CVD prevention, and the association between thiamine reduction and the risk of kidney disease and heart disease in people with diabetes. There is, as yet, no firm evidence to support the use of vitamin supplements in people with diabetes.

Chromium, magnesium and zinc are all utilised in carbohydrate metabolism and have been the focus of studies in diabetes. Studies report conflicting results for a benefit of supplementation in terms of glycaemic control. The current advice from Diabetes UK is that there is insufficient evidence to recommend any vitamin or mineral supplement for people with diabetes.

Functional foods

Food such as chilli, karela (bitter gourd) and spices (cinnamon and fenugreek) have been shown to lower blood glucose levels, and are frequently used in traditional medicine. Although they have hypoglycaemic effects, these are unpredictable and they are not currently recommended.

Weight management

Weight loss can improve glycaemic control and reduce cardiovascular risk and all cause mortality in people with

type 2 diabetes (Aucott *et al.*, 2004), although there is little evidence for its effect in people with type 1 diabetes. Strategies used to promote weight reduction in people with diabetes include physical activity and dietary, behavioural, pharmacological and surgical interventions.

Dietary interventions

Dietary interventions for weight loss in people with type 2 diabetes have been widely researched, but many of these studies have methodological flaws and were short term, so it is difficult to draw firm conclusions for clinical practice. Different dietary strategies have been used, including low fat diets, low calorie diets, low carbohydrate diets, very low calorie liquid diets, meal replacements and commercial slimming clubs. Regardless of the type of diet used, dietary interventions for obesity have small but significant effects on body weight and improve glycaemic control (Aucott *et al.*, 2004). However, there is no evidence for the most effective diet for inducing weight loss in people with diabetes, and the advice from Diabetes UK is that those with diabetes can adopt any strategy that is recommended for people without diabetes (see Chapter 7.13.2).

Physical activity

Physical activity is not an effective strategy for weight loss for people with diabetes when used in isolation (Boule *et al.*, 2001), but a combination of diet and physical activity is more effective for weight loss than either strategy alone (Shaw *et al.*, 2006). There are very few studies investigating the effects of different types and intensity of physical activity in weight loss and guidelines cannot be formulated for the relative benefits of aerobic or resistance training.

Behavioural therapy

Many different psychological techniques have been used to promote weight loss, including behavioural and cognitive therapy, group therapy, psychodynamic therapy and humanistic therapy. All behavioural interventions have been shown to promote significant weight loss, and adding dietary or physical activity interventions to these increases weight loss (Dyson, 2010). Although the majority of studies do not include people with diabetes, the evidence suggests that behavioural therapy as an adjunct would improve weight loss in people with diabetes (see Chapter 1.3).

Pharmacological and surgical interventions

There is evidence of significant weight loss with both pharmacological and surgical interventions for people with diabetes, although in the UK only one pharmaceutical agent (orlistat) is available (NICE, 2006). Dietary advice is part of the educational package that should be offered to those who adopt these interventions for weight loss.

Considerations for particular groups

Children and adolescents

The aims of dietary treatment of diabetes in children and adolescents are similar to those for adults, with an addi-

tional emphasis on providing sufficient energy and nutrients for optimal growth. The International Society for Pediatric and Adolescent Diabetes (ISPAD) has published clinical practice consensus guidelines and the broad approach is that of child centred, individualised care based upon healthy eating recommendations suitable for the whole family (Smart *et al.*, 2009). A multidisciplinary team approach is recommended, with a specialist paediatric dietitian providing education and support to the child, the family, the school and other carers (see Chapter 3.8.8).

Teenagers often have poor glycaemic control and although this may be partly due to lifestyle factors, increased insulin resistance accompanies the adolescent growth spurt, which contributes to higher glucose levels. Body weight changes rapidly during adolescence and both excessive weight gain or weight loss may occur. Inappropriate weight gain requires review and advice about dietary intake, insulin dose and physical activity. Weight loss may be associated with insulin omission in order to control weight and/or an eating disorder. Erratic lifestyles, rebellion and peer pressure can all affect diabetes control and may need specialist psychological input.

A summary of nutritional recommendations is shown in Table 7.12.4.

Energy balance

Childhood and adolescence are times of rapid growth and it can be challenging to meet increased energy demands for optimal growth while maintaining target blood glucose levels. Children with diabetes tend to be heavier than those without diabetes; this may be due to over insulinisation and is associated with snacking to prevent hypoglycaemia. Energy intake can vary greatly from day to day, especially in young children, and dietary advice should be flexible, adaptable and reviewed regularly.

Table 7.12.4 Nutritional recommendations for children and adolescents with diabetes (Smart *et al.*, 2009)

Nutrient	Recommendation
Carbohydrate	50–55% of energy intake
Sucrose	Up to 10% of total energy intake
Dietary fibre	2.8–3.4g/MJ
Total fat	30–35% of total energy intake
Saturated fat + trans fatty acids	<10% of total energy intake
Polyunsaturated fat	<10% of total energy intake
Monounsaturated fat	10–20% of total energy intake
Protein	10–15% of total energy intake
Salt	<6g of sodium chloride daily
Vitamins and antioxidants	Encourage natural sources
Diabetic foods	None

Carbohydrates

These should not be restricted in children as this may affect growth. Sugar may provide up to 10% of energy, although excessive consumption in the form of sugar sweetened beverages has been linked to weight gain in children. Denying children all foods containing sugar can have psychological effects and is not recommended. Education about carbohydrate foods is regarded as necessary and the approach recommended is that of the ADA, with three levels of carbohydrate counting (Gillespie *et al.*, 1998).

Fat, protein, vitamin and minerals

Recommendations for these nutrients are no different from those for the general population and are in line with guidelines for promoting health.

Education models

Education models for the delivery of dietary education for children have been developed and include food pyramids and plate models that are designed to promote optimal glycaemic control and reduce the risk of cardiovascular disease. As there are no studies showing that one method is better than another, and there is no international consensus for the most effective tool, it is recommended that appropriate education models should be adapted to the needs of the individual child and family.

Physical activity

This should be promoted for children and adolescents, but it is the commonest cause of hypoglycaemia and needs careful planning on an individual basis. For most children, extra carbohydrate is needed for activity and this is especially true of unplanned activity. Children taking part in regular training sessions or competitive sport will need specialist advice from a paediatric dietitian.

Type 2 diabetes

Type 2 diabetes was formerly unknown in children, but its prevalence is increasing as obesity rates rise. Most children and adolescents with diabetes are obese and will require lifestyle management. There is little evidence for the most effective strategies for management, but recommendations for adults can be adapted for children and should include guidelines for weight reduction, increased physical activity and avoiding energy dense foods and sugar sweetened beverages (Flint & Arslanian, 2011).

Pregnant and lactating women

Women with diabetes who become pregnant are at greater risk of miscarriage, congenital malformation, stillbirth and neonatal death. They should be offered preconception care and advice, and this should be continued during pregnancy. Dietary advice should be offered as part of the education package for women with diabetes and those who develop gestational diabetes (NICE, 2008c).

Preconception care includes advice about establishing optimum glycaemic control and body weight before pregnancy and, in those attempting pregnancy, taking 5 mg of folic acid/day until the 12th week of pregnancy to reduce the risk of neural tube defects (see Chapter 3.2).

Antenatal advice should include standard education about food safety and healthy eating for pregnancy. A multidisciplinary team including a specialist dietitian should provide the education. Glycaemic control is of paramount importance during pregnancy and guidelines recommend that blood glucose levels as near to the normal ranges as possible should be maintained. Insulin resistance increases during pregnancy and women should be advised to increase insulin doses in order to control glucose levels. Body weight monitoring during pregnancy is not recommended by the National Institute for Health and Care Excellence in the UK, although other authorities have issued guidelines and recommend weight gains close to those suggested by prepregnancy weight (Institute of Medicine, 2009; Kitzmiller *et al.*, 2008).

Postnatal care includes support and advice about breastfeeding, which should be encouraged in all women. Insulin requirements are reduced following delivery and breastfeeding may induce hypoglycaemia. Women with diabetes can manage blood glucose levels during breastfeeding by frequent blood glucose tests and a combination of insulin reductions and increased carbohydrate intake. Women with gestational diabetes are at greater risk of type 2 diabetes in the future and may benefit from dietary advice to reduce future risk, especially if they are overweight.

Older adults

Older people with diabetes show reduced physical function, health status and impaired cognitive function compared with those without diabetes (Sinclair *et al.*, 2008), and there is some evidence of poorer nutritional status both in hospital and the general community. The guidelines for management of glycaemia and cardiovascular risk are the same as those for adults, but in the older person with comorbidities, functional dependence or limited life expectancy the targets should be relaxed with the emphasis on avoidance of both symptomatic hyperglycaemia and hypoglycaemia. Nutritional assessment and support for the older person with diabetes who is malnourished should be available (see Chapter 10).

Related comorbidities

Coeliac disease, like type 1 diabetes, is an autoimmune condition and the two are often associated. Approximately 2% of adults and 10% of children with type 1 diabetes have diagnosed coeliac disease and many more may remain undiagnosed. Coeliac UK has produced guidelines for the dietary management of diabetes and coeliac disease in the UK, and recommend individualised advice from a specialist dietitian (see Chapter 7.4.7).

Cystic fibrosis related diabetes (CFRD) is a unique type of diabetes with features of both type 1 and type 2 diabetes and occurs in 40–50% of adults with cystic fibrosis (CF). Insulin is used to treat CFRD and the aim of treatment is to maintain both body weight and blood glucose levels as near to the normal range as possible. Most people with CF are advised to eat an energy dense diet to maintain a healthy body weight and this advice continues to apply to those with CFRD, where the emphasis is

on dose adjustment of insulin to match foods eaten rather than dietary restriction.

Disorders of the pancreas, including acute and chronic pancreatitis and cancer of the pancreas, can affect insulin production and may be associated with diabetes. All these conditions are also associated with malabsorption and malnutrition and the support of a specialist dietitian is essential.

Both HIV and AIDS are associated with insulin resistance and increase the risk of developing type 2 diabetes by a factor of four. Diabetes pharmaceutical agents are of limited use in HIV due to interactions with antiretroviral medications, and the main options for treatment are diet and physical activity.

Eating disorders such as anorexia nervosa and bulimia are 2.4 times more common in adolescent girls with type 1 diabetes. The deliberate omission of insulin to aid weight loss, termed diabulimia by the media, has serious health consequences in terms of the development of DKA and diabetes associated complications. Eating disorders in people with type 1 diabetes affect physical and emotional health and cause impaired metabolic control. All members of the diabetes team should be alert to the possibility of eating disorders and insulin dose manipulation, and urgent referral to eating disorder units may be necessary.

Nutrition support

There is very little evidence available for the role of nutrition support in people with diabetes, but the general recommendation is to follow local protocols and guidelines for those without diabetes. Many feeds and supplements are glucose based and will exacerbate hyperglycaemia, and this should be managed by adequate diabetes medication rather than dietary restriction. Diabetes specific formulae (providing energy derived from monounsaturated fat and fructose) have been shown to help glycaemic control, but these are expensive and are not available in the UK.

Palliative care

In common with guidelines for people without diabetes, end of life care for people with diabetes should ensure non-intrusive dietary and management regimens tailored to individual need. The main emphasis is to avoid symptoms of hyperglycaemia and hypoglycaemia as the risk of long term cardiovascular and microvascular complications is not relevant. In line with changes in dietary intake, adjustment of medication may be required.

External agency residents

People in hospitals, prisons, care homes and boarding schools are not in charge of their own nutrition and often have restricted food choice. It is recommended that people with diabetes, their carers and associated staff have sufficient education and/or training to enable healthy food choices where possible. All food provided should

include snacks and meals that allow food choices that are in line with dietary recommendations for diabetes. In addition, all residents with diabetes should have access to a registered dietitian and a nutritional care plan for each individual should be developed.

Fasting

Fasting is a significant part of many religions and, although people with diabetes are often exempt, many will choose to respect fasts. Little evidence is available to formulate guidelines, and consideration should be given to the timing and doses of medication, and the carbohydrate and energy density of foods taken when a fast is broken.

7.13

Obesity

7.13.1 General aspects and prevention

Linda Hindle

Key points

- Obesity in the UK has trebled in 20 years; about a quarter of adults are obese, and almost a third of children are either overweight or obese.
- Obesity is a serious health risk; it reduces life expectancy and is associated with significant physical morbidity, especially diabetes, and reduced quality of life.
- It is caused by a combination of sedentary lifestyles and poor dietary habits superimposed on a latent genetic susceptibility to weight gain.
- Preventing obesity requires action at all levels, from individual and family counselling, through local initiatives in schools and workplaces to government policies to support and facilitate healthier choices. Environmental changes have the greatest potential to reverse the rising prevalence of obesity.
- Dietitians have a role in obesity management and prevention as a part of their posts, but also as advocates for health in their communities.

Obesity is an excess of body fat to the point that it seriously endangers health. It is defined in terms of body mass index (BMI), which is a measure of relative weight for height and a proxy measure for excess fat, defined as:

$$\text{BMI} = \text{weight (kg)} / \text{height (m)}^2$$

(measured in indoor clothing and without shoes)

The World Health Organization (WHO, 1998) classification of obesity in adults is shown in Table 7.13.1.

Obesity in children and adolescents is normally defined in clinical practice as a sex and age specific BMI plotted at or above the 98th percentile based on 1990 BMI data percentile classification charts (SIGN, 2010; NICE, 2006). When population data are collected, children are defined as obese if their BMI is at or above the 95th percentile of the reference curve for age (see Chapter 7.13.4).

However, BMI is an imperfect index because it does not measure body composition and fails to discriminate between lean and fat tissue (Prentice & Jebb, 2001). Thus, individuals with a particularly well developed muscula-

ture may be classified as obese using the BMI alone. In recent years there has been growing interest in the use of waist circumference as an alternative classification system (Lean *et al.*, 1995; McCarthy *et al.*, 2003). This provides a guide to the extent of the abdominal fat stores and a more sensitive measure of long term health risks. This measure may be more appropriate for Asian communities (World Health Organization Expert Consultation, 2004). Current recommended cut-off points for waist circumference for adult Caucasians and Asians are shown in Appendix A7. Table 7.13.2 shows waist measurements in adults as a predictor of health risk; age/gender specific charts are available for children. However, in childhood current recommendations are that waist measurements should not be used for diagnosis purposes, but may be useful in the clinical situation to monitor progress (NICE, 2006; SIGN, 2010).

It may be preferable to make more specific measurements of body fatness. The development of techniques such as bioelectrical impedance analysis has made this a practical reality for clinical practice. Table 7.13.3 gives

Table 7.13.1 Classification of body mass index (BMI) and risk of comorbidities in adults (WHO, 1998; WHO Expert Consultation, 2004)

Classification	BMI (kg/m ²)	BMI (kg/m ²) Asian origin	Risk of comorbidities
Underweight	<18.5	<18.5	Low (but risk of other clinical problems increased)
Normal range	18.5–24.9	18.5–22.9	Average
Overweight	25.0–29.9	23–27.4	Increased risk
Obese class I	30.0–34.9	27.5–32.4	Moderate
Obese class II	35.0–39.9	32.5–37.4	Severe
Obese class III	>40.0	>37.5	Morbid obesity

Table 7.13.2 Waist measurements in adults as a predictor of health risk (WHO, 2008)

	Men	Asian men	Women	Asian women
Waist circumference (cm)				
Increased risk	≥94		≥80	
Substantially increased risk	≥102	≥90	≥88	≥80
Waist to hip ratio				
Increased risk	≥0.9		≥0.85	

Table 7.13.3 Healthy body fat ranges extrapolated from body mass index cut-offs in adults (Gallagher *et al.*, 2000)

	African American (%)	Asian (%)	Caucasian (%)
Underweight	<20	<25	21
Healthy	20–32	25–35	21–33
Overweight	32–38	35–40	33–39
Obese	>38	>40	>39

useful reference ranges for adults, which broadly correspond to the traditional BMI cut-offs for Caucasian adults. Body fatness centile charts for children are available, although there is still debate about their use in children.

Prevalence

Obesity is the most common nutritional disorder in the world. Globally, there are >1.5 billion overweight adults; at least 500 million of these are obese (Finucane *et al.*, 2011). A systematic review of the economic burden of obesity worldwide concluded that obesity accounted for 0.7–2.8% of a country's total healthcare costs, and that obese individuals had medical costs 30% higher than

normal weight people (Withrow & Alter, 2011). Total healthcare costs attributable to obesity and overweight are projected to double every decade and to account for 16–18% of total US healthcare expenditure by 2030 (Wang, 2008). In the UK the proportion of adults categorised as obese increased from 13% in 1993 to 22% in 2009 for men and from 16% in 1993 to 24% in 2009 for women [Health and Social Care Information Centre (HSCIC), 2010]. By 2050 obesity is predicted to affect 60% of adult men, 50% of adult women and 25% of children (ForeSight, 2007).

The prevalences of obesity and overweight rise with age from a relatively low level in the 16–24 year age group to a peak at 65–74 years, after which there is a modest decline. There is also a clear social class gradient in adult obesity, especially in women, where more than twice as many women in social class IV and V are obese relative to professional women in social class I (HSCIC, 2010). There are differences in both the prevalence and impact of obesity between ethnic groups, with Asian populations at an increased risk of obesity related comorbidities at a lower BMI (World Health Organization Expert Consultation, 2004).

There are particular concerns about the rate of increase in overweight and obesity among children and young people, which has approximately trebled in the last 20 years. In the UK, data from the National Child Measurement Programme (NCMP) indicated that 10.5% of boys and 9.2% of girls (all children 9.8%) aged 4–5 years and 20.4% of boys and 17% of girls (all children 18.7%) aged 10–11 years were classified as obese according to the British 1990 population monitoring definition of obesity (≥95th centile) (NCMP, 2009/10). Children are more likely to become obese if they have obese parents. Obese children are more likely to become obese adults than their peers and the degree of obesity tends to increase with age. This suggests that the burden of obesity will increase markedly in the future unless there is effective action to tackle excess weight gain (Wang, 2011).

Impact of obesity on health

Obesity is an independent risk factor for premature death, but it is also strongly associated, probably causally, with a number of other serious medical conditions (Table 7.13.4). Overall, obese people are two to three times more likely to die prematurely than their lean counterparts and, on average, obesity reduces life expectancy by about 9 years (Calle *et al.*, 1999). The morbidity associated with obesity can be broadly divided into metabolic, mechanical and psychosocial disorders (Bray, 1985). Insulin resistance, hyperlipidaemia and hypertension are strongly associated with excess weight, especially in the abdominal region, and characterised by an increased waist circumference. The clustering of these risk factors is described as the metabolic syndrome and strongly predicts an increased risk of cardiovascular disease (CVD) and diabetes. The increase in the risk of developing type 2 diabetes with excess weight is particularly striking (Diabetes Prevention Program Research Group, 2002). It is

Table 7.13.4 Health risks of obesity (WHO, 1998)

Greatly increased (relative risk >3)*	Moderately increased (relative risk 2–3)*	Slightly increased (relative risk 1–2)*
Type 2 diabetes Gallbladder disease Dyslipidaemia Insulin resistance Breathlessness Sleep apnoea Metabolic syndrome	Cardiovascular diseases Hypertension Osteoarthritis (knees) Hyperuricaemia and gout	Certain cancers, including colon, kidney, prostate (men), postmenopausal breast and endometrial (women) Reproductive hormone abnormalities Polycystic ovary syndrome Impaired fertility Low back pain due to obesity Increased anaesthetic risk Foetal defects associated with maternal obesity

*All relative risk estimates are approximate.

also important to recognise that regardless of baseline weight, further weight gain increases the risk further.

In recent years the links between obesity and cancer have been recognised and, after smoking, excess weight is the most important modifiable risk factor to reduce the risk of cancer. Obesity is particularly associated with post menopausal breast cancer, colon cancer and cancers of the reproductive system (Calle *et al.*, 2003). Other conditions such as stroke, fatty liver, gallstones and reproductive problems, including polycystic ovarian syndrome and infertility, are all increased in obese subjects.

Mechanical problems, including osteoarthritis, chronic low back pain and breathlessness, are rarely life threatening, but contribute to decreased mobility, reduced work productivity and impaired quality of life. Sleep apnoea is a particular problem for many obese patients. The health risks of obesity in young adults are particularly marked and there is a tendency for the relative risk to increase with age.

Studies are beginning to show that the early origins of many of these conditions, especially metabolic diseases, can be seen among obese children. There is an increasing prevalence of type 2 diabetes in paediatric practice. Evidence that overweight in childhood is a risk factor independent of adult weight is limited. However, since there is tracking of childhood weight into adulthood, the health concerns for obese children are substantial (Lobstein *et al.*, 2004).

There is also an association between obesity and decreased psychological wellbeing, but this is not a simple relationship (Stunkard & Sobel, 1995). Obesity does not cause psychological problems, but the social stigma attached to excess weight can leave many obese people, especially children or those with morbid obesity, with

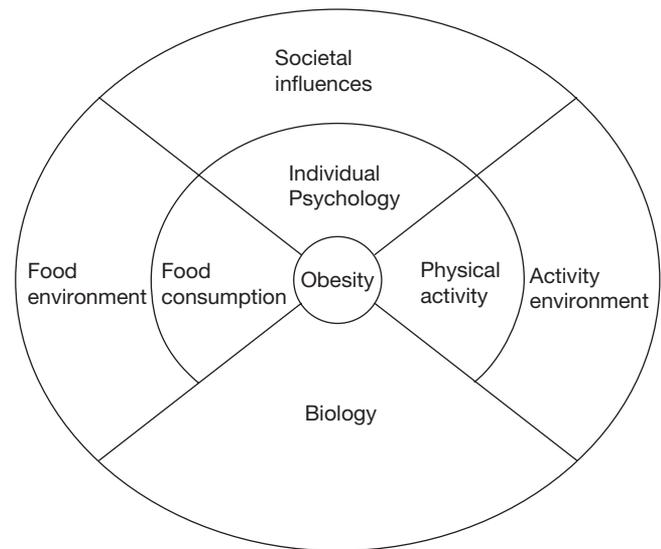

Figure 7.13.1 Factors affecting obesity – a simplified Foresight systems map [from Foresight (2007)]

significant psychological morbidity, including depression and low self esteem. In some cases this may contribute to a downward spiral of increasing weight and declining psychosocial functioning. Dietitians are not isolated from prevailing cultural attitudes towards obese people, and establishing an empathic, non-judgemental relationship with an obese patient makes an important contribution towards effective therapy.

Obesity is a serious health risk. There is good evidence that losing even small amounts of weight can decrease the occurrence or severity of risk factors for disease, e.g. insulin resistance and dyslipidaemia, etc., but there is only limited evidence as yet from long term prospective studies with hard outcomes on overall impact, such as incidence of diabetes or reduced mortality. Nonetheless, the decrease in obesity related morbidity with weight loss of even 5–10% among obese people (15–20% in those with a BMI >35 kg/m²) brings significant benefits to the individual, including reductions in medication for other diseases, and improvements in physical functioning and quality of life (SIGN, 2010).

Aetiology

Obesity occurs as a consequence of a long term excess energy consumption relative to an individual's energy use, leading to an accumulation of excess fat. The causes of this imbalance can be traced to a number of factors, including specific genetic traits, which may convey a metabolic predisposition, behavioural factors and environmental circumstances (Jebb, 1997). The Foresight report (2007) referred to a complex web of societal and biological factors that have, in recent decades, exposed inherent human vulnerability to weight gain; in a complex full system obesity map, over 100 variables directly or indirectly influence energy balance. A simplified model divided the Foresight map into seven interrelated themes, as shown in Figure 7.13.1. The themes were:

- *Biology* – the influence of genetics and ill health.
- *Activity environment* – the influence of the environment on an individual's activity behaviour.
- *Physical activity* – the type, frequency and intensity of activities an individual carries out.
- *Societal influences* – the impact of society, e.g. the influence of the media, education, peer pressure or culture.
- *Individual psychology*.
- *Food environment* – the influence of the food environment on an individual's food choices.
- *Food consumption* – the quality, quantity (portion sizes) and frequency (snacking patterns) of an individual's diet.

Genetics and metabolism

There are some diseases in which obesity is a major feature; the most significant of these are the Prader–Willi and Bardet–Biedel syndromes. A further group of patients may develop obesity as a consequence of an endocrine disorder, e.g. hypothyroidism or Cushing's syndrome. These patients represent a tiny proportion of all cases of obesity and usually present with additional symptoms that can be readily identified and usually successfully treated. In children, short stature for age and weight is an indication that further medical tests may be required (SIGN, 2010).

There has been growing interest in the impact of genetics on the development of obesity. Single gene defects have been identified in rare disorders associated with severe obesity, including defects in the *ob* gene, resulting in congenital leptin deficiency, mutations in the leptin receptor, defective POMC (pro opiomelaninocortin) processing and mutations in the MC4 receptor gene (Farooqi & O'Rahilly, 2005). Individuals with these monogenic disorders have a powerful drive to eat and in them conventional management alone is rarely successful in achieving weight loss. However, once the specific mechanism driving food intake is identified, it becomes a potential target for specific therapeutic interventions. For example, recombinant leptin therapy in children with mutations in the *leptin* gene has resulted in substantial weight loss (Farooqi *et al.*, 1999).

A much greater proportion of the population is likely to exhibit polymorphisms in other genes that have a significant but less dramatic effect on body weight, e.g. mutations in uncoupling proteins, the β_3 adrenergic receptor or PPAR γ (Hainer *et al.*, 2008). These genes may influence a wide range of metabolic and behavioural characteristics that together determine an individual's susceptibility to obesity. Whether this genetic predisposition becomes apparent may depend on the environmental and behavioural choices of the individual.

There has been extensive research into putative metabolic differences between individuals that may account for differences in susceptibility to obesity. Previous suggestions that obese persons have a markedly lower metabolic rate than lean individuals have been categorically refuted, since increases in weight are associated with

increased energy needs (Prentice & Poppitt, 1996). However, this does not preclude differences between individuals in the preobese period. Studies in Pima Indians have shown that a relatively low metabolic rate is associated with an increased risk of future weight gain (Ravussin *et al.*, 1988). Similarly, some studies of post obese subjects have shown minor differences in energy expenditure compared with age and weight matched never obese controls (Astrup *et al.*, 1999). However, these studies are thwarted by difficulties in accounting for subtle differences in body composition. Defects in diet induced thermogenesis and impairments in fat oxidation have also been suggested as metabolic defects that may increase the risk of obesity, but the net effects on energy expenditure are extremely small (Astrup *et al.*, 1996).

In recent years increasing attention has been given to the metabolic control of appetite. A hierarchy of mechanisms, including orosensory, gastrointestinal and neuroendocrine factors control food intake (Blundell & Tremblay, 1995). Defects in any part of these complex pathways may lead to a dysregulation of appetite. This is an area of much current research, particularly given the finding that most of the monogenic obesity syndromes are characterised by metabolic defects in the appetite control system rather than in energy expenditure.

It is only in recent years that it has been acknowledged that behavioural traits may have a genetic basis. However, voluntary behaviour has the potential to override a genetic and metabolic susceptibility to obesity by increasing energy expenditure through voluntary exercise and decreasing energy intake through dietary restraint.

Activity

Physical activity is considered to be protective against the development of obesity. In prospective studies, individuals who maintain a high level of activity gain significantly less weight than inactive people (Coakley *et al.*, 1998). There appears to be a stronger association between sedentary behaviours or physical inactivity and obesity [World Cancer Research Fund (WCRF), 2009]. Television viewing in particular has been linked to the development of obesity because of the combination of sedentary behaviour and snacking on energy dense foods (Reilly *et al.*, 2005).

Studies of exercise as part of a weight loss programme have generally shown little or no increase in weight loss with increased activity, but there is a reduced risk of weight regain (Pavlou *et al.*, 1989). Together these data suggest that physical activity may help to attenuate the rate of weight gain rather than accelerating weight loss. Physical activity recommendations to prevent obesity advocate 45–60 minutes of moderate to intense physical activity daily (Department of Health, 2004; Saris *et al.*, 2003). Increases in physical activity offer additional health benefits and reduce the risk of premature death from CVD and some cancers, as well as reducing the risk of type 2 diabetes.

Table 7.13.5 Evidence for factors that might promote or protect against overweight and weight gain (WHO/FAO, 2003b; Swinburn *et al.*, 2005)

Evidence	Decreases risk	No relationship	Increases risk
Convincing	Regular physical activity High dietary fibre/NSP intake		Sedentary lifestyle High intake of energy dense foods
Probable	Home and school environments that support healthy food choices for children Breastfeeding		Heavy marketing of energy dense foods and fast food outlets Adverse social and economic conditions (developed countries, especially for women) High sugar drinks
Possible	Low glycaemic index foods	Dietary protein content	Large portion sizes High proportion of food prepared outside the home (western countries) 'Rigid restraint/periodic disinhibition' eating patterns
Insufficient	Increased eating frequency		Alcohol

NSP, non-starch polysaccharide.

Diet

A number of dietary factors that may protect against, or conversely promote, the risk of obesity have been identified (WCRF, 2009; WHO/FAO, 2003) (Table 7.13.5). In recent years there has been a tendency to move away from the study of specific foods or nutrients and towards more general dietary patterns. Two of the strongest risk factors for obesity are energy density and portion size.

A series of controlled experimental studies has clearly shown that an increase in the energy density of food increases energy intake through a mechanism described as passive over consumption (Prentice & Poppitt, 1996). This reflects the fact that energy dense diets contain more energy per unit weight and so, if portion size is unaltered, the energy consumed will be greater on energy dense diets. Such diets tend to be high in fat and/or added sugars and low in foods such as fruit and vegetables, which add bulk yet little energy. Energy dense diets fail to stimulate the body's satiety system in proportion to their energy content and hence facilitate over consumption. The energy density theory helps to explain the success of low fat (low energy dense) diets in treating obesity, at least in the short term. However, in the longer term, there are issues relating to compliance and the possible adaptation of the appetite control mechanisms such that long term weight loss is limited unless additional strategies are employed to restrict intake (Bray & Popkin, 1998).

The scientific basis of the energy density theory confines its applicability to solid food. Beverages have a quite different impact on the body's innate appetite control system and liquid calories are much less satiating than the equivalent energy as food. Energy rich drinks, including sugar rich soft drinks and alcoholic beverages, may pose a specific risk factor for obesity due to their low satiating properties (Jebb, 2005).

Portion size also has powerful effects on spontaneous energy intake (Rolls, 2003). A series of studies has now demonstrated that people tend to consume more when

offered larger portions, but that the sense of fullness is unaltered and subjects fail to compensate at the next eating occasion. In this way a small energy excess may accumulate incrementally. There is no evidence linking increased frequency of eating with obesity.

Understanding the importance of these dietary habits in the risk of developing obesity helps to tailor strategies for weight loss, which may include a focus on the type of food consumed in order to reduce energy density, an increase or decrease in certain foods, education on appropriate portion sizes and the development of a structured eating plan.

Environmental factors

At a global level, the marked increase in obesity that accompanies urbanisation and economic development provides strong evidence that environmental factors *per se* play a strong part in the aetiology of obesity or unleash a latent genetic predisposition to obesity (Prentice *et al.*, 2005). There is a growing body of research investigating the impact of the built environment on the risk of obesity (Foresight, 2007). Over the last 50 years technology has altered the way people live their lives in developed countries; labour saving devices, cars and internet shopping have reduced our activity level at the same time as we have become surrounded by relatively inexpensive, ready to eat, high calorie foods offered with incentives such as buy one get one free or supersize offers. The Foresight report termed the interplay of these factors as the obesogenic environment, which is defined as the total sum of influences in the environment on promoting obesity in individuals and populations.

Geographical analyses of, for example, the greater density of fast food outlets in poorer neighbourhoods than wealthier districts, is focussing attention on the social and cultural determinants of health inequalities. In today's world it can reasonably be argued that weight gain is a natural response in humans endowed with an

ancient metabolism designed to withstand famine rather than feast (Prentice, 1997).

Prevention

Prevention of obesity is the key, long term public health goal. This includes the primary prevention of weight gain in lean subjects, secondary prevention of further weight gain in those who are obese, or tertiary prevention through maintenance strategies to avoid weight regain following successful weight loss. There is the greatest population level gain from preventing the development of obesity in the first place, rather than treating obesity once it has occurred, although all of the above are needed. The Foresight (2007) report highlighted the long term, large scale commitment needed to successfully tackle the obesity epidemic, and noted the similarities between this and tackling climate change, both requiring whole societal change with cross government action and long term commitment.

There are important differences between the medical and public health views of the obesity problem and these differences have implications for solutions (Jeffrey, 2002). The medical perspective considers obesity to be an individual level variable; individuals are obese because their body fatness is high compared with population norms and biological ideals. This is caused by differences in individual susceptibility to obesity related to differences in genetics, behaviour, psychology and metabolism. Interventions therefore aim to modify these susceptibilities in the individual as well as helping the individual to cope with an environment that promotes a high energy diet and minimal activity. Population approaches to prevent obesity from this perspective seek to industrialise interventions by scaling them up to wider audiences at lower unit costs.

A review of obesity prevention initiatives in adults and children found most had a focus on educational messages encouraging increased physical activity and a more healthier diet, and concluded that overall the outcomes were modestly positive with the strongest results seen in programmes for children that have high physical activity components (Linde & Jeffrey, 2010). However, the authors noted that the overall effects seen in these studies are considerably smaller than the rate of increase in population obesity, so this approach alone will be ineffective at reversing the rising prevalence of obesity. The solution is more complex than just helping individuals to change their diet and become more active, although these are part of the solution. Policy makers need to weigh the relative benefit of effective interventions reaching a modest number of people against the less effective interventions reaching wider populations (Gortmaker *et al.*, 2011).

Public health models of obesity prevention focus on factors outside of the individual and consider the environment where people live. Thus, the priority to tackle obesity is changing the environment. There has been little research into effective ways of achieving this and therefore options to change the environment are being devel-

oped based on strategies that have been successful in other areas of public health, particularly tobacco control.

It has been argued that obesity prevention interventions should be universal across entire societies, including people of every age and regardless of risk factors, given that there are too little data available on effective ways to identify and manage an individual's obesity risks to justify a population strategy that would devote resources to sorting people by risk or readiness (Linde & Jeffrey, 2010). However, there are specific times in the life course that have greatest potential to impact on obesity (NICE, 2006), including maternity when there is the opportunity to affect the future health risk of the child and the mother; early childhood when there is a high level of parental control and eating, and activity patterns and preferences are being established; and school age when there are opportunities through schools to regulate eating and activity, and to influence the family through the school. Evidence from a growing number of studies has indicated that treating obesity before puberty may have more long lasting effects on relative weight than providing similar treatment after puberty or in adulthood (Jeffrey, 2002).

Specific evidence relating to successful strategies for the prevention of obesity is limited. The paucity of well conducted studies partly reflects the scale and complexity necessary to conduct such studies, especially those involving complex interventions. The Australian Assessing Cost Effectiveness (ACE) in Obesity and ACE Prevention studies have assimilated a broad range of evidence for the prevention of obesity (Vos *et al.*, 2010; Carter *et al.*, 2009). These studies appraise both prevention and treatment interventions in children and adults. Interventions were assessed for comparative effectiveness and cost effectiveness. Of 20 interventions, eight were found to be both health improving and cost saving, and a further three were cost effective (Table 7.13.6). The conclusion from the ACE studies is that policy approaches generally show greater cost effectiveness than health promotion or clinical interventions. No one intervention, however effective, will be sufficient to reverse the obesity epidemic in isolation. Solutions need to be multifaceted, with initiatives throughout governments and across several sectors. Interventions that might have quite small effects when assessed in isolation may still constitute important components of an overall strategy (Gortmaker *et al.*, 2011). Swinburn *et al.* (2005) proposed a model for obesity prevention using an investment portfolio approach. In this way a strategy is developed incorporating a range of options of varying likelihood of success and varying potential health returns on the investment necessary to deliver the intervention. This proposed approach can be incorporated into a structured planning framework to prevent obesity (Gill *et al.*, 2005). This begins by building the case for action, identifying contributory factors and the points for intervention, defining opportunities for action, evaluating potential interventions and then selecting a portfolio of policies, programmes and appropriate actions. The Institute of Medicine (2010) developed a systems approach framework for obesity prevention in

Table 7.13.6 Cost effectiveness results for selected interventions evaluated in Australia (source: Gortmaker 1991, p. 841. Reproduced with permission of Elsevier)

Intervention type	Target population (years)	Strength of evidence*	DALYs saved
10% unhealthy food and beverage tax (Sacks <i>et al.</i> , 2011)**	Adults	4	559 000
Front of pack traffic light nutritional labelling (Sacks <i>et al.</i> , 2011)**	Adults	5	45 100
Reduction of junk food advertising to children [†]	Children (0–14 years)	2	37 000
School based education programme to reduce television viewing [†]	Children (8–10 years)	3	8600
Multifaceted school based programme including nutrition and physical activity [†]	Children (6 years)	3	8000
School based education programme to reduce sugar sweetened drink consumption [†]	Children (7–11 years)	3	5300
Family based targeted programme for obese children [†]	Obese children (10–11 years)	1	2700
Multifaceted targeted school based programme [†]	Overweight and obese children (7–10 years)	3	270
Gastric banding adolescents (Ananthapavan <i>et al.</i> , 2010) [†]	Severely obese adolescents (14–19 years)	1	12300
Family based GP mediated programme (Moodie <i>et al.</i> , 2008) [†]	Overweight/obese children (5–9 years)	3	510
Gastric banding in adults**	Adults with a BMI over 35 kg/m ²	1	140 000

*This classification (1 = strongest; 5 = weakest) is based on criteria adopted in ACE Prevention (Vos *et al.*, 2010). 1 = sufficient evidence of effectiveness; 2 = likely to be effective; 3 = limited evidence of effectiveness; 4 = may be effective; 5 = inconclusive or inadequate evidence.

**Interventions drawn from ACE-Prevention study (Vos *et al.*, 2010).

[†]Interventions drawn from ACE-Obesity study (Carter *et al.*, 2009).

DALY, disability adjusted life years; BMI, body mass index.

the USA that proposed a comprehensive plan with integrated actions throughout society; a coordinated approach to communications; interventions across all demographics; and use of diverse intervention combining initiatives focused on health promotion, the environment and addressing social norms. It recognised the need for long term plans and investment in research, and highlighted that obesity must be considered alongside other societal challenges, such as climate change and poverty reduction, because of the common causes and solutions.

Many community dietitians will be involved in obesity prevention programmes, possibly including intersectoral initiatives and broader environmental policies. However, all dietitians should be vigilant to the potential opportunities for health promotion in their everyday work as well as their role as advocates for health outside their direct clinical practice (see Chapter 4.2).

7.13.2 Management of obesity and overweight in adults

Catherine Hankey

Key points

- Moderate weight loss, usually 5–10% of body weight, is the most realistic target for weight management programmes.
- Clinical guidelines advocate structured approaches to weight management using multicomponent interventions for weight loss and weight maintenance components.
- Diet composition can affect compliance with dietary advice, but the effectiveness of approaches depends on the generation of an energy deficit below requirements and learning the behaviours to sustain it.
- Physical activity assists weight maintenance, but alone has little effectiveness for weight loss.
- Weight loss usually slows after 12 weeks, when weight maintenance becomes the target; more than one cycle of weight loss and maintenance are often required to achieve clinically important weight change.
- Medication and surgical approaches are valuable for some patients.

The prevalence of adult overweight and obesity in the UK and worldwide remains at epidemic proportions, and is still increasing (Berghofer *et al.*, 2008). This increased prevalence is reflected in increased body mass index (BMI) across all ages, with older adults increasingly affected. Individuals with a BMI of $>35 \text{ kg/m}^2$ present particular management challenges. The scale of increase in this group, often considered to have severe and complicated obesity, is increasing internationally (WHO, 1998). In Scotland, the incidence of a BMI of $>35 \text{ kg/m}^2$ is 5% and 11% for men and women, respectively.

This increased prevalence has direct effects on particular areas of healthcare. One pertinent example is the increased obesity incidence in women of child bearing age. Pregnancies associated with excessive weight gain and postnatal weight retention are more frequent in those at social disadvantage (Heslehurst *et al.*, 2010) and present particular management challenges.

Obesity incurs considerable additional healthcare and other costs. This is illustrated by the example of drug prescribing in primary care for the obese; this has almost doubled for the majority of drug categories (Counterweight Project Team, 2005). Health economic evaluations have warned of the enormous financial costs that will result from no action to challenge the relentless rise in obesity (Walker, 2003).

Approaches to challenge the international increases in body weight comprise of prevention, which whilst an

attractive option (King *et al.*, 2011), does not meet the needs of over three-quarter of adults who are already obese, and weight management. Effective and clinically important weight management is defined as weight loss of 5–10% of body weight for those with a BMI below 35 kg/m^2 , or 15–20% for those whose BMI exceeds 35 kg/m^2 , and followed by weight maintenance for a period of at least a year (SIGN, 2010). The Scottish Intercollegiate Guidelines Network (SIGN) stated that a weight loss of $>15\%$ would be required to show health benefits in adults whose BMI is $>35 \text{ kg/m}^2$ or for those with comorbid conditions, such as type 2 diabetes, with a BMI of 30 kg/m^2 . The health benefits of moderate weight loss include improved physical symptoms and biochemical indices, such as plasma lipid profiles, as well as reductions in blood pressure, plasma insulin and glucose. Other benefits include decreases in degenerative joint pain and improved gynaecological health.

Effective weight management needs to be a structured process with clear assessment and management approaches. Often, weight loss is thought of as the only element of weight management, but a weight maintenance phase is required, and is arguably equally important in consolidating weight loss. It is in this context, rather than the target of achieving a BMI in the healthy reference range, that the different strategies for weight management in adults will be discussed. Surgical approaches for weight management, whilst important,

are specific and fundamentally different from the others, and are considered separately in Chapter 7.13.3.

Assessment of overweight and obesity

Body mass index

Body mass index is the most widely accepted way to interpret body weight in terms of health risk. A BMI of 18.5–24.9 kg/m² is healthy and of 25.1–29.9 kg/m² is overweight (WHO, 1998). A BMI of 30 kg/m² is considered obese, and in excess of 40 kg/m² morbidly obese. Cut-offs differ according to ethnicity, and are lower for South Asian and oriental adults (WHO, 2004). Overall raised BMI has a very broad, often non-specific effect on wellbeing, making people feel less well and less energetic. Poorer general health and poor wellbeing scores reflect this. Reduced physical health and quality of life associated with obesity can contribute to impaired mental wellbeing (Hassan *et al.*, 2003).

Waist circumference and waist to hip ratio

A BMI does not consider body shape and the increased likelihood of negative health effects that are associated with abdominal obesity. This can be illustrated by the case of two women, who, while of the same BMI, age and ethnicity, have large differences in body shape. They are highly likely to show very different health risks. To quantify these differences, measures of body shape have been developed and examined in the context of health risk.

Waist circumference is a simple measurement that can indicate the need for weight management (Lean *et al.*, 1995); those with a larger waist circumference are at greater health risk (Han *et al.*, 1995). The target values for waist circumference have been divided into three zones; green, amber (action level 1) and red (action level 2), as shown in Table 7.13.7. A healthy waist measurement, reflecting low health risk, will be in the green zone; one reflecting moderate health risk in the amber zone (action level 1); and one reflecting high risk in the red zone (action level 2).

Waist circumference should be measured midway between the lowest rib and the iliac crest. Careful identification of the waist using these landmarks will ensure that waist measures can be replicated easily, which is especially important as part of a programme of weight

management. Practitioners can advise patients of where their waist measurement sits in terms of health risk, and they can then monitor themselves. A rule of thumb is that a 1-cm decrease in waist measurement is associated with close to a 0.5 kg of weight loss.

Waist to hip ratio (WHR) is another measure of body shape that has been used to classify health risks, but has been largely superseded by waist circumference measurements. Its value should be considered with caution as there are difficulties in measuring WHR and the errors are greater in women than men (Wing *et al.*, 1992). Furthermore, interventions that reduce body weight will reduce BMI and waist and hip circumferences, but produce small or no changes in the WHR. The limitations of using WHR as a measure of body shape are demonstrated using the example of the INTERHEART case control study. It showed a graded and worldwide significant association with one of the many consequences of obesity, myocardial infarction risk (Yusuf *et al.*, 2005). However, the study provided no evidence that WHR was a better predictor than waist circumference alone for other forms of cardiovascular disease, such as sudden death and stroke. Other metabolic consequences of obesity, such as diabetes, infertility or cancer, were not reported.

Dietetic approaches to weight loss

The accepted target for success or good compliance with weight loss regimens is now between 5% and 20% of body weight, with the outdated target of a BMI within the healthy reference range having been discarded. These targets should be considered in the context of populations living in an obesogenic setting, such as the UK, which favours body weight increases steadily across adulthood. This rate has been estimated at between 0.5 and 1 kg annually (Heitmann & Garby, 1999). For those in receipt of medication prescribed for the treatment of long term chronic disease, unintentional weight gain occurs frequently, and can reach up to 10 kg over 52 weeks (Leslie *et al.*, 2007). Simply arresting or slowing the almost inevitable weight gain in adulthood can therefore be considered a therapeutic success. However, the health benefits can be considerable from clinically important weight loss either in early adulthood, particularly in younger people, through to older people. The effectiveness of a reduced energy regimen in self directed slimming is almost impossible to gauge. However, one estimate indicated that a 10% decrease in overweight was achieved by only 10% of the population attempting to lose weight (Perri *et al.*, 1992). It is against estimates of this nature that the success of weight loss programmes is currently being judged. Most conventional professional dietetic approaches use one to one interviews, which are inherently expensive in terms of staff time, whilst group based approaches are mainly, but not entirely, used by commercial organisations.

Evaluation of studies examining different approaches to achieve intentional weight loss can be carried out using data from those who completed the study (completers analysis) or from all those who entered the study [inten-

Table 7.13.7 Action levels for waist circumference

	Green zone (normal)	Amber zone (action level 1)*	Red zone (action level 2)**
Women	<80 cm <32 inches	80–87 cm 32–35 inches	≥88 cm ≥35 inches
Men	<94 cm <37 inches	94–101 cm 37–40 inches	≥102 cm ≥40 inches

*Action level – increasing health risks.

**Action level 2 – high health risks, seek advice to lose weight.

tion to treat analysis (ITT)]. Arguably, data should be analysed using both approaches to determine the best case scenario (the completers analysis), as well as an insight into the initial treatment intent, not the treatment eventually administered. Intention to treat analysis should minimise the risks of misleading interpretation of effectiveness that can arise in any intervention research, and provides insight into how generalisable the intervention can be in usual care. It is useful in counteracting the effects of the high attrition rates usually observed in weight management studies, some predictors of which are raised BMI, low aerobic fitness and socioeconomic status (Roumen *et al.*, 2011); however, a consistent set of predictors has not been identified (Moroshko *et al.*, 2011).

All approaches designed to achieve intentional weight loss are dependent on the maintenance of an energy deficit between energy intake and expenditure. The most commonly used approaches to achieve such energy imbalance include dietary change to reduce energy intake and increased physical activity to increase expenditure.

Energy deficit approach

Conventional dietary restriction for many years was with the 1000kcal (4.2MJ) diet, but compliance as measured by body weight changes was recognised to be poor. The value of moving away from severe energy restriction was endorsed by Frost *et al.* (1991) who confirmed in their audit of two dietetic weight management approaches, that greater energy restriction did not lead to a greater weight loss in free living subjects. Patients were allocated to either a 1200-kcal regimen, or an individualised prescription based on the Lean & James formula (1986) together with a daily energy deficit close to 600 kcal below estimated energy expenditure. The prescriptions recognised that the heavier a person becomes the greater their energy requirements. In addition to body weight, age and gender also influence the individuals' energy requirements. A mean prescription of 1700kcal/day over 3 months produced a 5.0kg weight loss, compared with a 3.0kg loss achieved with a standard 1100kcal/day approach (Frost *et al.*, 1991). Formal evaluation of the energy deficit approach for 12 weeks versus a blanket generalised low calorie (1500 kcal/day) approach using a randomised controlled design has been carried out (Leslie *et al.*, 2002). Weight loss did not differ between the treatments (4.3kg with the energy deficit approach versus 4.9kg with the generalised low calorie diet). Target weight losses, calculated using estimated energy requirements, and assuming total compliance with each approach were 7.0 and 13.0kg, respectively. The weight losses achieved using the energy deficit approach were closer to those predicted than they were for the generalised low calorie approach, confirming the findings of Frost *et al.* This moderate energy deficit approach is currently being used as part of a national study of weight management in primary care (McCombie *et al.*, 2012). The energy deficit approach for weight management is advocated in UK

national weight management programmes (NICE, 2006; SIGN, 2010).

Differing macronutrient composition

Increased protein/low carbohydrate diets

There are consistent findings from metabolic studies and epidemiological observations that high carbohydrate/low fat diets assist weight loss and prevent regain. Increased protein/low carbohydrate diets, whilst opposing current public health advice, achieve weight loss by using the positive effects of protein on controlling appetite (Weigle *et al.*, 2005).

High protein/low carbohydrate dietary advice is not new; the Atkins diet has generated huge international interest since launch in 1972 and has been republished (Atkins, 1998). The dietary principles of the high protein/low carbohydrate diet are to achieve weight loss, weight maintenance and good health by limiting carbohydrate intake to between 20 and 30g/day, whilst consuming unprocessed foods rich in protein and fat in unlimited quantities. Foods to be eaten freely are red meat, fish, poultry, eggs and fats. Foods that are severely restricted are most fruit, some vegetables, rice, pasta and other grain products. Initial weight loss with a high protein/low carbohydrate diet is mostly due to glycogen losses (Eisenstein *et al.*, 2002). The satiating effects of protein also encourage weight loss, as was shown in a 26-week randomised controlled trial (RCT) of overweight and obese subjects (Foster *et al.*, 2003). Dietary advice was to consume either a high carbohydrate or a high protein/low carbohydrate diet *ad libitum*. A significantly greater weight loss (−8.9 versus −5.1kg) was achieved with the high protein/low carbohydrate approach. Efficacy and safety of low carbohydrate diets were considered in a systematic review (Bravata *et al.*, 2003), which concluded that there was insufficient evidence to make recommendations for or against this approach. Three further robust studies of longer duration were subsequently published, allowing more conclusive findings. Two 1-year studies (Eisenstein *et al.*, 2002; Brinkworth *et al.*, 2004) and a 2-year study (Foster *et al.*, 2010) compared low and high carbohydrate diets. The studies reported no differences in weight loss according to dietary treatment (−4.1% versus −2.9% and −4.4% vs −2.5%, respectively for the 1-year studies), and at 2 years weight loss for all participants was 7 kg (7%). Two further systematic reviews compared low carbohydrate (<30g/day) and low fat diets (<30% of energy/day) and confirmed that both are effective at 12 months in achieving modest weight loss (Hession *et al.*, 2009, Nordmann *et al.*, 2006). Mean weight losses were mostly clinically important at 6 months, with a 4.1kg difference in favour of the raised protein approach. However, at 1 year this difference had decreased to <2 kg, indicating small and probably unimportant differences between the groups. The attrition rate was 36% overall in the studies included in the review (and is usually around 30% in studies of weight management), although the authors indicated this was significantly lower in the low carbohydrate groups, although the actual numbers were unreported.

Although no studies have reported any actual negative health effects of a low carbohydrate diet in terms of cardiovascular risk factors, questions remain as to the long term health effects of this approach. This approach is at odds with international dietary guidelines and may be detrimental to renal function and bone health, and increase cancer risk, especially in those with existing obesity related disease (Harper & Astrup, 2004). At present there appears to be no advantage in following a low carbohydrate diet in terms of weight loss.

Low glycaemic index

Glycaemic index (GI) is defined as the incremental positive area under the blood glucose curve following 50 g of carbohydrate from a test food divided by the incremental area following 50 g of a reference food (glucose) (Jenkins *et al.*, 1981). Lentils, pasta and apples are examples of low GI foods, and high GI foods include cornflakes, rice and white bread. It has been proposed that a low GI diet would have beneficial effects on appetite by reducing energy intake and thus inducing an energy deficit and encouraging weight loss. However, a review of studies in this area found weight loss was no greater with a low GI compared with a high GI diet (−1.5 kg versus −1.6 kg) and that effects on satiety did not differ (Raben, 2002). A systematic review (Thomas *et al.*, 2007) confirmed these findings, and indicated that there was insufficient evidence to justify a role for a low GI diet in weight management. The weighted mean difference reported between a low GI and a comparator diet was −1.1 kg (95% CI −2.0 to −0.2). However, the relatively few studies were short term and included participants who were not obese, making interpretation difficult.

Very low calorie diet regimens

Very low calorie diets (VLCDs) provide preprepared meals, usually in the form of liquid drinks but they occasionally allow a daily meal based on food. The term is used when energy provision from the entire regimen is <800 kcal/day (National Task Force on the Prevention and Treatment of Obesity, 1993). This national committee concluded that supervision by a physician and the selection of patients with a BMI of >30 kg/m² should provide appropriate and adequate safeguards to VLCD use; to date these recommendations remain valid. The recommended VLCD composition includes 1 g of protein/kg of ideal body weight/day to minimise muscle breakdown.

Cholelithiasis has been shown to be the most frequent clinical complication associated with the use of VLCDs, with a reported 10% incidence of clinically recognisable symptoms of gallstones after 16 weeks of VLCD therapy (Yang *et al.*, 1992). The potential dangers with VLCDs are increased with prolonged use and if the person has underlying heart disease. A 12–20-week period is acceptable (National Task Force on the Prevention and Treatment of Obesity, 1993). Publicity concerning VLCD regimens and their advocacy by celebrities generated interest for a systematic review and meta analysis (Tsai & Wadden, 2005). Studies compared the use of VLCDs for intentional weight loss with low calorie diets (LCDs) com-

prised of conventional food over the long and short term. Participants had a BMI of 35–40 kg/m², with and without type 2 diabetes. Short term weight loss at 13 weeks was 16% and 10% of body weight in the VLCD and LCD participants, respectively. However, over the longer term, these statistical and clinically important differences observed in favour of VLCDs were lost. After a mean 1.9 years, weight losses were 6.3% and 5.0% respectively. Interestingly, attrition was similar for both treatments, at close to 23%. In practice, VLCD compliance is rarely complete, with patients tending to revert to their usual diet and lifestyle, using VLCDs only sporadically. However, the use of VLCD regimens can be justified in certain situations where quick weight loss is required, e.g. before surgery. Furthermore, it may be that a VLCD approach could be used in those who are obese with a chronic condition, the obvious one being type 2 diabetes. Short term use could be of value if it illustrates to the participant that they are able to lose weight, thus opening the door to other food based weight management programmes more suitable for use over the longer term.

Physical activity strategies to weight loss

The established health benefits of physical activity include reduced blood pressure, improved lipids [especially high density lipoprotein (HDL) cholesterol and triglyceride concentrations] and increased insulin sensitivity. The potential mechanisms linking exercise with weight loss include enhanced resting metabolic rate, preservation of lean tissue, increased total daily energy expenditure and post exercise oxygen consumption (Hill *et al.*, 1994). The influences of physical activity on hunger and satiety are conflicting, with both increases and decreases being reported. A J shaped relationship with appetite involving a paradoxical increase in appetite with complete inactivity has been suggested.

When physical activity or exercise alone is used in the treatment of obesity, weight losses are modest and average 2–3 kg (King & Tribble, 1991). When compared with no intervention, in this case waiting list controls, physical activity achieved greater weight loss, but much less than achieved with dietary interventions (NICE, 2006). However, evidence does exist that exercise alone can produce larger reductions in weight when it is of sufficient frequency, intensity and duration, and there appears to be a dose–response relationship between level of exercise and degree of weight lost. Given the limited ability and desire of overweight and obese adults to exercise, it seems that energy restriction rather than physical activity should remain the focus of the weight loss element in weight management.

A combination of diet and exercise generally produces greater weight losses than diet alone (Skender *et al.*, 1996). One study randomised dieters to an exercise or no exercise group and found that the exercise group lost an average of 10.9 kg during the 12-week intervention period compared with an average of 6.6 kg in the diet only group (Svendsen *et al.*, 1994). Subjects in the exercise group had improved plasma lipids, although weight loss was no dif-

ferent. The National Institute for Health and Care Excellence (2006) reviewed the evidence to answer the question 'does physical activity, 45 minutes three times per week, combined with a 600 kcal energy deficit diet lead to additional weight loss in comparison to diet alone?' Median weight loss across three studies was 5.6 kg with diet and activity, compared with 4.10 kg for diet alone. A meta analysis examined the same issue, this time considering long term (2-year) effectiveness of diet plus exercise interventions versus diet alone (Wu *et al.*, 2009). At 2 years there was a 1.1 kg or 0.5 kg/m² difference in favour of interventions that harnessed activity and diet. Interestingly, the authors indicated that for both interventions partial weight regain was evident. However, there are often issues when reviewing this topic as dose and duration of physical activity often differ between interventions.

Physical activity may be of most value in the treatment of obesity by encouraging weight maintenance. Fogelholm *et al.* (2000) randomly allocated those who had successfully lost weight to either a moderate or higher intensity walk programme or control. The moderate activity programme was as effective as the higher intensity one in preventing the 2.6 kg regain in the inactive control subjects.

Behaviour modifications in weight management

Behaviour modification has been described as a process that identifies unproductive habits, which are then replaced with adaptive behaviour patterns. A review of the use of behavioural approaches to change health behaviours can be found in Chapter 1.3. Behaviour therapy in weight management addresses two main aims. First, a reduction in the food energy consumed and second, an increase in physical activity and thus total energy expenditure to facilitate weight loss. The most widely used approaches for behaviour modification have been summarised by Avenell *et al.* (2006). These comprise reflective approaches that encourage the individual to reflect on their own actions, self monitoring food intake to identify eating behaviour cues before introducing control methods, stimulus control, changing eating patterns and revising weight loss expectations in line with realistic and clinically important targets. Together with education in nutrition and strategies to manage lapses, self monitoring has been considered vital to the success of these approaches as subjects then contribute to and define a programme of care with which they feel most comfortable. Cognitive approaches are often used in parallel with behavioural methods to combat barriers to weight loss that exists within the patient's framework of beliefs. The administration of behaviour therapy can be either through group teaching or individual counselling.

Wadden (2005) reviewed the results of treatments that included behaviour therapy for weight reduction in the years 1974–2002. Forty-two weight reduction studies were published in four behavioural journals over this period and the rates of weight loss were between 0.4 and 0.5 kg/week across all treatments. This encouraging finding must be tempered by the quality of studies as a

recent meta analysis reported that behavioural studies of weight management have in the main been of poor methodological quality, with few following a randomised controlled design or being of a long duration (Ostman *et al.*, 2004). The Scottish Intercollegiate Guidelines Network (SIGN, 2010) reviewed the effectiveness of such approaches and found no studies that showed behaviour modification alone to be effective in inducing weight loss. In reported three small studies whose focus was on behaviour and did include a dietary element, weight loss was 3.8 kg compared with 0.5 kg for a passive intervention (self help). In clinical practice, behavioural skills are important to improve communication between professionals and patients, and encourage maximum patient participation. It is likely that some elements of behavioural approaches are already in use in dietetic practice and that together with dietary advice they contribute towards effective weight management.

Multicomponent weight loss interventions

In the UK clinical guidelines for weight management (NICE, 2006; SIGN, 2010) advocate the use of multicomponent weight loss programmes, comprising three elements; diet, exercise/physical activity and behaviour therapy. This approach has undergone recent thorough investigation (Loveman *et al.*, 2011) in a systematic review that assessed both the clinical and cost effectiveness of multicomponent weight management programmes over the long term in overweight and obese adults. The included studies, largely non-UK based, were diverse in nature and hence meta analysis was precluded. Weight loss was moderate across all studies, although in general weight change appeared to be greater in the intervention groups than comparator groups. Those studies incorporating a longer term follow-up observed weight regain in a majority of subjects. Differences in study design prevented the drawing of firm conclusions concerning the effectiveness of multicomponent weight management. Assessment of cost effectiveness, which is increasingly relevant to justify implementation of all interventions, was also problematic. A preliminary cost effectiveness assessment was carried out with two studies, despite each having limitations, namely a duration of only 36 months, use of prescription antiobesity drugs in some participants and follow-up of <18 months. Each study used a lifetime chronic disease model approach to evaluate the effect of changes in an individual's weight. The models included the costs and benefits from avoiding chronic illnesses such as coronary heart disease and diabetes. Other models are broader and include a wider range of chronic diseases. However, both studies concluded that the long term multicomponent interventions were cost effective, with estimates varying between -£473 and £7200 (US\$12640). As used in cost effectiveness studies, this was expressed as quality adjusted life years gained. The authors cautiously suggested that long term multicomponent weight management interventions in general promoted weight loss in overweight or obese adults, but emphasised that small weight changes and

regain were common. Some evidence suggested that multicomponent intervention may be cost effective, but this finding was by no means conclusive. No UK based RCTs were included in the review, a research need was expressed to evaluate the effects of long term multicomponent weight management interventions in a UK setting.

It is unlikely, if not unknown, for any study to draw firm and final conclusions in any research area. However, there are two US based studies following randomised designs that seem to provide robust conclusive findings in relation to dietary composition and follow-up at 2 years. Sacks *et al.* (2009) recognised the possible advantages of different dietary composition in weight loss diets. Using a factorial model, adults were randomised to one of four diets varying in macronutrient composition, but all regimens incorporated an energy deficit of 750kcal/day. Weight loss was 6kg at 6 months. Participants were then followed up for 2 years. Attrition was low at 20% and, despite weight regain, losses of 4kg were maintained, with about 15% of participants maintaining a weight loss of >10%. The authors concluded that the reduced calorie diet, irrespective of macronutrient focus, could lead to clinically meaningful weight loss. Another 2-year study, set this time within primary care, illustrated how behavioural weight loss counselling could best be delivered by using lifestyle coaches (Wadden *et al.*, 2011). All participants were prescribed identical goals for diet and physical activity, but were provided with different levels of support to achieve them. Dietary advice to achieve an energy intake of between 1200 and 1500 kcal was given to participants weighing <113.4kg, and for up to 1800kcal if weight was greater. All were advised to exercise for up to 180 minutes/week and given a pedometer. Usual care comprised quarterly visits that included 5–7 minutes reviewing weight change. Brief lifestyle counselling included an additional 15 minutes/month with an auxiliary healthcare provider, while enhanced counselling support offered the option of further tools. This allowed participants to choose the medications orlistat or sibutramine (no longer licensed for use) after 6 months or meal replacement products. Enhanced care attempted to mimic practice in primary care, providing participants with the opportunity to influence their care, guided by practice staff, by choosing one or more of these additional tools. At 2 years usual care achieved weight losses of 1.7kg, lifestyle counselling 2.9kg and enhanced support 4.6kg. Initial weight loss was at least 5% in 21%, 26% and 34% of participants of the three groups, respectively. The enhanced support option was significantly more effective than the other interventions in achieving clinically important weight loss. These two studies effectively illustrate the short and long term effectiveness of weight management approaches.

Weight management in different settings

Group versus individual therapy

Group therapy offers obvious and important benefits for decreasing cost and improving professional resource

management (Bitzen *et al.*, 1988; Chenoweth, 1990). Whilst the group environment is undoubtedly unsuitable for some shy or reluctant socialisers, for those agreeable to this approach it allows additional harnessing of structure and peer support not accessible to the subject undergoing individual one to one dietary counselling. Commercial organisations utilise group settings for their sessions. The effectiveness of these was considered earlier. However, other programmes such as Counterweight also offer group based treatments, when these are possible, within the primary care setting.

The Australian Gutbuster waist loss programme was a group programme designed for men who were recruited to a 6-week course and then followed for a year. The programme involved advice on exercise, dietary fat and alcohol intake. Average waist circumference losses of 4% were achieved and lifestyle advice led to lowered fat and alcohol intakes. A more advanced programme that included six additional fortnightly sessions saw falls in waist circumference of 10% (Egger *et al.*, 1996). In contrast to the majority of group based interventions, this approach showed the value of group programmes for weight management in men.

There may be cost benefits from using group approaches to weight management, but this is not entirely clear, as the class number may be small. A recent systematic review (Paul-Ebhohimhen & Avenell, 2009) included RCTs, but not those examining commercial weight treatments. At 12 months a weight difference of 1.4kg was seen between group versus individual approaches. Subanalyses indicated that financial incentives within group treatments increased weight loss. Subsequent examination by these authors indicated that financial incentives themselves were not a useful tool to maximise weight loss.

The Counterweight programme (an example of weight management in primary care)

Primary care has been advocated by clinical guidelines as a suitable but underutilised setting for weight management. Counterweight is a unique nationwide programme, originally set only in primary care, that harnesses the best evidence based approaches for weight management (Counterweight Project Team, 2008). Primary care staff, including practice nurses, health trainers or healthcare support workers, attend an 8-hour training course, and are subsequently mentored to agreed competency levels by Counterweight specialists. Approaches for delivery are largely one to one, although groups are used where appropriate. Lifestyle change focuses on both diet and physical activity, with key behaviour change strategies underpinning the intervention. The overall aim is for patients to develop skills to manage weight in the long term. Dietary change is based on either the 600-kcal energy deficit approach or on individualised goal setting. As with any weight management approach, the intensity of the intervention can affect both the main outcome, weight change, and the cost and utility of the programme. Counterweight participants receive six appointments over 3 months, delivered on a group or one to one basis,

then follow up sessions every 3 months for a year, and then annually (Counterweight Project Team, 2004a,b). This level of intensity probably reflects realistic implementation resource availability within the NHS. As the project harnesses current evidence, there is no requirement to prove its effectiveness in terms of biochemical measures and/or experimental design, such as a RCT. A continuous improvement model to develop the model was employed (Petticrew *et al.*, 2012), and the 5-year outcome data were the starting point for this (Counterweight Project Team, 2008). These data indicate that mean weight loss was 3.0 kg at 12 months (% CI -3.5 to -2.3 kg) and at 24 months was 2.3 kg (95% CI -3.2 to -1.4). Clinically beneficial weight loss of >5% was achieved in 30.7% of the attending population at 12 months and in 31.9% at 24 months. Counterweight achieves and maintains clinically important weight loss.

A multidisciplinary weight management service (a secondary care specialist centre in Glasgow)

The management of obesity by healthcare professionals (dietitians, doctors, nurses, physiotherapists and psychologists) is generally fragmented and each professional group has developed management programmes largely independently of each other. Dietitians offer both inpatient and outpatient services in most general hospitals and in the community. There is little evidence that input to dietetic weight management from specialist health professionals occurs regularly. Practice nurses offer weight management advice to many overweight clients, although this appears to be on an *ad hoc* basis (Hoppe & Ogden, 1997). Physician led obesity clinics are found in only a few UK NHS centres. A specialist weight management service using a multidisciplinary team based approach bringing together dietitians, psychologists, physiotherapists, physicians and surgeons was advocated by SIGN (1996). Greater Glasgow Health Board piloted this innovative service and 3 month outcome data have been published (Morrison *et al.*, 2012). This first phase evaluation indicated that 72.4% of all referrals participated in the programme, with 37.5% completing phase 1 (12 weeks). Of these 809 completers, 35% achieved a clinically important weight loss of 5 kg or more. These data have indicated some approaches to potentially improve service effectiveness. Further longer term data are eagerly awaited from this unique service.

Although multidisciplinary working is widely advocated to take on the task of weight management, there still appears to be reluctance amongst many health professionals. A survey of GPs, practice nurses and dietitians found all three groups of professionals felt underskilled to effectively manage both obesity and overweight (Hankey *et al.*, 2004). Similar findings were reported in a survey of secondary care consultants (Leslie *et al.*, 2005). In both studies dietitians were identified as the professional group most likely to take on weight management, but were considered too scarce to assume a major role. It is unlikely that the views of these health professionals have altered since these studies were completed,

and in fact it is likely that resources are scarcer given the current financial climate. However, in order to evaluate these assertions, it is proposed to return to the Scottish dietetic profession and seek their views on obesity and weight management once more, which will be especially valuable given the recent publication of the revised SIGN (2010) obesity guideline.

Community pharmacy (a possible setting for community based weight management)

The sheer number of adults who are overweight or obese means use of as wide a range as possible of potential opportunities to deliver weight management are justified. Community pharmacists occupy a position of trust and are easily accessible to many. Recent evidence evaluating the effectiveness of community pharmacists in terms of weight management has been systematically reviewed (Gordon *et al.*, 2011). The review indicated that only scant research data exist within this field, and certainly a dearth of robust studies of up to 12 months' duration. Whilst RCTs would appear inappropriate in this setting, further investigation into the clinical and cost effectiveness of weight management in pharmacies is justified.

Commercial slimming organisations

A number of commercial slimming organisations operate in the UK and offer a regular service to those seeking assistance with weight management. Slimming groups are accessible, convenient and relatively inexpensive, and currently their role in the UK is expanding, with partnerships with the NHS becoming established (Stubbs *et al.*, 2011). The 12-week treatment data appear promising, with a 4.0 kg weight loss and 1.5 kg/m² reduction in BMI, but further data concerning both attrition rates and information on longer term weight change (at least 1 year), are required to justify the value of this programme (Stubbs *et al.*, 2001).

In addition to this audit, a number of studies have formally examined the effectiveness of commercial approaches. Dansinger *et al.* (2005) in their randomised study comparing commercial organisations with other dietary approaches showed that at 1 year weight loss with the commercial organisation Weight Watchers was similar to that with other approaches tested at 3.0 kg. Another comparison between a commercial slimming organisation and a self help group found a 4 kg weight loss at 1 year with the commercial programme and a 1 kg weight loss with self help (Heshka *et al.*, 2003). A review (Tsai & Wadden, 2005) of published evidence from commercial and self help groups concurred with these findings. Best results were a 3.2% weight loss at 2 years for Weight Watchers. The effectiveness of a primary care referral to a commercial provider for weight loss treatment was evaluated using a randomised controlled design (Jebb *et al.*, 2011). Participants were randomly allocated to usual care or to receive the commercial programme for 12 months. The attrition rates were similar for both arms

of the study at 46% and 39%, respectively. However, the weight loss after 12 months in the commercial setting was more than double that of usual care (5.06 kg versus 2.25 kg). This finding is encouraging and in excess of that achieved in any other study. The intensity of the commercial intervention, either two or three appointments/month, may have strongly influenced the weight loss, favouring success. Uncertainty remains as to the cost effectiveness of such an intervention, and whether the level of intensity applied in this study could be justified and replicated in usual care. The findings of an audit of the same commercial programme contrast with the study findings, indicating that provision of 12 sessions within an NHS referral scheme, delivered over a 12-week period, showed a lower median weight change when all referrals were considered (-2.8 kg/3.1%) and an attrition rate of 46% (Ahern *et al.*, 2011).

The Internet

The Internet appears to offer promise as a tool to facilitate weight management, and in theory this could be at low cost. To date there are relatively few studies of Internet delivered intervention, but in general these show moderate weight loss and some positive effects on weight maintenance. The setting itself is restricted to those who are computer literate and have access to the Internet. These interventions can be either commercial or delivered through national health care routes. McConnan *et al.* (2007) examined the effect of a combination of dietary and physical activity advice, along with behaviour therapy, in an NHS setting. Patients were randomised to receive usual care or the Internet delivered intervention. Weight loss did not differ between the treatments and was <2 kg. In contrast, two other internet based approaches were compared in a 12-month study, and showed weight losses of 8.3 kg (SD 7.9 kg) and 4.3 kg (SD 6.2 kg), respectively. The higher weight loss was seen with the structured behavioural intervention compared to a self help approach (Gold *et al.*, 2007). Internet based delivery certainly appears to offer promise, alongside challenges, such as determining outcome to a remotely delivered intervention, and further evaluation is justified.

Antiobesity medication

There is only one antiobesity medication available for prescription by physicians for the management of obesity and comorbid conditions, although a number of others are under development. There were two others, an appetite adjuster, sibutramine, and a selective endocannabinoid receptor blocker, rimonabant. Both were removed from use in response to negative health events possibly related to their use. The medication still available for use, orlistat (tetrahydrolipostatin), induces malabsorption (antinutrients). Other medications under development for weight management operate through appetite suppression (or satiety promotion), or by thermogenesis to increase energy expenditure. Importantly, for dietetic practice, the only medication available for use in obesity

per se should be taken in combination with a programme of diet, exercise and behaviour therapy.

Malabsorption

Lipase inhibition induces partial malabsorption of dietary fat by inhibition of triglyceride hydrolysis. The chemically synthesised hydrogenated derivative of lipostatin (orlistat) is a potent inhibitor of gastric, pancreatic and carboxylester lipase. Beales & Kopelman (1994) have suggested that the principles by which the medication operates are sound, although there are possible risks, possibly correctable, of fat soluble vitamins A, D, E and K depletion. Predictable side effects from malabsorption, altered bowel habit, and also bacterial overgrowth of the small bowel have led to around a 37% patient withdrawal from therapy (Sjostrom *et al.*, 1998). A low fat/low energy diet reduces symptoms and maximises weight loss, which at 1 year was 10.2% in the controls versus 6.1% in those receiving medication. At 2 years the difference in weight loss due to orlistat was 3.6 kg. About 20% of patients who took part in studies of orlistat lost at least 10% of body weight, which was twice the number on placebo. This medication is now available in the UK with medical prescription as an over the counter product. The success of this initiative is unknown; however it is sold at a dosage of approximately half its prescription dosage, and is expensive.

Hypoglycaemic agents for diabetes and obesity

Although not classified as an antiobesity agent as such, and only appropriate for use in the management of type 2 diabetes, the glucagon like peptide 1 (GLP 1) receptor agonist does reduce body weight close to clinically important levels. Liraglutide has been licensed for use since 2009 and shows a beneficial effect on both body weight (-3 kg at 26 weeks) (Buse *et al.*, 2009) and diabetic control (a reduction of 1.5% in HbA_{1c}). The medication is administered subcutaneously once daily, and its mode of actions are to improve blood glucose control, mediated by increased insulin secretion, delay gastric emptying and suppress post prandial glucagon secretion.

Maintenance of weight loss

A formal description of weight maintenance is valuable and of particular importance when judging the effectiveness of weight management interventions. Long term weight maintenance has been defined as a change of <3% of body weight (Stevens *et al.*, 2006). A common failing in almost all conventional approaches for weight loss is leaving weight maintenance to chance, so that regain is usual and most often almost complete. Many researchers have found that weight loss is relatively easy to achieve, but that weight maintenance is more challenging. There are a number of follow-up studies that have examined long term weight loss after treatment, but they are not technically addressing weight maintenance. A meta analysis in overweight and obese adults examined long term

weight loss after diet and exercise (Curioni & Lourenco, 2005). The findings showed inclusion of physical activity and diet together led to a 20% greater sustained weight loss of 6.7 versus 4.5 kg for diet alone after 1 year. However, in both groups almost half the initial weight loss was regained after 1 year. Douketis *et al.* (2005) confirmed the conclusions of this review that all dietary approaches achieve moderate weight loss, with the exception of surgery, after 2–4 year follow-up. In a bid to challenge the perception that almost no one succeeds in long term weight maintenance, Wing & Hill (2001) identified the characteristics of successful weight losers within the national weight control registry of successful long term weight maintainers. These individuals were defined as 10% weight losers who sustained this loss for a least 1 year, but at 5 years mean weight loss was 30 kg. Common characteristics of maintainers in the registry were the consumption of a low fat diet, a high level of physical activity and regularly weighing themselves and taking responsibility for monitoring their own weight.

The European wide multicentre Diogenes study (Larsen *et al.*, 2010) examined dietary composition in the context of preventing weight regain post weight loss. Adults from eight European countries were randomly assigned to one of five *ad libitum* diets to prevent weight regain over a 26-week period; a low protein/low GI diet, a low protein/high GI diet, a high protein/low GI diet, a high protein/high GI diet, or a control diet. A mean weight loss of 11 kg was seen using a very low calorie diet, and only the low protein/high GI diet was associated with clinically important weight regain (+1.7 kg). Although successful weight maintenance strategies have yet to be defined, there are many reflective papers that consider the factors that prevent weight gain (Swinburn & Egger, 2002).

Conclusions

There is a range of clinical approaches for the achievement of weight loss. The outcome in the majority of these interventions is moderate weight loss, which has been acknowledged to confer health benefits. Long term weight maintenance, dependent on effective weight maintenance strategies, is increasingly recognised as a key element. The moderate energy deficit approach has been shown to lead to a weight loss of close to 5.0 kg over 12 weeks, and has been used within longer term studies and also the Counterweight programme. The value of this approach may lie with an emphasis on eating conventional foods and the introduction of regular meal patterns. The effect of diet composition on weight loss is minimal, although the consumption of a high carbohydrate diet in the longer term should be advocated to reduce the risk of long term chronic disease. Physical activity in addition to dietary intervention can offer opportunities for improved maintenance of weight loss, although physical activity programmes alone result in minimal weight losses. Very low calorie diet approaches are valuable in inducing short term weight loss of up to 10–15 kg, either presurgically or in a setting where subsequent dietary management is proposed. Medical supervision is required, together with

a minimum BMI of 30 kg/m² and long term management in these cases.

A wide range of treatments for overweight have been tested, and the majority achieve a modest (5–10%) weight loss, which is sufficient to improve clinical outcomes for type 2 diabetes, plasma lipids, hypertension and other risk factors for ischaemic heart disease. This weight loss is usually achieved over 12 weeks, after which it is difficult for many to achieve further loss. Greater weight loss is usually possible for patients with surgery.

Particular weight management challenges are presented by emerging sectors of the overweight and obese populations. These include the severe and complicated groups, those who are obese and pregnant and likely to retain weight gained in pregnancy, and older people for whom physical activity may be particularly challenging; there are likely to be others.

Weight maintenance following weight loss is crucial to sustain the health benefits of weight losses seen with any of the approaches described for weight management. However, effective approaches for the achievement of weight maintenance have yet to be defined and tested. Many health professionals can contribute to effective weight management programmes; however, given the scale of the problem, the role of the dietitian is perhaps greater in terms of training others to enable them to challenge the epidemic of overweight and obesity.

7.13.3 Bariatric surgery

Gail Pinnock and Mary O'Kane

Key points

- Bariatric surgery is an effective long term treatment of obesity.
- Following surgery, clients show significant improvement in comorbidities.
- Clients are at possible risk of micronutrient deficiencies following surgery.
- Long term dietetic support is essential.

The weight loss associated with diet, medication and life-style change is not always sufficient to improve health of obese clients, and it is now recognised that surgery should be considered, especially in the morbidly obese (NICE, 2006). Bariatric surgery (obesity, weight loss or metabolic surgery) is currently the most effective long term treatment of morbid obesity (Schweitzer *et al.*, 2006; Shah *et al.*, 2006). Maximum weight loss following bariatric surgery varies depending on the procedure (See Table 7.13.8) (Das *et al.*, 2003). The benefits of surgery are well established, with resolution of comorbidities occurring in a significant number of cases (Karlsson *et al.*, 2007; Smith *et al.*, 2008).

Recent data compiled from the National Bariatric Surgery Registry (NBSR, 2011) show average excess weight loss of 58% 1 year after surgery and remission of type 2 diabetes in 85.5% of cases 2 years post surgery. Therefore, it has been suggested, especially in the USA, that surgery be considered as a primary treatment for those with a body mass index (BMI) of $>30 \text{ kg/m}^2$ and type 2 diabetes.

There was a nine-fold increase in bariatric surgical procedures between 2003 and 2008 (O'Neill, 2010), with over 7000 undertaken within the NHS in 2009–2010 (NHS, 2011). There are no reliable data on procedures carried out in the private sector.

Table 7.13.8 Bariatric surgery procedures

Procedure	Mechanism of action	Excess weight loss (%)	Impact on nutrition	Supplementation recommended
Intragastric balloon	Restrictive	10	Reduced intake	Multivitamin and mineral supplement
Adjustable gastric band (AGB)	Restrictive, no malabsorption	50	Reduced intake Effect on satiety	Multivitamin and mineral supplement
Sleeve gastrectomy	Restrictive, no malabsorption	50–60	Reduced intake Effect on satiety	Multivitamin and mineral supplement. May also need calcium supplement, vitamin D and vitamin B ₁₂ injections
Roux-en-Y gastric bypass (RYGB)	Restrictive, possible malabsorption	65–68	Reduced intake Effect on satiety Calcium, iron and vitamin B ₁₂ absorption affected May experience dumping syndrome	Protein (60–80 g/day) Multivitamin and mineral supplement, calcium supplement, vitamin D, vitamin B ₁₂ injections
Long limb gastric bypass	Restrictive and malabsorptive, may experience steatorrhea affecting absorption	65–68	Reduced intake Effect on satiety Macronutrient malabsorption possible Calcium, iron and vitamin B ₁₂ absorption affected May experience dumping syndrome	Protein (60–80 g/day, may need 80–100 g/day if malabsorbing) Multivitamin and mineral supplement, calcium supplement, vitamin D and vitamin B ₁₂ injections
Duodenal switch (biliopancreatic diversion with duodenal switch) (DS)	Restrictive and malabsorptive, steatorrhea affecting absorption	>70	Reduced intake Effect on satiety Macronutrient malabsorption possible Calcium, iron and vitamin B ₁₂ , fat soluble vitamin absorption affected	High protein (80–100 g/day), low fat diet Multivitamin and mineral supplement, high doses of fat soluble vitamins, calcium supplement, vitamin B ₁₂ injections

Clinical guidelines

In the UK NICE (2006) guidance (recommends surgery as a treatment option if all the following criteria are met:

- BMI $>40 \text{ kg/m}^2$.
- BMI $>35 \text{ kg/m}^2$ with significant disease, e.g. type 2 diabetes, high blood pressure, obstructive sleep apnoea, that could be improved with weight loss.
- Appropriate non-surgical measures have been tried but failed to achieve or maintain adequate, clinically beneficial weight loss for >6 months.
- Has been receiving or will receive intensive management in a specialist obesity service.
- Generally fit for anaesthesia and surgery.
- Commits to need for long term follow-up.

Surgery can be considered as a first line treatment option for those with a BMI of $>50 \text{ kg/m}^2$. However individual NHS trusts may impose their own criteria in addition to those of NICE (2006).

Each treatment centre is required to have a multidisciplinary team (MDT) that can effectively select and manage these complex patients (NICE, 2006). A comprehensive assessment in which the benefits of surgery can be balanced against the risks is essential to enable the patient to make an informed choice in consultation with the MDT. For some patients, the risks may be too great and surgery declined.

Surgical procedures

Bariatric surgery works by gastric restriction, malabsorption or a combination of these; most surgery is performed laparoscopically to shorten the recovery time. The choice of surgical procedure depends on several factors, including the MDT decision, the patient's comorbidities and patient preference. Details of the surgical procedures are shown in Table 7.13.8 and Figure 7.13.2, Figure 7.13.3, Figure 7.13.4, Figure 7.13.5 and Figure 7.13.6).

Roux-en-Y gastric bypass (RYGB) is the most frequently performed procedure, followed by sleeve and adjustable gastric band (AGB) (Burton & Brown, 2011). Duodenal switch is rarely used because of a greater risk of malnutrition and then only for patients with considerable weight to lose; it may be done as a two stage procedure. The intragastric balloon is placed endoscopically into the stomach and then inflated with saline. It is a short term measure, viable for 6 months, and therefore outside NICE guidance.

Novel, less invasive techniques are being developed, although they are not yet in common use in the UK.

Gut hormones

The gastric bypass, sleeve gastrectomy, long limb bypass and duodenal switch affect some gut hormones, including ghrelin, glucagon like peptide 1 and peptide YY, involved in glucose regulation and appetite control, although the mechanism has not yet been elucidated (Rosen & Pomp, 2009). This results in improvements in

diabetes control and reduced appetite; however, appetite eventually returns. The exact mechanism has not yet been fully elucidated.

Excess weight loss following surgery

Weight loss following surgery is expressed as excess weight loss (the amount of weight above a BMI of 25 kg/m²). The fastest rate of loss is in the first year, whilst maximum loss is usually achieved in 18 months to 2 years. Unless permanent lifestyle and dietary changes are made, weight regain may occur.

Surgical complications

Mortality rates vary depending on the procedure, but are lower when this is carried out by experienced surgeons in specialist high volume centres, where it is a relatively safe intervention. Complications include anastomotic leaks, bleeding, infection, strictures and obstructions or

incisional hernias (Mechanick *et al.*, 2008). In some situations the dietitian will be required to provide nutritional support. Careful consideration will have been given to the risks and benefits of surgery before the decision to proceed.

Long term complications

The benefits of surgery of improvements in glycaemic control, hypertension, sleep apnoea and hyperlipidaemia are well established (Karlsson *et al.*, 2007; Smith *et al.*, 2008). However, long term problems have been reported, such as nutritional deficiencies (Pournaras & le Roux, 2009; Slater *et al.*, 2004) (Table 7.13.9), metabolic bone disease, renal stones, anastomotic ulcers, strictures and obstructions (Mechanick *et al.*, 2008).

Role of the dietitian

The dietitian is an essential and respected member of the MDT (NICE, 2006), who is involved in the presurgical assessment and preparation, through to post surgical and long term nutritional support and follow-up.

Presurgical assessment

The presurgical dietetic assessment covers the following:

- Weight and dieting history.
- Dietary assessment, including eating behaviours and recognised eating disorders.
- Psychological issues – beliefs, behaviours, motivation, support mechanisms.
- Alcohol and smoking.
- Assessment of the patient's understanding of the impact of surgery on diet and lifestyle.
- Physical activity.
- Current medical history, including comorbidities.
- Past medical history, including past surgery.
- Medication.

Preparation

Once the patient is accepted for surgery, the dietitian continues to work with them, developing coping strategies to enable them to manage the changes needed post surgery. Patients are also encouraged to follow a liver shrinkage diet for 7–14 days before surgery (Fris, 2004). This may be liquid or food based and low in energy and carbohydrate, which reduces the size of the liver, making surgery easier.

Post surgery

After surgery, the dietitian is usually the first point of contact for patients with problems or queries. Typical issues include regurgitation, vomiting, food intolerances, vitamin and mineral supplementation and changes in bowel habit. If persistent vomiting occurs, thiamine deficiency may develop extremely quickly and urgent supplementation, followed by surgical review, is essential.

Table 7.13.9 Incidence of micronutrient deficiencies in bariatric surgery

Vitamin mineral deficiency	Presurgery	Adjustable gastric band	Sleeve gastrectomy	Gastric bypass	Biliopancreatic diversion ± duodenal switch
Thiamine	Uncommon	Uncommon unless protracted vomiting occurs	Uncommon unless protracted vomiting occurs	Uncommon unless protracted vomiting occurs	Uncommon unless protracted vomiting occurs
B ₁₂	10–13%	Uncommon	Uncommon	12–33%	Uncommon
Folate	Uncommon	Uncommon	Uncommon	Uncommon	Uncommon
Iron	9–16% of adult women	Uncommon	May occur	20–49%	May occur
Vitamin A	Uncommon	Rare	Rare	Rare but may occur	50% at 1 year 70% at 4 years
Vitamin D and calcium	60–70% (vitamin D)	May occur	May occur	Common Increased risk of metabolic bone disease with low vitamin D, hypocalcaemia and secondary hyperparathyroidism	Very common Increased risk of metabolic bone disease with low vitamin D, hypocalcaemia and secondary hyperparathyroidism
Zinc	Uncommon	Uncommon	Uncommon	May occur	Common
Selenium	Uncommon	Uncommon	Uncommon	May occur	Common
Protein	Uncommon	May occur	May occur	May occur	May occur

A consensus statement for supplementation, gathered from a recent audit of good practice, will shortly be released by BOMSS (see BOMSS website for details).

Short term management

The patient progresses from liquids to puréed foods and then onto normal textured foods. The dietitian must ensure that patients meet their fluid and protein requirements. Diet information is available from the British Obesity and Metabolic Surgery Society (BOMSS) (www.bomss.org.uk).

It is crucial that patients establish new eating behaviours, such as eating slowly, stopping as soon as they feel full and chewing food well. They must also avoid eating and drinking at the same time; initially, this is because the small stomach makes it difficult and subsequently because fluid pushes food through quickly, enabling them to eat more, which slows the rate of weight loss. Patients often struggle with textures such as bread, roast or grilled meat and fibrous vegetables. To compensate, patients may resort to a sloppy, poor quality diet. Unfortunately, foods such as chocolate and crisps tend to be well tolerated.

Long term management

The patient must be encouraged to have a balanced, low fat diet. Reduced stomach capacity can result in grazing throughout the day and a regular meal pattern is necessary to avoid this. To minimise the risk of nutritional deficiencies, patients are advised to take a multivitamin and mineral supplement long term (Aills *et al.*, 2008); problems may occur with non-compliance. Regular blood tests should be carried out and supplementation adjusted as needed. Protein malnutrition may occur after any of the procedures because of food intolerances (especially meat) and alternative sources of protein should be sug-

gested. Following a restrictive and malabsorptive procedure, patients should be encouraged to consume 60–100 g of protein/day. Patients who experience dumping syndrome and related symptoms of hypoglycaemia will need additional support.

Patients need continued dietetic support throughout the weight loss phase to encourage permanent dietary and lifestyle changes. This is equally important in helping with long term weight maintenance.

Women of childbearing age are discouraged from becoming pregnant within the first 12–18 months of surgery. Thereafter, they should be reminded of the importance of nutrition preconception. They may need to change their vitamin supplement to one that does not contain vitamin A; however, those who have had a duodenal switch may need to continue to take high doses of fat soluble vitamins throughout pregnancy.

7.13.4 Childhood obesity

Laura Stewart and Jenny Gillespie

Key points

- Obesity is the most common childhood nutritional disorder worldwide and therefore is an important area for dietitians.
- Managing childhood obesity is challenging due to the need to engage the child or young person, parents or carers and the whole family.
- The consequences of childhood obesity are seen in childhood, adolescence and later in adult life.
- Interventions should be family based, with at least one of the parents involved.
- Changes in diet, physical activity and sedentary behaviours (television watching, computer use and playing video games) should be targeted equally.
- It is important to ensure that normal growth occurs when dietary intake is restricted.

Obesity is the most common childhood nutritional disorder in the world (World Health Organization, 2003; Lobstein *et al.*, 2004) and therefore is an important area for dietitians. Managing childhood obesity is challenging due to the need to engage not only with the child or young person but also with their parents and the entire family.

Dietitians may see overweight and obese children individually in a clinical setting or as a group, e.g. in the community (Stewart *et al.*, 2005; Sacher *et al.*, 2010; Rudolf *et al.*, 2006; Edwards *et al.*, 2006). This chapter explores the knowledge and skills a dietitian new to this area requires to deliver a childhood weight management programme in either situation (Sahota *et al.*, 2010). Dieti-

tians working in childhood obesity need to have an appreciation not only of the complex behavioural issues that need to be explored, but also of the causes and the consequences of childhood obesity.

The prevalence of childhood obesity in the UK dramatically increased over a short number of years during the early 1990s (Reilly & Dorosty, 1999; Chinn & Rona, 2001). Due to the complex manner in which data on child weight are collected, it is difficult to give prevalence figures across the UK in age bands. The National Obesity Observatory (www.noo.org.uk) gives up to date information on prevalence figures for the four UK home countries as well as international comparisons.

Aetiology

Since excess weight gain occurs in a state of positive energy balance, the aetiology of obesity is multifactorial, involving an interaction of the modern obesogenic environment and family lifestyle choices. Increased intakes of energy dense foods (particularly fast foods and snacks), more time spent watching television and playing computer games with a coincidental decrease in the amount of physical activity undertaken by children have all been advocated as the causes of the childhood obesity epidemic (Mulvihill & Quigley, 2003; House of Commons Health Committee, 2004; Prentice & Jebb, 1995).

Non-lifestyle related causes

A child or adolescent who is obese but also short for stature should have been seen or be referred to a paediatric endocrinologist for further investigation to exclude possible underlying rare endocrine causes of their obesity, such as hypothyroidism, growth hormone deficiency, Cushing's syndrome and pseudohypoparathyroidism (SIGN, 2010; Han *et al.*, 2010). Young children, particularly those under 2 years who have had a rapid weight gain, are severely obese and appear to be hyperphagic, may have a rare genetic cause to their obesity and referral to a paediatrician for further investigations would be advisable (Han *et al.*, 2010). There are also a number of syndromes that are associated with obesity, such as Prader–Willi syndrome, Down's syndrome and Fragile X.

Definition

Body mass index (BMI) is generally recognised as the most appropriate measure for diagnosing childhood obesity and overweight (Lobstein *et al.*, 2004; SIGN, 2010). It is calculated as for adults as weight (kg)/height (m)²; however it is only meaningful when it is plotted correctly on age and sex specific centile charts (UK 1990 data). UK BMI centile charts with UK 1990 data are available from Harlow printing (www.healthforallchildren.co.uk) and all dietitians working with obese children should use these charts for diagnosis and monitoring of management (SIGN, 2010; NICE, 2006; Cole *et al.*, 1995; Reilly, 2010; Reilly *et al.*, 2010) (see Chapter 3.8.2). There is a debate about the most appropriate centile cut-off points for defining childhood overweight and obesity. However, in the UK, both the National Institute for Health and Care Excellence (2006) and Scottish Intercollegiate Guidance Network (2010) recommended the use of the 98th centile on the BMI charts to define obesity and the 91st centile to define overweight for clinical use. For epidemiological studies the 95th centile and 85th centiles should be used to define obesity and overweight, respectively (see Chapter 3.8.2).

Consequences

The consequences of childhood obesity have been reported in childhood, adolescence and later in adult life.

Clustering of cardiovascular risk factors, such as high blood pressure, dyslipidaemia, abnormalities in left ventricular mass and/or function, abnormalities in endothelial function, and hyperinsulinaemia and/or insulin resistance, have been reported in children and adolescents. There is evidence that these cardiovascular risk factors are seen in adults who were obese in childhood or adolescence (Han *et al.*, 2010; Reilly, 2005; Reilly *et al.*, 2003). Type 2 diabetes, a disease previously only seen in older adults, is now being reported in adolescents (Han *et al.*, 2010; Drake *et al.*, 2002; Sinha *et al.*, 2002). In girls, psychological problems in relation to low self esteem and behavioural problems, as well as longer term social and economic consequences of achieving a lower income have been reported (Drake *et al.*, 2002; Sinha *et al.*, 2002).

There is good evidence to suggest that obesity in childhood and adolescence does persist, often referred to as tracking into adulthood. The risk of tracking into adulthood can be compounded by parental obesity, the level of obesity and obesity in adolescence (Reilly, 2005; Reilly *et al.*, 2003; Whitaker *et al.*, 2010). Therefore, it is important to treat childhood obesity as early as possible and involving the parents/carers is considered to be important.

Assessment

At the first session with the child, the dietitian needs to obtain baseline measurements of weight and height and to plot these on centile charts. Body mass index should be calculated and then plotted at the correct age on the appropriate centile chart for sex. Although taking the waist measurement can be difficult in obese children, it is a useful tool in monitoring progress in the clinic; however, there are no agreed cut-off points for defining those at health risk (Reilly *et al.*, 2010).

A diet history is useful to elicit information on the family diet and eating pattern; however, it is very important that this does not become a barrier to effective communication. Often the typical day model or a lifestyle diary is utilised as they are seen as more client centred and child friendly information collection methods. The typical day and lifestyle diary are also more effective for ascertaining information on the levels of physical activity that the child normally undertakes, as well as screen time. However dietary information is extracted, the number of takeaway meals the child and family have, the amount and types of snacks the child eats and the amount of pocket money that the child has to spend must be considered. Other details such as age of onset of obesity, eating patterns and family dynamics are most helpful.

Management

Management should encompass the following points:

- It should only be commenced when the parents are ready and willing to make lifestyle changes.

- It should be family based, with at least one of the parents involved.
- Lifestyle changes in diet, physical activity and sedentary behaviours, e.g. screen time – television watching, computer use and playing video games, should be targeted equally.
- Weight maintenance is an acceptable goal of treatment; with height increasing and the BMI decreasing over time (SIGN, 2010; NICE, 2006).

Qualitative studies have identified barriers in the initial access to and subsequent continuation of child weight management programmes, particularly those linked to stigma and difficulty in recognition of the child's overweight status by parents and even in some cases by healthcare professionals (Reid, 2009; Parry *et al.*, 2008; Towns & D'Auria, 2009). It is important for dietitians to be aware of this challenge and of the need to undertake appropriate training of gate keepers in both recognising overweight in children and discussing unhealthy weight in a non-judgemental manner with parents or carers (Stewart, 2008; Chadwick *et al.*, 2008).

Rapport

Childhood weight management clinics have previously reported a high drop out rate (Stewart *et al.*, 2004; Denzer *et al.*, 2004) and dietitians therefore need to carefully consider their manner and approach with the child and family. Successful treatment of obesity demands a sustained commitment and effort from the whole family, and the dietitian must endeavour to maintain a positive attitude and help motivate the child and family towards weight control. The role of the dietitian, whether seeing children and their families individually, in community groups or as part of a multidisciplinary team, is to educate the child and family on the necessary lifestyle changes and to help facilitate behavioural change. It is important that this is done in a positive, enthusiastic, non-judgemental and sensitive manner. Indeed, the development of rapport between the dietitian, child and family has emerged as an important element for families in considering an intervention to be successful (Sahota *et al.*, 2010; Stewart *et al.*, 2008). The whole family should be encouraged to attend sessions and to make necessary lifestyle changes. The dietitian needs to work with the parents/carers to ensure that they are on board with ownership and responsibility in supporting the child and family lifestyle changes. Parents and carers should be encouraged to be positive role models to the child and the family on making the necessary lifestyle changes and to give concrete, timely praise to the child when the child makes positive behaviour changes. It should also be emphasised that the healthy lifestyle messages need to be conveyed to both parents, other family members, teachers and other carers.

Some dietitians may work with individual children and their families or hold group sessions. Where group sessions are used, it is not uncommon to hold some separate sessions for the children and parents. Indeed, most parents appreciate the opportunity to discuss problems

they have encountered with other parents, and with the dietitian without the child present. Those dietitians working with individual children and their families should also consider seeing the parents separately from the child as this can lead to important information being revealed that parents would not wish to discuss in front of the child (Stewart *et al.*, 2005).

Consideration needs to be given to the most appropriate model of seeing and interacting with different age groups. Although not based on evidence, there are suggestions that for preschool and lower primary school age children the intervention should be targeted directly at the parent or carer; for upper primary aged children jointly at the child and parent or carer; and for teenagers directly at the adolescent with the parent in a supporting role.

Behavioural modification

The NICE (2006) and SIGN (2010) guidelines suggested that the use of behavioural change tools in the management of childhood obesity are essential (SIGN, 2010; NICE, 2006). Most of these techniques are employed within lifestyle change programmes to assist the client in raising their awareness of lifestyle, focusing on the aspects of their lifestyles which require change, and developing strategies to implement and monitor those changes.

In a review of the use of behavioural change tools in childhood obesity Sahota *et al.* (2010) concluded that using a package of tools was more effective than any one particular tool. Table 7.13.10 summarises the tools a dietitian would be expected to deploy, along with supporting parents to role model and give concrete praise. Tools for problem solving, goal setting, modelling and self monitoring should all be used to help increase self efficacy and positive reinforcement for change (Newman *et al.*, 2004; Elder *et al.*, 1999). Behavioural change is a process and the dietitian's role is to facilitate change by helping the child and parent or carer make small steps using SMART (specific, measurable, achievable, realistic, timed) goals (Rollnick *et al.*, 1999).

Diet

The main drive of dietary change is to reduce the total energy intake in the child's diet. Calorie counting is not normally used with children and the dietitian needs to ensure that they can convey the necessary information about dietary energy reduction effectively to the child and family. In a review of the dietary interventions, Collins *et al.* (2006) showed that no one type of dietary manipulation was more effective than another in childhood obesity. Children and their families should be encouraged to reduce the total amount of energy consumed by decreasing foods high in sugar and fat and replacing them with foods lower in energy, such as fruit and vegetables. It is also important to ensure that portion sizes of all foods are appropriate for age; the most commonly used models are the UK eatwell plate and traffic light scheme (Collins *et al.*, 2006).

Table 7.13.10 Brief description of behavioural change techniques (source: Stewart *et al.*, 2008, table 2, p. 466. Reproduced with permission of Wiley-Blackwell Publishing)

Goal setting	Goals for necessary changes in diet, physical activity levels and screen time are agreed between child, parent and dietitian. Goals should be SMART – specific/small, measurable, achievable, recorded and timed
Contracting	The signing of a 'contract' between the child, parent and dietitian establishes a commitment to achieving the goals in the allotted time period
Rewards for reaching goals	The parent agrees to give a reward to the child for achieving the agreed lifestyle change goals. This is a positive reinforcement for the setting and attainment of goals. The reward should be small, inexpensive and non-food or screen time. The parent should also be encouraged to use praise
Self monitoring	Recording targeted lifestyles, i.e. diet, physical activity and screen time. This enhances motivation by increasing self awareness of lifestyle behaviours and allows the child and parent to monitor progress towards set goals
Environmental/stimulus control	Encouraging changes in the environment to help to: <ul style="list-style-type: none"> • Reduce the cues that encourage the behaviours requiring change, such as the parent not buying certain foods or the child not walking past a certain shop on the way home from school • Promote new healthier behaviours or routines
Problem solving	Helping the child and family to identify possible 'high risk' situations that may make it difficult to stick to their goals, e.g. holidays, parties and wet weather, as well as identifying barriers to change and developing possible solutions to these barriers. This could be done as a paper exercise or as simulation and role play
Preventing relapse	Near the end of the programme it is important to discuss and offer strategies to help avoid relapse into old behaviours. These include planning ahead for difficult situations and continuing with or returning to goal setting and self monitoring

It is important to ensure that normal growth occurs when dietary intake is restricted. Plotting weight and height on UK growth charts as well as BMI is useful to ensure appropriate growth monitoring, as well as regular nutritional assessment and comparison with appropriate age and sex nutrient requirements. Adequate, but not excessive, quantities of protein, vitamins and minerals for age need to be consumed. Very occasionally a child who dislikes certain foods and does not consume a nutritionally adequate diet may need a supplement of vitamins or minerals (particularly iron and calcium). Written information, including a list of unrestricted foods and foods to be controlled, should be given to the parents and child. Many parents find food labelling confusing and appreciate advice and help with understanding what to look for in and how to read labels on packets.

The problem of foods eaten outside of the home and beyond the parents' influence, and where necessary solutions, should be explored. Suggesting that money previously spent on sweets, chocolate, etc. be used for other items of the child's choice, e.g. games, books and clothing, is sometimes useful, particularly for indulgent grandparents.

Physical activity

Children should be encouraged to increase their overall activity levels to 60 minutes of moderate to vigorous activity each day (SIGN, 2010). Many overweight and obese children dislike team sports and physical education at school and it is therefore important to help the child and family find local activities that they may enjoy and are not embarrassed to take part in. Research has shown that increasing lifestyle activities, such as walking and taking the stairs rather than lift, can be particularly effective in controlling weight on a long term basis (Epstein *et al.*,

1985). Working together with local community groups and leisure partners can be helpful in supporting children and their families to increase their levels of activity and make it enjoyable.

Screen time

Current recommendations are that the amount of time children spend watching television, playing video games and using computers should be no more than 2 hours/day or an average of 14 hours over a week (SIGN, 2010; Epstein *et al.*, 2000; Gortmaker *et al.*, 1996). Some children and parents do find this change particularly difficult and the dietitian needs to help with setting SMART goals to reduce screen time over time.

Outcomes

Weight maintenance in combination with increasing height growth is an acceptable goal of treatment, as this will lead to BMI decreasing over time. For older adolescents, particular those in the very severe BMI range, weight loss may be required and a weight loss of 0.5–1.0 kg/month could be advised (SIGN, 2010). There is emerging evidence to suggest a range of a decrease in BMI standard deviation (SD) scores of between –0.25 (Ford *et al.*, 2010) and –0.5 (Reinehr & Andler, 2004) may lead to an improvement in insulin resistance, dyslipidaemia and cardiovascular risk factors.

Radical therapies

In general, slimming foods, drinks as a replacement for a meal and extreme restrictive diets that exclude food groups are not considered appropriate for this age group.

Both the NICE (2006) and SIGN (2010) guidelines recommended that antiobesity drug therapy could be considered for prescription to obese adolescents who are attending a specialist weight management clinic. In addition, SIGN (2006) recommended that antiobesity drugs should only be prescribed for adolescents with severe obesity (BMI >99.6th percentile) and with comorbidities. Currently, orlistat is the only antiobesity drug available for use in the UK. It is recommended that adolescent patients are regularly reviewed throughout the period of use, with careful monitoring for side effects (NICE, 2006).

Although bariatric surgery in children and adolescents is uncommon in the UK, both guidelines suggest that it could be considered for weight loss in post pubertal adolescents with very severe obesity and comorbidities; importantly, surgery should only be undertaken in a centre of excellence in adult bariatric surgery (SIGN, 2010; NICE, 2006). Since long term side effects of bariatric surgery in adolescents are unknown, it is highly desirable that follow-up should be for life.

Prevention

The increasing prevalence of childhood obesity demonstrates the clear need for a range of management options. It has been recognised that prevention strategies that target all children, including those who fall into the healthy weight range, must also be considered. There are strong arguments towards prevention as a useful approach, particularly on a cost basis, as it is considered to be cheaper to prevent rather than treat obesity (Barlow & Expert Committee, 2007). There is evidence to suggest that children involved in prevention interventions can change their behaviour, although the effectiveness of such interventions is still poorly understood (Summerbell *et al.*, 2009). Dietitians, particularly those working in the area of public health nutrition, have a key role to play in prevention strategies, including the planning, development, delivery and evaluation of interventions that take place in a range of settings and at all ages, from birth through to adolescence. Prevention programmes that take place in schools and also target parents would appear to be an effective route (Gortmaker *et al.*, 1999).

Government policies, such as England's Healthy Weight, Healthy Lives (Department of Health, 2008) or Scotland's Preventing Overweight and Obesity – A Route Map Towards Healthy Weight (The Scottish Government, 2010) drive most health promotion activity related to childhood obesity prevention. Initiatives tend to be educational or health promoting in nature and encourage healthy weight through promotion of healthier food choices and/or increased physical activity. Several countries now have examples of such programmes, including national guidance on the nutritional content of school meals, school walking buses and family based community physical activity programmes.

Social marketing is an emerging approach to obesity prevention. Government, business, health, education and others come together in a society wide movement with the aim to empower whole communities, families and indi-

viduals to make positive behavioural changes linked to a healthy lifestyle. French *et al.* (2010) describe social marketing as the systematic application of marketing, alongside other concepts and techniques to achieve specific behavioural goals for a social good. Current examples of UK social marketing campaigns relevant to childhood obesity include Change4Life in England & Wales, Take Life On One Step At a Time in Scotland and Get A Life-Get Active in Northern Ireland (see Chapter 4.2).

7.14

Cardiovascular disease

7.14.1 General aspects

Catherine Hames

Key points

- Cardiovascular disease (CVD) encompasses coronary heart disease (CHD), stroke and peripheral vascular disease.
- Cardiovascular risk assessment should be used to assess overall risk and to stratify for treatment need.
- Those with existing CVD should be treated preferentially to those who are healthy but have a raised CVD risk.
- A cardioprotective diet is the first line of dietary support for those with, or at risk of, CVD. Risk factors may require additional treatment if dietary support and other lifestyle changes are insufficient to reduce them to acceptable levels.
- The cardioprotective diet includes moderate intakes of fish, including oily fish, reducing saturated fat and replacing it with monounsaturated or polyunsaturated fats, plenty of fruit and vegetables, legumes and nuts, a regular meal pattern, moderate alcohol intake if desired, limited intake of salt and processed foods, and modest intake of lean meat and meat products.

The aetiology of cardiovascular disease (CVD) is multifactorial and strongly associated with risk factors such as hypertension, dyslipidaemia, smoking, lack of physical activity and diabetes mellitus. Cardiovascular disease and its risk factors have similarities in their aetiology and dietary management.

Prevalence and costs

Cardiovascular disease is the most common cause of death in the UK and the major cause of premature death [British Heart Foundation (BHF), 2010]. In 2009, 180 000 people in the UK died of CVD, which was one in three of all deaths. It accounted for more than 45 000 premature deaths, with more than one in four deaths in men and one in five deaths in women before the age of 75 years. Death rates from CVD are highest in Scotland and the North of England, and lowest in the South of England. It is thought that this may be partly attributable to the socio-economic differences in the populations within these areas. South Asian people living in the UK, who includes immigrants from India, Pakistan, Bangladesh and Sri Lanka have a 50% greater risk of premature death from CHD and stroke (BHF, 2010). Data from England and Wales show African-Caribbean people have a lower than average risk of CHD, but a three-fold higher risk of stroke.

Death rates in the UK continue to remain relatively high in comparison with some other Western European Countries, despite death rates from CVD falling in the UK at one of the fastest rates in Europe (BHF, 2010).

The National Service Framework launched in 2000 had aimed to reduce CVD by 40% by 2010; this target was met 5 years early (Department of Health, 2000). This is in line with the overall reduction in risk since the 1970s after the introduction of statin drugs (reducing blood cholesterol levels), improved screening, prevention and post cardiac event treatments, and an increase in smoking cessation (BHF, 2010).

Coronary heart disease (CHD) is the major cause of mortality in patients presenting with stroke, diabetes and renal disease. Patients receiving renal replacement therapy are 16–19 times more likely to develop CHD than matched controls, with the rate for people with diabetic nephropathy being even greater (Wheeler, 1997; Holt & Goldsmith, 2010). Men with diabetes have over three times the risk of cardiovascular mortality than men without diabetes (Khaw *et al.*, 2001). Those with diabetes and renal disease should be regarded as being at increased risk of CVD, regardless of other risk factors, e.g. dyslipidaemia, hypertension or obesity.

As well as the human cost, CVD has an economic cost for the UK. In 2006 CVD cost the UK health system £14.4

billion. Of this cost, 73% was attributed to hospital care and 20% to medication.

Aetiology

Cardiovascular diseases are interrelated; their causation is due to atherosclerosis, developing slowly over many years and/or thrombosis (blood clots) developing suddenly and causing an acute episode, such as a myocardial infarct or stroke. The incidence of CVD is related to modifiable risk factors, such as dyslipidaemia and hypertension, which in turn can be linked to lifestyle factors, e.g. high saturated fat intake, smoking and lack of physical activity. Therefore, improving lifestyle factors can lead to a reduction in cardiovascular events (De Backer *et al.*, 2003; Wood *et al.*, 2008). The aetiology of atherosclerosis and thrombosis are discussed further in Chapter 7.14.2.

Absolute risk assessment

The risk of CVD is calculated by assessing the combined risk of a number of modifiable and non-modifiable risk factors. In the past, someone's CVD risk was dependent on assessment and treatment of one or two individual risk factors (such as cholesterol level or blood pressure), largely as a result of the NHS being organised into specialist areas. It is now appreciated that a more holistic view of risk factor assessment is essential. As a result, cardiovascular risk assessment is becoming more sophisticated, using lifestyle and risk data to give an overall measure of the risk of a cardiovascular event or death over a set time period. There are a number of risk equations that input information on sex, age, systolic blood pressure, total cholesterol [or total cholesterol to high density lipoprotein (HDL) ratio], diabetes and smoking behaviour to predict 10-year risk of fatal cardiovascular events.

Until 2010 the risk estimation score in the UK was calculated using the American Framingham equations (NICE, 2010). The Framingham equation was developed based on a historic American cohort dating from the 1940s (Anderson *et al.*, 1991). As a result, Framingham equations can overestimate risk by up to 50% in contemporary North European populations. This overestimation is more often seen in people living in more affluent areas. In contrast, it may underestimate risk in higher risk populations, such as those that are more socially deprived. A further disadvantage is that the equation does not take into account family history, with respect to premature death from CHD, ethnicity or social deprivation (NICE, 2010).

In addition to the Framingham risk equations, the National Institute for Health and Care Excellence (NICE, 2010) and Scottish Intercollegiate Guidelines Network (SIGN, 2007) have recommended the use of the following risk assessment tools scores, which have the advantage of including other variables such as social deprivation and family history:

- ASSIGN (developed using a Scottish cohort) (Woodward *et al.*, 2007).

- QRISK (using data from UK general practice databases) (Hippisley-Cox *et al.*, 2007).

In addition, the SCORE risk equation and relative risk chart (Conroy *et al.*, 2003) are recommended by the European Society of Cardiology (Perk *et al.* 2012). These are thought to give a more accurate estimate of risk due to the large European dataset used. Lastly, the Joint British Societies 2 (JBS2, 2005) guidelines recommend an adjusted Framingham equation. This guidance is currently under review; the new guidelines (JBS3) will use lifetime risk based on adjustments of the current published risk equation and be available at www.jbs3risk.com.

Due to the numbers of risk scores available and variability in the scores used in different regions of the UK, there is a need to establish which score is most applicable to the UK. Current guidance suggests that those with a 10-year risk of CVD of >20% should be considered as high risk (NICE, 2010; JBS2, 2005; ESC, 2007). However, it should be remembered that these equations can only provide an estimate of risk and clinical judgement should always be applied to improve the accuracy of the assessment.

It should be noted that the equations calculate absolute risk (also known as total or global risk), which is defined as the percentage chance of an individual developing a CVD event over a given period of time, e.g. a 10-year risk of 20%. NB: Risk equations should not be used for people with pre-existing CVD.

Prevention

It has been estimated that more than half of deaths and disability from heart disease and stroke could be prevented by modifications to lifestyle, such as diet, activity and smoking (Iqbal *et al.*, 2008). All current guidelines agree that when treating people with elevated risk of CVD the lifestyle factor priorities are (in no particular order of priority):

- Smoking cessation.
- Increased physical activity.
- Management of blood pressure.
- Management of lipids.
- Management of diabetes.
- Healthy food choices.
- Weight management and limiting central obesity.

It is important that dietitians treat the whole person, rather than simply providing dietary themselves or referring the individual for advice on other lifestyle factors. Further details can be found for coronary heart disease in Chapter 7.14.2, for dyslipidaemia in Chapter 7.14.3), for hypertension in Chapter 7.14.4), for stroke in Chapter 7.14.5), for diabetes in Chapter 7.12), for management of obesity and overweight in adults in Chapter 7.13.2) and for renal disease in Chapter 7.5.

Despite a reduction in mortality rates from CVD in the UK, the European wide Eurospire III survey showed that the majority of patients with CHD surveyed were still not achieving the recommended lifestyle, blood pressure

and lipid targets, despite an increase in medications and screening (Kotseva *et al.*, 2009). In England, health checks have been introduced to identify individuals at risk of developing heart disease, stroke, kidney disease or diabetes, with the focus on preventing these diseases (NHS, 2009). Each screening includes the measurement of cholesterol (total cholesterol and HDL cholesterol), blood pressure and body mass index (BMI), and these are then used to calculate CVD risk. Health checks (www.healthcheck.nhs.uk) are offered to those aged 40–74 years who have not been diagnosed with hypertension, atrial fibrillation, transient ischaemic attacks, hypercholesterolaemia, heart failure or peripheral arterial disease. Eligible people are invited to attend every 5 years. It is estimated that this scheme could prevent 1600 strokes and heart attacks, prevent 4000 people from developing diabetes and detect 20000 people with diabetes or chronic kidney disease each year (Department of Health, 2008).

Further to this, NICE (2010) has produced guidance on the prevention of CVD that outlines recommendations to improve risk factors at a population level. These guidelines target food and drink providers, marketing, media, the family support sector, national non-governmental organisations, e.g. charities, and farming associations.

The cardioprotective diet

The cardioprotective diet is the first line of dietary advice in protection against the main CVDs. It can be used in primary or secondary prevention and in conjunction with specific dietary advice given on individually relevant risk factors (diabetes, renal disease, dyslipidaemia, hypertension, overweight). This diet should be encouraged in those with an increased risk of CVD, not only in those with established risk factors such as dyslipidaemia or obesity.

Effectiveness

The cardioprotective diet stems from the Mediterranean diet. The value of eating a Mediterranean style diet came into focus in the late 1950s when men living in Crete, parts of Greece and southern Italy were shown to have the least likelihood of developing CHD (Willett *et al.*, 1995). The premature death rate from heart attack for Greek men was 90% lower than that of American men, with Greek men enjoying the longest life expectancy in the world. However, this is no longer true today, as the traditional Greek diet has become increasingly westernised. Therefore, the focus has been on the benefits of the traditional Mediterranean diet prior to the 1960s. Several elements of this diet have been proposed as being especially protective, and there is now some experimental evidence from randomised controlled trials to support its protective role in high risk populations. The cardioprotective diet is very similar to the proposed cancer protec-

tive diet and so may confer other health benefits over those seen in CVD (WCRF, 2007).

Influence on cardiovascular disease

The cardioprotective diet exerts its effects on CVD by altering a wide range of risk factors in a positive way. These may include effects on:

- Blood pressure, lipid oxidation and inflammation (reducing injury to coronary arteries).
- Lipid profile, homocysteine levels and insulin resistance (reducing fibrous plaque formation).
- Platelet aggregation, clotting factors and arrhythmias (reducing the occurrence of thrombosis leading to heart attack and stroke).

The effects of the diet on the cardiovascular system and its benefits alongside statins are summarised in Chapter 7.14.2. Chapter 7.14.3 discusses the effects of diet on blood lipids.

A selection of the guidelines that have been developed in CVD management over the last 5 years is:

- Lipid modification: Cardiovascular risk assessment and the modification of blood lipids for the primary and secondary prevention of cardiovascular disease. NICE CG 67 (2008, revised March 2010).
- Risk Estimation and the prevention of Cardiovascular Disease – A National Clinical Guideline. SIGN 97 (2007).
- Secondary prevention in primary and secondary care for patients following a myocardial infarction. ESC guideline (2007).
- Dietetic guidelines on food and nutrition in the secondary prevention of cardiovascular disease (Mead *et al.*, 2006).
- Diet and Lifestyle Recommendations – A Scientific Statement From the American Heart Association Nutrition Committee (American Heart Association Nutrition Committee, 2006).
- JBS2: Joint British Societies' guidelines on practice prevention of cardiovascular disease in clinical practice. Prepared by the British Cardiac Society, British Hypertension Society, Diabetes UK, HEART UK, Primary Care Cardiovascular Society and The Stroke Association (2005).

From these guidelines and additional information the main elements of the cardioprotective diet have been summarised as discussed below.

Fats

Saturated fat

It is recommended that saturated fatty acids should contribute <10% of total dietary energy. A recent systematic review by Hooper *et al.* (2012) concluded that replacing saturated fat with unsaturated fat might reduce the risk of vascular disease and CHD. However, they concluded that it was unclear if monounsaturated (MUFAs) or polyunsaturated fats (PUFAs) have any further benefit. The

Table 7.14.1 Main sources of saturated, unsaturated and *trans* saturated fats in the diet

Saturated fat	<i>Trans</i> saturated fats	Polyunsaturated fat	Monounsaturated fat
Butter, lard, ghee, dripping Fatty meats – beef, lamb, corned beef, sausages, beef burgers, streaky bacon Dairy products – full fat milk, cream, full fat yoghurt, cheese Pies, cakes, biscuits, chocolate and pastry products Coconut	Baked products Cakes, biscuits, pastries Convenience foods, e.g. takeaways, ready meals	Oils – sunflower, soya, linseed, sesame seed, fish Margarines Soyabeans	Olive oil, rapeseed oil, peanut oil (ground nut) Almonds, walnuts, peanuts, avocados

cardioprotective diet was shown to be more effective if followed for 2 years or more. Replacing saturated fat with carbohydrate (starchy) foods did not confer any clear health effects. In addition, they concluded that it was not clear if healthy people benefitted as much as those at risk of CHD or who had CHD.

Practical tips for reducing saturated fat and replacing them with unsaturated fats include:

- Remove fat from meats and avoid processed meats.
- Remove skin from poultry.
- Avoid deep fried snacks and dishes.
- Replace butter, ghee and lard with a vegetable oil such as olive or rapeseed oil; replace full fat dairy products with low fat alternatives or soya products.
- Replace high fat snacks such as crisps, chocolates and biscuits with fruit and nuts.
- Read food labels – aim for <1.5 g of saturates/100g.

Trans saturated fats

It is recommended that *trans* saturated fats should contribute <2% of total dietary energy. *Trans* fatty acids are produced in the hydrogenation of vegetable oils that are used in the production of margarine and shortening. *Trans* fats can also be formed by subjecting PUFAs to high temperatures (220°C). It has now been demonstrated that *trans* fatty acids raise low density lipoprotein (LDL) cholesterol whilst lowering HDL (Ascherio & Willett, 1997). If possible, saturated and *trans* saturated fats should be replaced with unsaturated fatty acids (MUFAs and PUFAs). Table 7.14.1 lists some of the main sources of saturated, unsaturated and *trans* saturated fats in the diet.

Omega-3 fatty acids

n-3 Fatty acids are the long chain PUFAs, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). They do not have a cholesterol lowering effect; however, they are thought to be protective by improving endothelial function and have anti-inflammatory and antithrombotic effects. In primary prevention, the advice for the general population is to consume one portion of white fish, e.g. haddock and cod, and one portion of oily fish/week, where a portion equals 140g. In secondary prevention,

Table 7.14.2 Fish sources of n-3 fatty acids. High sources per average serving are above the dashed line

Mackerel – frozen or fresh	
Kippers – fresh, frozen or canned	
Pilchards – fresh or frozen	
Tuna or trout – fresh or frozen	
Sprats – fresh or frozen	
Mackerel – smoked or canned	
Sardines – fresh or frozen	
Herring – pickled, fresh or frozen	
Sild or skippers – canned	
Salmon – canned in brine or smoked	
Crab – fresh	
Herring – canned	
Trout – smoked	
Swordfish (only eat once a week)	
Salmon fish cakes	
Salmon fish paté	
Tuna – canned in oil	
Crab – canned brine	
Eel – fresh or jellied	
Fish paté – crab, salmon, sardines	
Cod or haddock – fresh or frozen	
Fish cakes or fish fingers (white)	
Tuna – canned in brine or water	

individuals should aim for –two to four portions (total 300g) of oily fish/week. If patients are unable to manage to consume oily fish, a fish body oil supplement may be recommended (NICE, 2007).

A systematic review, Hooper *et al.* (2006) concluded that it was not clear whether dietary or supplemental n-3 fats alter total deaths or cardiovascular events in people at risk or with CVD. Therefore, further research is required in this area. However, the evidence did not suggest that people at high risk should stop including n-3 in their diets; this is an area of growing research to ascertain the exact benefits. Table 7.14.2 shows the highest and lowest fish sources of n-3.

Vegetarian sources of the essential precursor fatty acid alpha-linolenic acid (ALA) include nuts, seeds, dark green vegetables, rapeseed oil, wholegrain cereals and soya products; however, conversion from the ALA to the active EPA and DHA by humans appears poor, especially in men (2–10%).

Table 7.14.3 Suggested population intakes of oily fish (SACN/COT, 2004)

Population group	Suggested lower limit	Suggested higher limit
Women of reproductive age and girls	One portion of oily fish/week	Two portions of oily fish/week
Pregnant and lactating women	One portion of oily fish/week (but avoid marlin, swordfish, shark and tuna)	Two portions of oily fish/week (but avoid marlin, swordfish, shark and tuna)
Women past reproductive age, boys and men	One portion of oily fish/week	Four portions of oily fish/week

Safety of oily fish and fish oils

Concern has been expressed over the relatively high levels of dioxins and polychlorinated biphenyls (PCBs) present in fish and fish oils (MAFF, 1999). The Scientific Advisory Committee on Nutrition (SACN) and the Committee on Toxicity (COT) issued a joint report in 2004 addressing these issues and suggesting healthy and maximal fish intakes for various population groups (SACN/COT, 2004). Their recommendations for the population are reproduced in Table 7.14.3. Dietitians should also note that levels of dioxins and PCBs are higher in fish liver oil supplements (cod or halibut liver oils) than in fish body oils (MAFF, 1999). Therefore, if fish oil supplementation is indicated, fish body oil rather than fish liver oil (which also contains less n-3 fat) should be recommended.

Salt

It is recommended that the adult population should decrease their salt intake to 6 g/day (2.4 g of sodium/day); this is the equivalent of one level teaspoon (SACN, 2003). The current intake in the UK is estimated to be 8.1 g/day (Sadler *et al.*, 2012); public health initiatives are currently aiming to reduce salt consumption to 3 g/day by 2025 (NICE, 2010). However, a recent systematic review (Taylor *et al.*, 2011) concluded that the benefit of reducing salt intake on clinically significant CVD events was not entirely proven in normotensive and hypertensive people, and that further randomised controlled trials were needed, especially on possible harmful effects of salt restriction in heart failure. They estimated that the benefits of salt restriction were '*consistent with the predicted small effects on clinical events attributable to the small blood pressure reduction achieved*'.

Examples of some common sources of salt in the diet include:

- Ready meals.
- Tinned and packet soups.
- Breads and breakfast cereals.
- Dehydrated meals.
- Processed meats such as bacon and sausages.

- Cooking and pasta sauces.
- Cheese.
- Stock cubes.
- Savoury snacks.

Practical advice to lower salt intake includes:

- Discourage adding salt when cooking or at the table.
- Discourage consumption of food with high salt content.
- Encourage the use of alternatives such as herbs and spices.
- Look for food containing <0.3 g of salt/100 g.

Stanols and sterols

Stanols and sterols are known to lower LDL cholesterol by interfering with biliary and dietary cholesterol absorption from the gut. Sterols and stanols are naturally occurring in the diet; however, a dose of 1.5–2.4 g of stanol/sterol esters/day (20–30 g of margarine or one yoghurt drink) is seen as an optimal intake. They have been shown to lower cholesterol by at least 10% (Thompson & Grundy, 2005). They have been granted a health claims title by the European Food Safety Authority (2010) with no known long term adverse effects (see Chapter 4.5 and Chapter 5.2). To obtain beneficial effects, supplemented foods should be used for at least 2–3 weeks. Currently, stanols and sterols are not recommended by NICE (2010) for primary prevention due to a lack of studies with clinical end points.

Fruit and vegetables

The recommendation is a minimum of 400 g (five portions)/day, with one portion being equal to 80 g of fresh fruit or vegetables (around 3 tablespoons), 30 g of dried fruit or 150 mL of unsweetened fruit or vegetable juice (this should only be taken once per day) (www.nhs.uk/LiveWell/5ADAY). All fruit and vegetables should be encouraged whether tinned, fresh, frozen or juiced. Fruit and vegetables contribute to soluble fibre and antioxidants, giving them a protective effect. They are also rich in folic acid. Fruit and vegetables have a relatively low energy and therefore aid weight management.

Nuts

Nuts are recommended as part of a cardioprotective diet, with almonds, walnuts and pecans seen to be most beneficial.

Soluble fibre

The high viscosity of soluble fibre reduces cholesterol levels by interfering with cholesterol absorption in the gut. Soluble fibre can be found in oats and other wholegrains, beans, pulses, fruit and vegetables, with a recommended intake of 15–20 g/day (Brown *et al.*, 1999). Wholegrain foods, which can include wholemeal breads, wholegrain breakfast cereals, wholegrain pasta and brown rice, should be encouraged to prevent constipation and help with weight control. Epidemiological evidence has suggested that high intakes of wholegrains have a protective effect on CHD risk, reducing the risk of both CVD

Table 7.14.4 Comparison of traditional high fat, low fat and cardioprotective diets

	High fat diet	Low fat/calorie diet	Cardioprotective diet
Meal plan	Refined cereal (such as cornflakes) with whole milk Coffee with full cream milk Two slices of white bread with butter, processed ham and mayonnaise, full fat yoghurt and a packet of crisps Two chocolate coated biscuits Fried fish and chips with a sprinkling of salt Fruit pie and ice cream	Refined cereal (cornflakes) Skimmed milk Black coffee Two slices of white bread, low fat spread, processed ham and low fat mayonnaise. Packet of 'lite' crisps and a low fat yoghurt Three salted rice cakes Breaded cod and oven chips, peas, with a sprinkle of salt Low fat ice cream	Porridge oats made with skimmed milk/soya milk and a chopped banana Glass of fruit juice Coffee Two slices of wholemeal bread with olive based spread, turkey and salad, apple and a low fat yoghurt Handful of almonds Salmon fillet with new potatoes (flavoured with mint), carrots and peas Stewed fruit and low fat yoghurt
Energy (kcal)	2310	1434	1470
Total fat (g)	135.0	46.1	45.5
Saturated fat (g)	48.0	10.9	7.4

and diabetes by up to 30%. However, this evidence has come mostly from observational studies. Large intervention trials with sufficient power would be required to determine a causal link (Peacock *et al.*, 2010).

Carbohydrates

The current recommendation is that carbohydrate should form 50–55% of total dietary energy (Department of Health, 1991); refined carbohydrates should be avoided. There is limited evidence that low glycaemia index (GI) food reduces CVD (Mead *et al.*, 2006). However, low GI diets may be beneficial in those with diabetes or metabolic syndrome and those with high triglycerides (see Chapter 7.12).

Soya protein

The recommendation is that 15–25 g (one to three servings)/day should be taken in exchange for other protein sources such as meats and dairy. Examples of products include soya milk, yoghurts, desserts, spreads, tofu, etc. Soya protein has been shown to lower LDL cholesterol by interfering with liver LDL cholesterol synthesis, and slightly to raise HDL cholesterol (Jenkins *et al.*, 2006; Harland & Haffner, 2008).

Dietary cholesterol

The recommendation is that no more than 300 mg/day should be consumed. It is known that dietary cholesterol can increase blood cholesterol levels; however within the UK, it is thought that dietary cholesterol is unlikely to have any significant impact on blood cholesterol levels (Leeds & Gray, 2001). Shell fish, eggs and offal are rich in cholesterol but are not high in saturated fat and so can be used as healthy alternatives to fatty meats in the diet. However, limiting dietary cholesterol may be required for those patients with inherited high cholesterol (familial hypercholesterolaemia (see Chapter 7.14.3)).

Folic acid

Elevated levels of homocysteine have been linked with CVD (Bazzano *et al.*, 2006) with high levels thought to

be a predictor for CVD. Folic acid and B vitamins (especially B₁₂ and B₆) intakes have been shown to lower homocysteine levels, but supplemented vitamins did not appear to affect cardiovascular events. It is recommended that dietary folate intake should exceed 400 µg/day to prevent elevated homocysteine levels. Promotion of food high in vitamins B₁₂, B₆, folate and riboflavin should be encouraged in a healthy diet.

There is no benefit from vitamin E or garlic supplementation in reducing CVD incidence.

Practical aspects

Practical dietary details are given in Table 7.14.4. The low fat diet will allow weight loss (similar to the cardioprotective diet) but will not provide the protective effects. The low fat diet contains no fruit and vegetables, is lacking in fibre, n-3 fatty acids and is higher in salt.

Cardioprotective dietary advice should always be set in the context of healthy eating guidance, such as the eatwell plate (see Chapter 4.2), to ensure the overall diet is balanced. Over focus on one nutrient (such as saturated fat reduction) can risk compromising the intake of others (such as iron and calcium) if dietary advice is not comprehensive. Other dietary therapeutic objectives, e.g. maintenance of careful glycaemic control in the management of diabetes, may also be relevant.

For frail or elderly people, who are at risk of being nutritionally compromised, especially if appetite and food intake are poor, oily fish, fruit and vegetables can be encouraged, but dietary fat content and composition only altered if this can be achieved with no loss of enjoyment or reduction in dietary energy density (see Chapter 3.3).

Specific considerations

Alcohol

The role of alcohol in the cardioprotective diet remains unclear because of the lack of intervention studies to establish its benefits, but there is clear evidence of the

hazards of excessive intakes. Epidemiological evidence suggests that for those at medium or high cardiovascular risk, a modest amount of alcohol is protective (Rimm *et al.*, 1996; Burger *et al.*, 2004; NICE, 2007). The benefits for those at low risk, e.g. young women, are more doubtful. For those at increased cardiovascular risk, a regular intake of 1–2 units/day of any alcohol probably confers maximal protection without adverse effects on triglycerides or blood pressure.

Gout

Some people at high cardiovascular risk will also have gout and may need to avoid high intakes of purines (see Chapter 7.9.3). As oily fish is rich in purines, increasing consumption is contraindicated. In these circumstances, fish oil capsules, which do not contain purines, should be advocated.

Lifestyle

The cardioprotective diet should always be discussed in the context of a healthy lifestyle and reference should be made to activity and exercise levels, smoking cessation and continued use of prescribed medication. More information on these aspects of lifestyle can be obtained from local cardiac rehabilitation programmes or the British Heart Foundation and British Association of Prevention and Cardiac Rehabilitation (BAPCR).

Dietetic participation in cardiac rehabilitation helps to ensure consistency in the delivery of health messages. It also allows dietitians to reinforce the lifestyle messages given by the team and ensures the team remains well informed on dietary issues. The recommendations for physical activity are:

- **Primary prevention** – all patients should be encouraged to increase physical activity to 30 minutes/day at moderate intensity for most days of the week.
- **Secondary prevention** – regular exercise building up to 20–30 minutes/day to the point of slight breathlessness; it is important to encourage cardiac rehabilitation.

Weight and waist circumference

Patients should aim for a healthy weight (BMI 18.5–25 kg/m²) and waist circumference (<102 cm in European men, <90 cm in Asian men, <88 cm in European women and <80 cm in Asian women) (see Appendix A7).

Acceptability

Patients are often apprehensive about the perceived restrictions of a cardioprotective diet and may be visibly relieved when the positive changes are described and encouraged. The approach to the patient should be determined by the stages of change model (see Chapter 1.3). Those who have never contemplated change will need a different approach from those who have already started to make changes, or have previously made changes but slipped back.

Whilst many people enjoy the cardioprotective diet there are also some who find particular elements of it very difficult. Many people struggle to increase their fruit, veg-

etables and oily fish intakes, whilst reducing and/or modifying their fat intake. Practical advice should be offered to promote dietary change, and giving examples of advocated foods will likely improve adherence, e.g. providing examples of oily fish recipes. Dietary advice should always be tailored to an individual's likes and dislikes.

The cardioprotective diet, like exercise and non-smoking, is protective as long as it is continued. To have eaten well or been fit last year is not helpful now. To help people maintain their healthier habits, regular review is advisable. This may involve dietetic review in a central location or the community, including delegation to other community staff (who must be trained, updated and provided with appropriate support materials).

Motivation can also be boosted by involving the whole family (Wood *et al.*, 2008). Where this occurs, the sense of isolation is reduced and the whole family group (who may also be at increased genetic or lifestyle risk of CHD) reap the benefits of risk reduction (Cousins *et al.*, 1992).

Monitoring and outcomes

Appropriate factors to monitor are shown in Table 7.14.5. It is important to remember that the benefits from dietary

Table 7.14.5 Possible factors to consider for monitoring and evaluation purposes in cardiovascular disease

Domain	Factors
Diet	Portions of oily fish/week Portions of fruit and vegetables/day Appropriate fat spread Appropriate milk Appropriate fats in cooking Units of alcohol taken/day or week Level of fat intake Level of salt intake
Emotional	Acceptability of diet Barriers to change Stages of change
Lifestyle	Smoking Exercise levels Lipid reduction medication Hypertension medication
Risk levels	Waist circumference Body mass index Weight change Total cholesterol Triglycerides HDL cholesterol LDL cholesterol Cholesterol to HDL ratio Blood pressure (systolic, diastolic) Factors relevant to diabetic or renal control
Outcomes	Myocardial infarction Angina frequency Stroke Coronary artery bypass graft Angioplasty Hospital admissions Death

HDL, high density lipoprotein; LDL, low density lipoprotein.

change depend on the extent to which other lifestyle changes have been achieved. These two aspects therefore need to be considered in conjunction in order to assess the effectiveness of risk reduction measures.

Updating the evidence

The UK Heart Health and Thoracic Dietitians Specialist Group regularly update their guidelines on the secondary prevention of CVD by including all relevant systematic reviews of the effect of diet on CVD and risk factors in people with CVD; the most recent is Mead *et al.* (2006).

Julie Hinchliffe and Jane Green

Key points

- Dietitians have a multifaceted role in primary and secondary coronary heart disease prevention.
- They should be able to advise on public health policy and strategy with key stakeholders, including multiagency work to enhance the local food economy.
- Food projects using principles of community development, and developing and evaluating local programmes to facilitate healthier eating must be supported.
- Training other healthcare professionals to deliver consistent key cardioprotective messages is an essential role for dietitians.
- Dietitians are involved in cardiac rehabilitation programmes for groups and individuals at risk of, or with existing, heart disease.
- Surgical patients and people with heart failure or cardiac cachexia may require nutritional support.

Coronary heart disease (CHD) is the most common manifestation of cardiovascular disease (CVD). A broad overview of CVD and the cardioprotective diet is given in Chapter 7.14.1. This chapter focuses on the aetiology and management of CHD, and the role of the dietitian in its prevention. Chronic heart failure (CHF) is also discussed, as CHD is the most common cause of this clinical syndrome.

Coronary heart disease can present clinically in a number of different ways, which may include:

- Stable angina – chest pain that is controlled, except on exertion.
- Acute coronary syndrome – myocardial infarction (heart attack) and unstable angina.
- Sudden death, with or without a history of angina, or infarction due to inherited cardiomyopathies or arrhythmias.
- Heart failure as a consequence of CHD of which cachexia is a sign of the end stage of the disease.

Acute coronary syndrome (ACS) is the umbrella term that encompasses:

- *ST elevated myocardial infarction (STEMI)* – the lumen of the artery is blocked by the volume of thrombus, resulting in acute ST elevation (an abnormality of the electrocardiogram), i.e. a traditional heart attack where oxygen supply is cut off, causing death to an area of the heart muscle (Table 7.14.6).
- *Non-ST elevated myocardial infarction (NSTEMI)* – the lumen of the artery is narrowed by the volume of the thrombus or blocks the artery only temporarily, resulting in a shortage of blood supply to the heart muscle that is less severe than in STEMI or intermittent. There is often some damage to the heart muscle, as evidenced by a rise in the cardiac specific serum biomarkers such as troponin.
- *Unstable angina* – new onset chest pain or discomfort, or abrupt deterioration in previously stable angina,

with chest pain or discomfort occurring frequently and with little or no exertion, and often with prolonged episodes. This often presents in a comparable way to acute myocardial infarction (MI), but without biomarker evidence of myocardial necrosis (NICE, 2010a).

Table 7.14.6 Investigative procedures for coronary heart disease

Investigation	Description
Electrocardiogram (ECG)	Monitors the progressive electrical stimulation of the heart muscle. An ECG provides a graph of the heartbeat. Portions of the graph are labelled PQRST (e.g. ST elevation describes a rise in a particular portion of this graph which indicates ischaemia)
Exercise stress testing	ECG recorded whilst the patient is exercising and having symptoms. It can assess whether pain on exertion is due to heart disease
24-hour ECG recording or Holter monitoring	Monitoring during everyday activity including that which produces symptoms
Echocardiography	Ultrasound is used to provide a picture of the heart. It can also be used to measure the speed of blood flow
Electrophysiology studies	Used to study arrhythmia
Angiogram	Radio-opaque fluid is infused into the heart and major vessels. It reveals the outline of the lumen of the coronary arteries and hence the extent of atheromatous disease. It is used in the process of decision making about coronary artery bypass grafting and angioplasty

Table 7.14.7 Risk factors for coronary heart disease (CHD)

Type	Risk factor	Comments
Unmodifiable	Age	Risk increases with age
	Gender	Due to the protective effects of oestrogen, premenopausal women have a lower prevalence of CHD than men of the same age, although this difference can disappear in some circumstances, e.g. coexistence of diabetes
	Genotype	Family history of CHD is strongly associated with increased risk, probably due in part to genetic differences in lipid metabolism or somatotype, e.g. propensity to central or peripheral fat distribution. CHD risk is also enhanced in certain racial groups
	Ethnicity	The risk of CHD is higher in the South Asian population. This includes those of Indian, Pakistani, Bangladeshi and Sri Lankan origin
	Socioeconomic status	The risk of CHD is higher in the lowest socioeconomic groups and lowest in the highest socioeconomic group. In all socioeconomic groups, cardiovascular disease has improved substantially over the past two decades, but the gap between poorer and more affluent sections of society has widened as the rate of improvement has been fastest in the more affluent groups
Modifiable	Smoking	Increases oxidative stress
	Diet	See text
	Physical activity	Physical activity positively influences adiposity, insulin resistance, lipid profile (increases HDL cholesterol) and reduces hypertension
	Hypertension	Increases risk of stroke, induces endothelial dysfunction and contributes to the instability of atherosclerotic plaque
	Lipid profile	Uptake of cholesterol by macrophages causes endothelial damage and is the core of the atherosclerotic plaque; higher LDL – carry cholesterol to be deposited in artery walls; lower HDL – carry excess cholesterol to liver for excretion; higher triglyceride level is inversely related to HDL and is also an independent risk factor. Lipids also influence thrombogenesis
	Abdominal obesity	Effect on CHD is due to consequences in terms of blood pressure, diabetes and cholesterol levels. A high waist measurement is a prerequisite risk factor for the diagnosis of metabolic syndrome (IDF 2005)
	Insulin resistance	Risk marker for cardiovascular disease. Insulin resistance and abdominal obesity are important causative factors in metabolic syndrome
	Psychosocial stress	Depression and social isolation or lack of quality support (SIGN, 2007a). The way that a person deals with stress can encourage less healthy behaviours, e.g. smoking, drinking too much alcohol and overeating

HDL, high density lipoprotein; LDL, low density lipoprotein.

Diagnosis will be based on a combination of presenting symptoms, e.g. chest discomfort, and investigations such as cardiac markers, e.g. troponins, and electrocardiograph changes, e.g. ST segment elevation. There will also be consideration of the patient's individual risk factors for CHD (Table 7.14.7).

Coronary heart disease is the most common cause of death in the UK, causing over 88000 deaths a year (BHF, 2010a). About one in five men and one in eight women die from the disease. A reduction in mortality from CHD has been shown in most developed countries with the exception of some Eastern European countries. Russia and the Ukraine have the highest mortality from CHD in Europe for both men and women. However, UK death rates compare less favourably with some other Western European countries, with only Ireland and Germany having a higher death rate than the UK (BHF, 2010a). Deaths from CHD also vary across the UK (BHF, 2010a):

- Highest in Scotland and the North of England and lowest in the South of England.

- Highest in the lowest socioeconomic group and lowest in the highest socioeconomic group.
- Higher in the South Asian community (BHF, 2010b).

Dietary factors may contribute to these differences, e.g. variation of fruit and vegetable consumption, but primarily these regional, socioeconomic and ethnic differences reflect health inequalities (see Chapter 4.2, Chapter 3.4 and Chapter 3.5).

Whilst mortality rates are reducing, morbidity rates are not falling as more people survive cardiac events and are living with CHD. This may be a reflection of advances in treatment, such as medications and revascularisation, and reductions in major risk factors such as smoking (BHF, 2010a). The current prevalence of CHD in the UK is estimated to be 2.7 million, of which 1.6 million are men and over 1 million are women (BHF, 2010a).

Pathogenesis

The pathogenesis of CHD is a complex interaction of a number of processes. Both atherosclerosis and

thrombosis are fundamental to the development of the disease and each is affected by diet. These two processes are described separately for ease of understanding, but in reality they are interlinked.

Atherosclerosis

The first step in the development of atherosclerosis is injury to arterial endothelium (the metabolically active lining of the artery). In areas of damage, macrophages ingest low density lipoprotein (LDL) and other atherogenic particles to form foam cells. When the macrophages die, the lipid remains in the arterial wall, accumulating over time to form a lipid core or pool (Figure 7.14.1). The formation of this fatty streak is the first stage in plaque development.

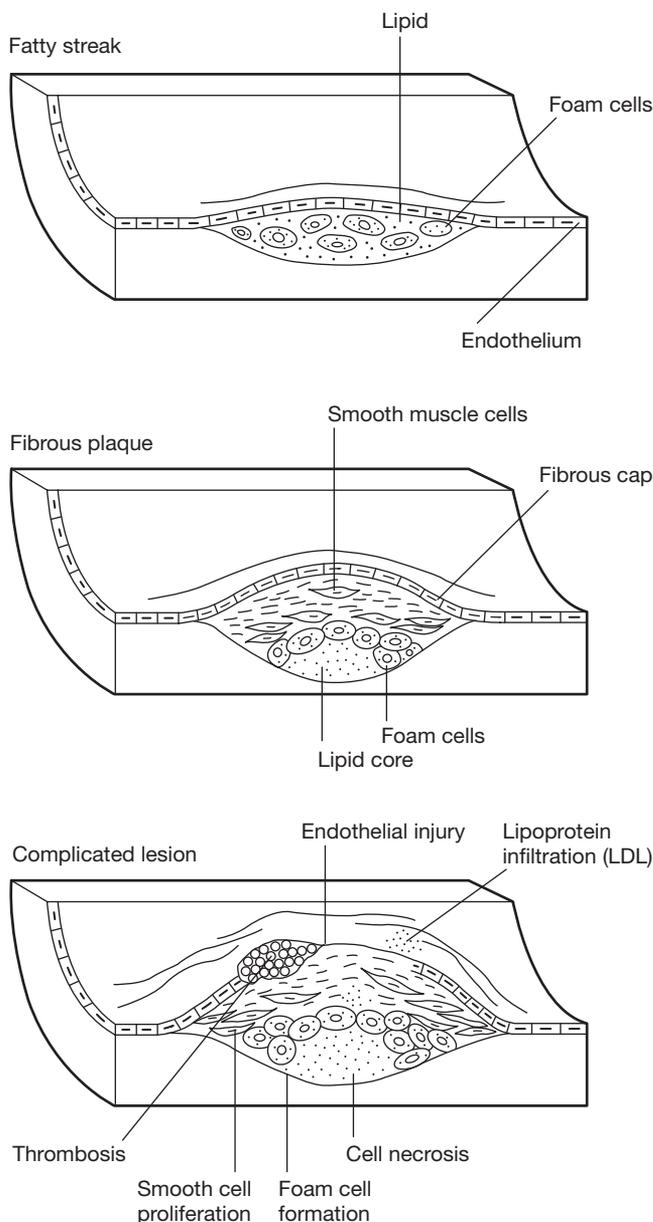

Figure 7.14.1 Stages of atherosclerosis (source: Thomas & Bishop 2007, figure 4.20.1, p. 605. Reproduced with permission of Wiley-Blackwell Publishing)

Subsequent proliferation of smooth muscle cells and development of collagen strands, minor thrombi and calcification in this area of lipid accumulation then result in the formation of atherosclerotic plaque. As the plaque grows, it protrudes into the lumen of the artery. The plaques are covered by a fibrous cap, which can rupture. If this happens, it triggers platelet aggregation and the formation of a blood clot.

The narrowing of the lumen of the coronary arteries as a result of plaque development can lead to an inadequate oxygen supply to the myocardium (heart muscle) at times of increased workload to the heart such as physical exertion. This is the cause of stable angina. Severe narrowing of the blood vessel leads to unstable angina or NSTEMI. Complete occlusion of the blood vessel by a thrombus (clot) will cut off the supply of oxygen to a section of the myocardium (heart muscle), resulting in a STEMI.

A description of lipoprotein metabolism and its influence on atherogenesis is given in Chapter 7.14.3. More detailed discussion of this subject can be found in the Cardiovascular Disease Report by the British Nutrition Foundation (BNF, 2005).

Thrombosis

Damage to the endothelium at the micro level, or to the cap of a plaque at the macro level, can trigger platelet activation and coagulation. As well as being a cause of acute coronary events, thrombosis is an integral part of plaque development as thrombi can become incorporated into the structure. The repair system is complex because the clot needs to be assembled at the site of damage and then removed when the repair is complete. Over 50 different chemicals are involved in the process, all of which are present in plasma all of the time. A shift in the balance of their activation determines whether the anticoagulants or procoagulants dominate. A brief summary of the coagulation process (Simmons, 1997) is:

- **Stage 1 – vasoconstriction.** In smaller vessels this is caused by release of thromboxane A_2 and serotonin from platelets. Thromboxane also activates other platelets.
- **Stage 2 – platelet plug formation.** Platelets become sticky when activated and form plugs that can cause minute ruptures in small blood vessels. They also release active compounds such as growth factors, which promote smooth muscle cell proliferation, a stage in the process of atherosclerosis.
- **Stage 3 – clot formation.** Platelet aggregation combines with the extrinsic and intrinsic pathways to produce a clot (Figure 7.14.2). Prothrombin activator catalyses the split of prothrombin to form thrombin. This in turn causes the polymerisation of fibrinogen to form fibrin threads. These form a mesh, which entrap platelets, plasma and blood cells to form the blood clot; this retracts, expressing the serum.
- **Stage 4 – fibrinolysis.** Plasminogen is activated to produce plasmin, a proteolytic enzyme that digests the fibrin threads. Raised levels of plasminogen activator

which is the first step in the development of atherosclerosis and can trigger thrombosis. The composition and concentration of the lipoprotein fractions, and hence their atherogenic capacity, are affected by diet. This is described in more detail in Chapter 7.14.3.

Diet and thrombogenesis

Many dietary factors influence haemostasis, such as:

- **Dietary fat (quantity and type)** (see Figure 7.14.2) – an increase in the total intake of fat causes postprandial activation of factor VII (FVII) and suppresses fibrinolysis (clot breakdown). Saturated fats increase platelet activity, whereas polyunsaturates have the opposite effect. n-3 Fatty acids attenuate thromboxane A₂ synthesis and thereby suppress platelet activation. (The anti-coagulant effect of aspirin is also achieved by inhibition of thromboxane A₂ production.)
- **Energy balance** – non-rapid weight loss improves fibrinolytic activity.
- **Alcohol consumption** – regular alcohol consumption reduces fibrinogen and FVII concentrations, but heavy drinking reduces fibrinolytic activity.

Diet and oxidative stress

Free radicals are implicated in the processes of both atherosclerosis and thrombosis via:

- Damage to the endothelium.
- Inhibition of prostacyclin and hence increase in platelet activation and aggregation.
- Oxidation of LDL and other atherogenic lipoproteins, leading to their preferential uptake by macrophages to form foam cells.

Epidemiological data suggest that consumption of fruit and vegetables has a protective effect against CHD, but randomised controlled trials using antioxidant vitamin supplements contradict this (Mead *et al.*, 2006). The European Prospective Investigation into Cancer and Nutrition (EPIC) – Heart study (Crowe *et al.*, 2011), a large observational study, showed that consumption of at least eight portions of fruit and vegetables a day gave a 22% lower risk of fatal ischaemic heart disease (IHD) compared with those consuming fewer than three portions a day. A one-portion (80g) increment in fruit and vegetable intake was associated with a 4% lower risk of fatal IHD. The mechanism by which fruit and vegetables reduce CHD risk at a population level is not yet fully understood and more research is required. The National Institute for Health and Care Excellence (NICE, 2007) recommends a Mediterranean style diet and advises against taking antioxidant supplements (vitamin E and/or C) or folic acid to reduce cardiovascular risk.

Diet and inflammation related factors

Inflammation underlies atherosclerosis and current evidence suggests that anti-inflammatory dietary components, such as n-3 fatty acids, and dietary antioxidants

may have a role in reducing injury to the coronary arteries, but more research is required.

Diet and homocysteine

Hyperhomocysteinaemia has been suggested to increase the risk of fibrous plaque formation, thrombosis and arterial injury. Despite epidemiological evidence of an association between these factors, it is not yet clear whether reduction of homocysteine levels by means of folic acid and other B vitamins will reduce CHD events (Mead *et al.*, 2006).

Indirect dietary influences

Indirect dietary influences on CHD development include obesity and its consequences, such as hypertension, hypertriglyceridaemia or type 2 diabetes.

Management

Coronary heart disease management has been shaped by the National Service Framework (NSF) for CHD (Department of Health, 2000) and more recently, the cardiac rehabilitation commissioning pack (Department of Health, 2010a). Alongside this, numerous guidelines have been produced to influence clinical care and the types of investigative procedures used (Table 7.14.8). Other national guidelines explicitly state the need for professional dietetic advice (Joint British Societies, 2005; British Association for Cardiac Rehabilitation, 2007); reviews are currently underway. Providing evidenced based dietary information to all people who have CHD will save more lives than concentrating dietary advice on just those in need of weight management or lipid reduction. The practice of prioritising dietetic time in secondary prevention to those with raised lipids is out of date since the advent of statin therapy (NICE, 2007; 2011).

Overall, the dietary management of CHD depends on the extent to which the disease has progressed and the way in which it is being clinically treated. In the early stages, the main priority will be to achieve change to a cardioprotective diet (see Chapter 7.14.1) in conjunction with other lifestyle risk reduction measures, e.g. increased physical activity. Following a major coronary event, this objective remains the same, but will need to be achieved as part of the stepwise process of cardiac rehabilitation (see later). Invasive surgical procedures may temporarily alter dietetic priorities in favour of nutritional repletion. The development of heart failure or cachexia may necessitate permanent change in these priorities. Understanding the medical and surgical management of CHD in terms of their physical and psychological consequences, e.g. on nutritional status or patient motivation, can help determine what these priorities should be.

Medical management

Medical treatment of CHD depends largely on its manifestation.

Table 7.14.8 Summary of recent coronary heart disease guidance

Society/institute	Guidance
Joint British Societies (JBS)	Guidelines on the prevention of cardiovascular disease in clinical practice (JBS, 2005) (currently being revised)
British Association for Cardiac Rehabilitation (BACR) (Now known as BACPR: British Association for Cardiac Prevention & Rehabilitation)	Standards and core components for cardiac rehabilitation (BACR, 2007) (currently being revised)
Scottish Intercollegiate Guidelines Network (SIGN)	Heart disease guidelines (SIGN, 2007a,b,c)
National Institute for Health and Care Excellence (NICE)	Myocardial infarction: secondary prevention (NICE, 2007) Lipid modification: cardiovascular risk assessment and the modification of blood lipids for the primary and secondary prevention of cardiovascular disease (NICE, 2008; reissued 2010c) Unstable angina and NSTEMI: the early management of unstable angina and NSTEMI. CG 94 (2010a) Stable angina CG126 (NICE, 2011) Chronic heart failure: management of chronic heart failure in adults in primary and secondary care (NICE, 2010b)
European Society of Cardiology (ESC)	Guidelines for the diagnosis and treatment of acute and chronic heart failure (ESC, 2008) Guidelines for the management of acute coronary syndromes in patients presenting without persistent ST segment elevation (Hamm <i>et al.</i> , 2011)

STEMI, ST elevation myocardial infarction; NSTEMI, non-ST elevation myocardial infarction.

Myocardial infarction – STEMI (Hamm *et al.*, 2011)

Medical treatment includes:

- Consideration of immediate primary percutaneous coronary intervention (PPCI) and revascularisation of the culprit lesion (see later).
- Initiation of appropriate pharmacological therapies for secondary prevention (see later).
- Assessment of left ventricular function.
- Management of cardiovascular risk factors.
- Referral to cardiac rehabilitation services.

Myocardial infarction – NSTEMI and unstable angina (NICE, 2010a)

Medical treatments include:

- Consideration for elective coronary angioplasty.
- Assessment of left ventricular function – recommended for all MI patients and to be considered in the management of unstable angina patients.
- Management of cardiovascular risk factors.
- Initiation of appropriate pharmacological therapies for secondary prevention (see later) and to improve angina symptom control as appropriate.
- Referral to cardiac rehabilitation services as appropriate.

National guidelines, e.g. Hamm *et al.* (2011), NICE (2010a) and SIGN (2007b) have identified four main prophylactic drug groups for the secondary prevention of CHD:

- **Antiplatelet drugs** – aspirin blocks the production of thromboxane, which is one of the chemicals responsi-

ble for platelet agglutination. The benefits of long term use of low dose aspirin in secondary prevention are well documented. For patients with a hypersensitivity to aspirin, clopidogrel monotherapy should be considered as an alternative.

- **Statins** – reduce plasma lipid levels (see Chapter 7.14.3).
- **Beta-blockers** – block the stimulating action of noradrenaline (norepinephrine), thus reducing the force and speed of myocardial contraction. The increase in diastolic interval allows for better coronary perfusion during exercise and a reduction in myocardial oxygen demand. They are used in the treatment of MI, angina, heart failure, arrhythmias and hypertension.
- **Angiotensin converting enzyme (ACE) inhibitors** – have a vasodilatory action through the decreased formation of angiotensin II and increase in protective bradykinin. The main indications for ACE inhibitor therapy include prophylaxis of cardiovascular events, hypertension and all grades of heart failure. Angiotensin II receptor antagonists [also referred to as angiotensin receptor blockers (ARBs)] are used when patients are intolerant to ACE inhibitors. Other vasodilators are nitrates, e.g. glyceryl trinitrate (GTN) spray for symptomatic relief of angina, and calcium channel blockers. Both work by inhibiting smooth muscle contraction in the vessel walls.

If patients do not tolerate oily fish consumption as part of a cardioprotective diet, NICE recommends 1g/day of n-3 fatty acid ethyl esters for up to 4 years post MI. n-3 Fatty acid supplementation should not be routinely initiated for patients who had an MI >3 months earlier (NICE,

2007). In addition, NICE makes lifestyle recommendations about physical activity, smoking cessation and alcohol consumption. NICE (2011) states there is no evidence that vitamins or fish oil help stable angina.

Surgical management

Following an angiogram (see Table 7.14.6) patients may be referred for an angioplasty and coronary artery bypass graft (CABG).

Angioplasty – percutaneous coronary Intervention

A balloon is introduced and inflated at the site where blood flow through the arterial lumen has been significantly reduced as a result of atherosclerotic plaque. Once in position, the balloon is inflated to increase the size of the arterial lumen. In some cases a small stent (a mesh tube that can be expanded to hold the artery open) is inserted. The term primary percutaneous coronary intervention (PPCI), also known as primary angioplasty, is used for the prompt restoration of flow in STEMI.

Coronary artery bypass graft

In this surgical procedure, one or more diseased coronary arteries are bypassed. Blood vessels (usually taken from the leg) are grafted onto the existing coronary arteries to bypass the occluded section. Access to the heart is gained via the sternum, which is broken in the process. Coronary artery bypass graft (CABG) is a major surgical procedure with all the metabolic and nutritional consequences that this implies (see Chapter 7.17.5). It should also be borne in mind that if patients are advised by the surgical team to lose weight prior to the procedure, some will undergo surgery in a nutritionally depleted state as a result of inappropriate crash dieting. If weight management is still an issue post CABG, patients should be informed that the sternum wound takes about 6 weeks to heal and therefore weight reduction should not be attempted during this time period. For planned CABG prehabilitation, a

combination of nurse counselling and a brief cognitive behavioural intervention (Heart OP Programme) has been found to reduce depression and cardiac misconceptions and improve physical functioning before CABG surgery (Furze, 2009).

Cardiac rehabilitation

The Department of Health (2010a) cardiac rehabilitation commissioning pack sets explicit standards for the provision of effective cardiac rehabilitation for high priority patients with CHD. These include NSTEMI, STEMI and unstable angina patients, including all those undergoing reperfusion, e.g. CABG, PCI or PPCI, and newly diagnosed chronic heart failure patients or those with a step change in clinical presentation. Furthermore, the pack recommends extension of services once high priority patient cardiac rehabilitation services have been successfully implemented to include heart transplant patients, patients who have undergone surgery to implant a cardioverter defibrillator or heart valve replacement for reasons other than ACS or heart failure. The pack recommends a seamless pathway involving six stages (Table 7.14.9), with the dietitian influencing the management of each stage. There is no evidence that cardiac rehabilitation is clinically or cost effective for managing stable angina (NICE, 2011).

Stage 1

Initial advice on lifestyle, including diet, is usually given by the ward staff (hence training of other healthcare professionals is an important role of the cardiac rehabilitation dietitian), but the ability of both patients and their families to assimilate information will be severely impaired by anxiety and stress in coming to terms with the diagnosis. In particular, patients receiving immediate PPCI have a very short stay in hospital and should receive stop gap information to ensure they are aware of their local cardiac rehabilitation programme.

Table 7.14.9 Role of the dietitian in cardiac rehabilitation (CR)

Stages	Service delivered by:	Description (Department of Health, 2010a)	Time scale	Role of the dietitian (Mead <i>et al.</i> , 2006; Fox <i>et al.</i> , 2004)
1	Acute services	Acute event in hospital	2–5 days as inpatient	Training CR staff or practice nurse to deliver consistent key cardioprotective dietary messages
2 and 3	Acute services and primary care	Telephone/home visit initial assessment completed and introduces CR core components Devise individual care plan based on patient risk factors and motivation	5–10 working days from receipt of referral/discharge from hospital	Ensuring dietary resources are up to date Referral criteria to dietitian is not based on lipid levels, but identifies patients struggling with the cardioprotective diet
4	Acute services and primary care	Hospital rehabilitation service – high risk patients Community based rehabilitation service – low risk patients Multidisciplinary approach	8–12 weeks	Deliver group sessions and/or individual consultations to achieve and sustain effective secondary prevention within multidisciplinary care
5 and 6	Primary care	Nurse led coronary heart disease clinics by practice nurses Community exercise classes	Week 12 and beyond	

Following major cardiac surgery, the immediate dietary objectives (to restore recent energy and nutrient losses) may be quite different from the longer term aims (e.g. to reduce fat intake). Some patients may require oral nutritional support measures and hence healthy heart food choices from the hospital menu may not be appropriate at this stage. Good communication between dietetic and nursing and medical staff is essential to ensure that the nutritional objectives are understood and that patients are given food that is appropriate for their nutritional needs.

Stage 2

The cardiac rehabilitation specialist nurse completes an initial assessment with the patient and introduces the core components of cardiac rehabilitation:

- *Lifestyle* – diet, exercise and, if appropriate, weight management and smoking cessation.
- *Risk factor management* – cholesterol, blood pressure and, if diabetic, glucose management.
- *Cardioprotective drug therapy* – rate, rhythm and thrombotic risk management and fluid status can be modified by non-medical prescribing cardiac specialist nurses.
- *Psychosocial wellbeing* – an anxiety and depression screening tool will be used to identify high risk clients to be referred to psychological specialists if needed and available.

Stage 3

A care plan is devised, realistic goals are set from the initial assessment and the patient is enrolled onto a cardiac rehabilitation programme that meets their needs; this may include home based cardiac rehabilitation programmes, e.g. the Heart Manual (Lewin *et al.*, 1992), or a formal cardiac rehabilitation exercise programme. There is usually very little direct dietetic contact during this phase.

Stage 4

A formal cardiac rehabilitation outpatient programme typically lasts for 6 weeks, with twice weekly supervised exercise sessions followed by group education. Community based programmes are becoming more common to improve access and increase participation by women and ethnic minority groups, whose uptake of hospital cardiac rehabilitation programmes is low. Dietetic input depends on the capacity of the service, but usually a dietitian will see the patient in group sessions and/or individually depending on availability of local resources (BHF, 2011). The patient's partner or carer should also be involved since they have an important role in helping the patient implement and maintain the diet and lifestyle measures necessary for secondary prevention.

Dietitians, as part of a multidisciplinary team approach to cardiac rehabilitation, can support patients to achieve and sustain effective secondary prevention (Fox *et al.*, 2004). However, the EUROASPIRE II survey (Kotseva *et al.*, 2004) found that only a third of patients attended the cardiac rehabilitation programme, and those that did

still did not achieve lifestyle and risk factor targets. The EUROACTION trial in eight European countries demonstrated that a multidisciplinary, family based programme improved lifestyle and reduced cardiovascular risk. The results showed that patients in the intervention group reduced their consumption of saturated fat; three quarters of patients and their partners achieved the recommended fruit and vegetable consumption, compared to just over a third of usual care patients, and twice as many in the former group met the recommended weekly intake of oily fish (Wood *et al.*, 2008).

Stages 5 and 6

At the patient's final discharge assessment from the cardiac rehabilitation programme they are signposted to lifestyle maintenance programmes to encourage them to continue to exercise, e.g. local heart care support group or community exercise classes. The patient is referred back to the care of their general practitioner (GP). The NSF for CHD (Department of Health, 2000) advocated the use of disease registers in primary care to provide long term follow-up for CHD patients. The General Medical Council's Good Medical Practice Guide (2006) encourages primary care teams to implement evidenced based care. For CHD this is realised in the Quality Outcome Framework (BMA/NHS Employers, 2011) with clinics run by practice nurses attended by patients for an annual review. Patients may be referred to a dietitian during this phase if they are still struggling to incorporate a cardioprotective diet into their lifestyle.

Chronic heart failure

Chronic heart failure (CHF) is a complex clinical syndrome caused by a reduction in the heart's ability to pump blood around the body. Whilst the most common cause is CHD, other causes include hypertension, valvular heart disease, cardiomyopathy, atrial fibrillation and alcohol abuse. Prevalence of CHF increases sharply with age to about 7% in men and women over 75 years (NHS IC, 2010). Patients with CHF often have a poor quality of life with high mortality rates (10–50% depending on severity). They have a worse prognosis than patients with breast and prostate cancer (NHS IC, 2010), and CHF has become one of the most common causes of hospital admissions. Due to the ageing population and improved survival in patients who develop CVD disease, such as MI, hospital admissions and the number of people diagnosed with CHF are expected to rise.

To address these issues, the NSF for CHD, Standard 11 (Department of Health, 2000) set out a service delivery agenda, and NICE (2010b) has produced clinical guidelines to improve CHF management. Specialist CHF services are currently being developed as it has been shown that they can reduce hospital admissions/mortality rates and improve symptoms (NHS IC, 2010).

The physical effects of CHF include:

- Inadequate cardiac output.
- Fluid imbalance.

Table 7.14.10 New York Heart Association functional classification of heart failure (Dickstein *et al.*, 2008)

Classification	Symptoms	Comments
Class I	Impaired left ventricular failure, but no symptoms, e.g. fatigue or breathlessness	No limitations to activities of daily living
Class II	Comfortable at rest but ordinary physical activity results in fatigue, palpitation or dyspnoea	Mild – slight limitations
Class III	Comfortable at rest but less than ordinary activity results in fatigue, palpitations or dyspnoea	Moderate – marked limitations
Class IV	Symptoms at rest. If any physical activity is undertaken, discomfort is increased	Severe – inability to carry out any activities of daily living without discomfort

- Pulmonary and other oedema.
- Dyspnoea.
- Fatigue.

Echocardiogram is now the gold standard for diagnosis in those patients with a medical history of MI. For patients with no previous history of MI, an echocardiogram is only needed if the B type natriuretic peptide (BNP) test is positive (NICE, 2010b). Heart failure is a progressive condition and is classified into four stages according to the severity of symptoms (Table 7.14.10).

Medical management

In CHF the main treatment objectives are to:

- Prevent progressive damage to the myocardium.
- Prevent or reverse further enlargement of the heart.
- Improve quality of life through symptom management.
- Prolong life (Opie & Gersh, 2009).

The main cause of CHF is left ventricular systolic dysfunction (LVSD), for which the recommendations for pharmacological management can include the following (NICE, 2010b, Dickstein *et al.*, 2008):

- Angiotensin converting enzyme (ACE) inhibitors are recommended as first line treatment. These can prolong life expectancy, delay progression and improve symptoms. ARBs may be used where ACE inhibitors are not tolerated.
- Beta-blockers are used in controlled heart failure alongside ACE inhibitors and have been proven to reduce mortality in low doses.
- Diuretics are used routinely for the relief of congestive symptoms and fluid retention (peripheral and pulmonary oedema); the removal of fluid and reduction in

blood volume reduces the workload of the heart. This can result in rapid improvement in dyspnoea and improve exercise tolerance.

Other agents such as aldosterone antagonists and digoxin may be considered in addition to the above treatment. Warfarin is recommended in patients with CHF and permanent, persistent or paroxysmal atrial fibrillation without contraindications to anticoagulation, with the aim of reducing the risk of thromboembolic complications including stroke.

Surgical management

Although medical management is the mainstay of treatment, some patients will benefit from invasive procedures (NICE, 2010b; Dickstein *et al.*, 2008) such as:

- Mechanical support cardiac resynchronisation therapy (CRT) with pacemaker function – recommended to reduce morbidity in patients in New York Heart Association (NYHA) classes III–IV who are symptomatic despite optimal medical therapy.
- Heart transplantation, however shortage of donor organs means that many potential recipients are unable to benefit from this.

Dietetic management

Many guidelines for CHF management (SIGN, 2007c; NICE, 2010b; Dickstein *et al.*, 2008) highlight the benefits of lifestyle changes, including dietary manipulation. However, there are no specific evidence based nutritional guidelines and more research is required. The therapeutic aims of dietary management are to:

- Maintain adequate energy intake to prevent obesity, malnutrition and cachexia.
- Reduce the workload for the heart by weight management, and sodium and fluid restriction.
- Provide a nutritionally adequate diet.
- Protect against further heart disease.

Dietetic management in CHF will therefore address the following:

- **Obesity** – should be avoided as it increases cardiac workload. Planned weight loss in CHF should be gradual as rapid weight loss can result in undesirable muscle loss and also increase the risk of inadequate or poor nutritional intake. Hence, weight reduction should not be routinely recommended in moderate to severe CHF (Dickstein *et al.*, 2008).
- **Malnutrition** – the combination of reduced nutritional intake and increased requirements place the CHF patient at risk of malnutrition (Gibbs *et al.*, 2000). Energy intake needs to be sufficient to meet nutritional needs and prevent deterioration in nutritional status. However, weight gain from increased fat stores should be avoided. Gain in adiposity should be distinguished from short term fluctuations in body weight caused by changes in fluid balance (see Chapter 2.2).

- *Cachexia* – see later.
- *Sodium restriction* – sodium and water retention, leading to expansion of extracellular fluid volume, are important components of CHF syndrome. Therefore, it is of little or no benefit to restrict fluid intake if patients who continue to use unlimited amounts of salt. Restricting salt is more relevant in advanced CHF. Severe salt restriction (<2, g/day) is rarely necessary. Where salt restriction needs to be considered, it should be at a no added salt level (see Chapter 6.6). Salt substitutes should be avoided as these are rich in potassium and may lead to hyperkalaemia, especially if patients are on ACE inhibitors and /or spironolactone. Salt restriction can affect food palatability and possibly compromise intake of energy and essential nutrients.
- *Fluid restriction* – an excessive amount of fluid should be avoided as it negates the positive effects of diuretics and induces hyponatraemia. Patients with advanced CHF, with or without hyponatraemia, may need to restrict their fluid intake. There is no evidence based calculation for the level of fluid restriction such as exists for patients with renal failure. In practice, a restriction of 1.5–2L/day is often advised. Daily weighing is advised for CHF patients to detect sudden or unexpected weight gains (>2kg in 3 days), which would indicate the need for adjustment of diuretic dose.
- *Maintaining nutritional adequacy* – particular attention should be paid to micronutrient intake since the use of diuretic and other drugs may result in significant urinary losses of potassium and water soluble vitamins. Since appetite is often poor, the diet may need to be relatively nutrient dense and meal frequency may need to be increased. Social factors such as support for food purchasing and preparation, particularly if the patient lives alone, should not be overlooked. Alcohol should only be consumed in moderation, and completely avoided if CHF has been caused by alcohol abuse.
- *Protect against further heart disease* – the key cardio-protective dietary messages should be incorporated (see Chapter 7.14.1). Research study results using 1g of n-3 fatty acid supplementation in CHF patients are promising, but further studies are needed prior to routine recommendation (GISSI, 2008).

Cardiac cachexia

Chronic heart failure can lead to cardiac cachexia. This complex condition affects many body systems (Anker & Coats, 1999). There is a loss of skeletal and heart muscle, and fat and bone tissue. There are neurohormonal and immunological changes, and impaired functioning. Many of the common symptoms, e.g. anorexia and fatigue, are similar to the cachexia of cancer and chronic infection (see Chapter 7.15.9). Cardiac cachexia has a poor prognosis (50% mortality rate within 18 months of diagnosis), with the amount of weight lost being a strong predictor of mortality. The incidence of cachexia with CHF is not exactly known, but may be about 9% and up to 68% for hospitalised patients.

Dietary management

Nutritional support is required to address anorexia that is exacerbated by:

- Dyspnoea – this increases fatigue during eating, and swallowing exacerbates the symptoms of dyspnoea.
- Oedema.
- Palatability of food, e.g. salt restriction, ACE inhibitors impairing taste.
- Drug reactions, e.g. aspirin, digoxin and ACE inhibitors all cause anorexia.
- Metabolic disturbances, e.g. hyponatraemia or renal failure.
- Depression.

The level of sodium and fluid restriction, and micronutrient needs should be discussed with the referring clinician. Overall, a multidisciplinary team approach is key to ensure that weight loss is minimised as part of the need to address quality of life issues during palliative care. It is now recommended that patients with two or more of the following indicators should be registered on the Gold Standards Framework register:

- CHF NYHA III–IV – shortness of breath at rest or on minimal exertion.
- Patients thought to be in the last year of life by the care team.
- Repeated hospital admissions with symptoms of heart failure.
- Difficult physical or psychological symptoms despite optimal medical treatment.

A discussion with the patient and carer about palliative end of life care should be approached by the care team to ensure an appropriate care plan and support are implemented (see Chapter 7.16; RCGP, 2008).

Dietitians are gradually becoming more involved in the management of heart failure cardiac cachexia, and at an earlier stage, but this is variable across the country. Since the number of hospital admissions this condition is increasing, it is likely that its management will adopt a rising profile in the clinical dietetic caseload. Current research is investigating the use of anabolics, anti-inflammatory drugs, appetite stimulants and nutritional supplements, which will strengthen the evidence base for dietetic practice in this area.

Public health prevention strategies

The multifactorial nature of CHD is reflected in public health strategy. Addressing health inequalities is an important issue as poor quality diet can result in inequalities in people's health. Poor diet can account for 30% of life years lost in early death/disability from diet related diseases such as CHD (National Heart Forum, 2004). Key documents to date that have shaped primary CHD prevention within the public health arena are outlined in Table 7.14.11 (see Chapter 4.2).

The evidence base for dietary aspects of primary CHD prevention is well known (Department of Health,

Table 7.14.11 Key UK public health documents that influence primary coronary heart disease (CHD) prevention

Key documents	Comments
Saving Lives: Our Healthier Nation (Department of Health, 1999)	National policy on public health, e.g. reducing death rate from CHD, stroke and related disease in people under 75 years of age by at least 40% by 2010
Healthy Lives, Healthy People (DH 2010b)	Updated Public Health Strategy to promote health and aim to create wellness service
Our Health and Wellbeing Today (Department of Health, 2010c)	Summary of evidence setting out the nation's health in 2010
Prevention of cardiovascular disease at population level (NICE, 2010b)	Department of Health commissioned NICE to produce public health guidance on prevention of cardiovascular disease (CVD) at population level. CVD includes stroke and peripheral arterial disease
Coronary heart disease: National Service Framework (NSF) for CHD – modern standards and service models (Department of Health, 2000)	Strategy to modernise CHD services. Standard 1 highlights that the NHS needs to work with partner agencies to address CHD prevention in the population
Coronary Heart Disease Ten Years On – Improving Heart Care (Department of Health, 2007)	Report of progress in CHD outcomes and prevention
CHD: Guidance for implementing the preventative aspects of the NSF (HDA, 2001)	Guidance on best practice to support healthier lifestyles: <ul style="list-style-type: none"> • Reduce smoking • Promote healthy eating • Promote physical activity • Reduce overweight and obesity
Tackling Health Inequalities. A programme for Action (Department of Health, 2003).	Highlights the need to address access issues, especially hard to reach groups. Services and initiatives need to narrow the health gap, not widen it further, as low income and minority ethnic groups are disproportionately affected by CHD
Securing Good Health for the Whole Population (Wanless, 2004).	
Tackling Health Inequalities: 10 years on. (Department of Health, 2009)	Update from publication of Acheson report 1998 leading to strategic review of health inequalities in 2008
England	
Choosing Health – making healthier choices easier (Department of Health, 2004)	Considers wider determinants and barriers to choosing a healthy lifestyle and inequalities, etc.
Choosing a Better Diet: a food and health action plan (Department of Health, 2005) www.dh.gov.uk	Government plans to improve nutrition and health
Scotland	
Eating for health – meeting the challenge: Co-ordinated action, improved communication and leadership for Scottish Food and Health policy (Scottish Executive, 2004) www.scotland.gov.uk	A strategic framework for food and health
Healthy Eating Active Living (HEAL) (Scottish Government, 2008)	An action plan to improve diet, increase physical activity and tackle obesity
Preventing Overweight and Obesity in Scotland. A route map towards healthy weight (Scottish Government, 2010)	Target areas – energy consumption, energy expenditure, early years, working lives
Wales	
Food and Well Being – Reducing Inequalities through a Nutrition Strategy for Wales. (Welsh Assembly Government, 2003) www.wales.gov.uk	Addresses widening gap in health between the most and least deprived communities
Northern Ireland	
Investing for Health (Department of Health, Social Services and Public Safety, 2003) www.dhsspsni.gov.uk	Plans to improve the health of all people and reduce health inequalities.
Developing New Public Health Strategy for Northern Ireland – Update September 2011 www.dhsspsni.gov.uk	An updated review of Investing in Health

1994) and implemented in practice via the eatwell plate model.

Drug–nutrient interactions (SIGN, 2007)

Cranberry juice should be avoided in patients prescribed warfarin as this may increase drug potency. St John's wort should be avoided in patients with CHF as this supplement can interact with warfarin, digoxin, eplerenone and selective serotonin reuptake inhibitors.

7.14.3 Dyslipidaemia

Linda Main

Key points

- Dyslipidaemia should not be treated in isolation but in conjunction with the assessment of cardiovascular disease risk.
- Dietary treatment and advice is still relevant despite statin therapy.
- There is a greater emphasis on increasing high density lipoprotein (HDL) cholesterol levels (by lifestyle as well as dietary means), as well as reduction in low density lipoprotein (LDL) cholesterol.
- Advances in statin therapy mean that a combination treatments are used to aggressively achieve target lipid levels.

Dyslipidaemia refers to the presence of high levels of lipids (cholesterol or triglycerides) or lipoproteins, the compounds in which they are transported in the blood. The clinical significance of dyslipidaemia depends upon a number of risk factors (including lipid levels) that contribute to total risk. Dyslipidaemia is associated with atherosclerosis – the process by which arteries become occluded, which in turn results in or contributes to a number of chronic conditions, including coronary heart disease, stroke and peripheral vascular disease.

Lipid metabolism

Cholesterol

Cholesterol is an essential part of the structure of all cell membranes, and a precursor of bile acids (needed for fat digestion and absorption), steroid hormones and vitamin D. Excess cholesterol can accumulate in blood vessel walls (atheroma), ultimately causing a restriction or inter-

ruption in the circulation; this process is called atherosclerosis. Depending upon where the restriction in blood flow occurs, it can result in angina, heart attack, stroke or claudication (pain on walking), and can contribute to other conditions such as erectile dysfunction and Alzheimer's disease. Populations with low levels of blood cholesterol have low levels of coronary heart disease (CHD) and those with high levels of cholesterol have high levels of CHD (Department of Health, 1994) (see Chapter 7.14.2). Approximately 20% of cholesterol is derived from the diet and the remainder is synthesised in the body. Cholesterol is produced in a multistage process mainly in the liver, although most tissues have the ability to make cholesterol.

Triglycerides

Triglycerides are the major storage form of fats and major source of energy in the diet. Many tissues have the ability

to synthesise triglycerides, including the gut, liver, muscle and adipose tissue (Durrington, 2007).

Lipid fractions (lipoproteins)

All lipids (cholesterol, phospholipids and triglycerides) are insoluble in water (hydrophobic) and therefore have to be transported in the blood as compounds called lipoproteins. Lipoproteins are classified according to their density and size. The composition, interplay and metabolism of lipoproteins are complex and beyond the scope of this chapter; however, the principal features are:

- Lipoproteins are globular complexes of lipids and proteins.
- The definitions of low density lipoprotein (LDL), very low density lipoprotein (VLDL) and high density lipoprotein (HDL) are artificial cut-off points.
- Each lipoprotein has a number of components that are metabolically active and constantly in flux, both in the circulation and within tissue fluids. They exchange components with each other.
- Lipoproteins interact with receptors and enzymes located on the surface of cells.

The main lipoprotein fractions are chylomicrons, LDL, VLDL and HDL.

Chylomicrons (from exogenous production)

Chylomicrons are the largest of the particles; they are rich in triglyceride (80–95%) with relatively small amounts of cholesterol (3–7%), phospholipid (3–6%) and protein (1–2%) (Durrington, 2007). They enter the circulation from the gut via the lymphatic system, taking triglycerides and cholesterol from digestion and newly synthesised cholesterol from the gut into the body. Lipoprotein lipase, present on the vascular endothelium of tissues (especially those with a high requirement for triglycerides, i.e. muscle, adipose and lactating breast tissue), releases triglycerides from the core of the chylomicron. Triglycerides are converted into fatty acids and monoglycerides, which are then taken up by the tissues. Over time the chylomicron becomes depleted of triglyceride and is removed from the circulation by the liver.

Very low density lipoproteins (from endogenous production)

Smaller and denser than chylomicrons, VLDLs are rich in triglyceride (59%) and contain about 10–15% cholesterol and 15% phospholipid; they account for around 10–15% of total serum cholesterol (Durrington, 2007). They are produced by the liver with the aim of supplying the tissues with triglycerides. Like chylomicrons, VLDLs become depleted of triglyceride over time under the influence of lipoprotein lipase.

Low density lipoproteins (from endogenous production)

Remnant VLDLs (triglyceride 10%, cholesterol 37%, phospholipid 22%, protein 20–22%) are known as LDL. Being smaller they are able to cross the vascular endothelium and enter the tissues where they are the major supplier

of cholesterol for membrane repair and growth, and in the specialised tissues for hormone and vitamin D synthesis. Low density lipoprotein cholesterol accounts for 60–70% of total serum cholesterol. The size of LDL particles varies and this is significant as smaller, denser LDL particles are more atherogenic than larger ones. This form of cholesterol is the major target of cholesterol lowering treatments.

High density lipoproteins (from endogenous production)

High density lipoprotein is composed of 20% cholesterol, 48% protein, 3% triglyceride and 27% phospholipid. These are the smallest lipoproteins and HDL cholesterol accounts for 20–30% of circulating cholesterol. The role of HDL is to collect excess cholesterol from the tissues and return it to the liver where it can be removed from the circulation by conversion to cholesterol rich bile acids that are excreted into the gut. This process is essential to prevent the build-up of surplus cholesterol in the tissues. The levels of HDL are thought to be important in preventing the formation of atheroma and are inversely correlated with CHD risk. The exact role of HDL now appears more complex than originally thought and is the subject of much ongoing debate.

Intermediate density lipoproteins

Intermediate density lipoproteins (IDL) are short lived intermediaries between VLDL and LDL.

Apolipoproteins

Apolipoproteins bind to lipids within the lipoproteins and are classified as A, B, C, etc. with further subclassifications (AI, AII etc.). They are sometimes referred to as Apo A, Apo B, etc. The principal apolipoprotein of HDL is apolipoprotein A and of LDL is apolipoprotein B. Apolipoprotein B is found in all adults but levels vary widely. The level appears to be genetically determined and is higher in adults descendant from African and Indian populations (Durrington, 2007). Europeans with a family history of early heart disease often have higher levels of apolipoprotein A.

Cardiovascular risk

Cholesterol

Raised blood cholesterol level is the single greatest risk factor for CHD and a main risk factor for cardiovascular disease (CVD) (HEARTUK, 2007). Cardiovascular disease is the leading cause of deaths worldwide (WHO, 2008), causing 27% and 32% of deaths in men and women, respectively, during 2004. Raised cholesterol is estimated to cause 18% of global cerebrovascular disease and 56% of global CHD (WHO, 2002). Reducing total cholesterol level reduces cardiovascular risk. On a population basis, a 1mmol/L reduction in LDL cholesterol is associated with a 12% reduction in all cause mortality, a 19% reduction in coronary mortality and a 21% reduction in vascular events [myocardial infarction (MI), coronary revascularisation and stroke] over 5 years [Cholesterol Treatment Trialists' Collaboration (CTTC), 2005].

Blood cholesterol concentrations (including LDL and HDL levels) are only one of many risk factors that influence the development of CHD, and so cannot predict individual CHD risk alone. A raised level poses a greater threat to an individual at high CHD risk than to someone at low risk. Similarly, the benefits from cholesterol reduction in a particular individual will be affected by other risk factors, e.g. smoking, hypertension, overweight or being physically inactive. It is now recognised that effective prevention of CVD requires multifactorial risk assessment and intervention (see Chapter 7.14.1). For this reason, blood lipid measurements must always be considered in the context of other risk factors and not in isolation. Emphasis is placed on the reduction in LDL cholesterol as this is considered the most atherogenic particle. Conversely, HDL cholesterol reflects cholesterol removal and high levels are therefore believed to be protective.

Triglyceride

Circulating triglycerides are present mainly in VLDL, which is made in the liver (endogenous production), and chylomicrons, which are produced by the gut following digestion (exogenous production). Until fairly recently it was believed that observed associations between blood triglyceride concentration and CHD risk simply reflected the more powerful predictive value of low HDL cholesterol levels (NB: low HDL and high VLDL triglyceride usually coexist). However, a number of studies have indicated a significant and independent association between serum triglyceride concentrations and the incidence of major coronary events (Stampfer *et al.*, 1996; Assmann *et al.*, 1996). A meta analysis that controlled for HDL cholesterol suggested that for every 1 mmol/L rise in serum triglyceride concentration, the relative risk of CHD increased by 14% in men and 37% in women (Hokanson & Austin, 1996). Kannel & Ramachandran (2009) reviewed the role of triglycerides in the aetiology of CVD and concluded that raised fasting or non-fasting triglycerides merit consideration as a prominent CVD risk factor because of their association with insulin resistance, highly atherogenic small LDL particles, low HDL cholesterol and the metabolic syndrome. At present no clear evidence exists from intervention trials to demonstrate that lowering triglyceride levels (independent of other risk factors) reduces major CVD events (Kannel & Ramachandran, 2009).

Genetic predisposition

Plasma concentrations of total cholesterol, LDL cholesterol, HDL cholesterol and triglycerides are heritable risk factors for CVD. So far 95 different genes involved in lipid metabolism have been identified and together these explain 25–30% of the genetic variance for each lipoprotein (Teslovich *et al.*, 2010). Consumer genetic testing may in the future be available as a more accurate method of identifying those at high CVD risk who would benefit from early treatment.

Diet and lifestyle

Many aspects of diet and lifestyle affect blood lipids and can contribute to dyslipidaemia. Diet should be central to the treatment of dyslipidaemia, either as a first line treatment or alongside drug therapy. Metabolic studies have demonstrated a cholesterol lowering effect from diet in the range of 5–35% dependent upon the baseline diet and the extent of dietary changes made (Jenkins *et al.*, 2002; 2003b; 2011). For most people 5–20% cholesterol reduction is more realistic, as shown by free living studies (Jenkins *et al.*, 2006; 2011).

Fat

Following a fat containing meal, blood triglyceride levels rise, triglyceride rich chylomicrons enter the bloodstream and VLDL triglyceride production by the liver will temporarily cease. The amount of fat consumed will determine the rise in triglyceride levels. Sustained reduction of both the total amount of fat in the diet and particularly of saturated fat can reduce total and LDL cholesterol. In populations that consume a western diet, replacing 1% of energy from saturated fat with polyunsaturated fats can reduce CHD incidence by 2–3% (Astrup *et al.*, 2011). Most lipid guidelines recommend a maximum of 10% energy from saturated fat, but may not refer to the replacement energy source (NICE, 2010a, Joint British Societies, 2005). Cholesterol levels can be reduced by substituting saturated fatty acids with unsaturated fatty acids (NICE, 2010a; Hooper *et al.*, 2001a,b; FAO/WHO, 2008; Astrup *et al.*, 2011). Evidence currently suggests that polyunsaturated fats may have a greater impact on reducing LDL cholesterol than monounsaturated fatty acids (Astrup *et al.*, 2011; FAO/WHO, 2008). While restriction of saturated fat intake is crucial, reduction in the total quantity of dietary fat may not always be necessary. However, despite the fact that the energy restriction of a low fat diet can promote weight loss, low fat diets can increase plasma triglyceride and lower HDL concentrations (Katan *et al.*, 1997). Substituting saturated fat with unsaturated alternatives may also make lipid lowering more palatable and improve compliance. Individual saturated fatty acids have different effects on blood cholesterol levels. Lauric (C12.0), myristic (C14.0) and palmitic acid (C16.0) all increase LDL cholesterol, but stearic acid (C18.0) does not (FAO/WHO, 2008).

Trans fatty acids

Industrially, *trans* fatty acids are produced by partial hydrogenation of vegetable and marine oils to produce hardened fats such as margarines, cooking fats and shortenings. They have been shown to increase total and LDL cholesterol levels, but unlike saturated fats they also lower HDL cholesterol (SACN, 2007; FAO/WHO, 2008). A 1% energy decrease in *trans* fats is estimated to reduce the risk of CHD by 12.5% (Oomen *et al.*, 2001). In the UK, the food and catering industries have made significant efforts to remove industrially produced *trans* fats from the food chain. *Trans* fatty acids should contribute no more than 2% of food energy (SACN, 2007) and are

currently estimated to provide 0.8% of food energy (Bates *et al.*, 2010), although some groups may have a higher intake.

Trans fatty acids from ruminant sources are low in most diets (FAO/WHO, 2008) and there is insufficient evidence to discriminate between the health effects of ruminant and industrially produced *trans* fats (SACN, 2007). Recent guidance from NICE (2010b) called for additional measures to monitor intakes in population subgroups and for action to reduce intakes through industrial food preparation.

Omega 3 fatty acids

The n-3 fatty acids eicosapentanoic acid (EPA) and docosahexanoic acid (DHA) at doses of 2–4g/day (in purified supplemental form) have been shown to reduce fasting and postprandial blood triglyceride levels (Roche & Gibney, 2000; Castro *et al.*, 2005). A dose of 1g/day of EPA and DHA (or three portions of oily fish/week) is recommended following a heart attack or MI as this reduces the risk of a second event (NICE, 2007). n-3 Fatty acids from fish or vegetable oils do not have a significant effect on cholesterol levels (Hooper *et al.*, 2004).

Cholesterol

Approximately 30–60% of dietary cholesterol is absorbed (Durrington, 2007) and contributes approximately 20% of the total circulating cholesterol. Most dietary cholesterol comes from foods that are rich in saturated fat, e.g. full fat dairy foods and fatty meats, and reducing saturated fat intake will therefore reduce dietary cholesterol. However, some foods rich in cholesterol are low in saturated fat, including egg yolk, liver and shellfish (prawns, crabs, lobster, squid, octopus and cuttlefish); molluscs (cockles, mussels, oysters, scallops and clams) are very low in cholesterol.

Dietary guidelines for prevention of CVD recommend a restriction of cholesterol intake to between 200 and 300 mg/day (NICE, 2010b; NIH, 2002). Mean daily intakes of cholesterol in the UK NDNS were 304 mg for men and 213 mg for women (Henderson *et al.*, 2003). Restriction of dietary cholesterol over and above that found in foods high in saturated fat is unlikely to have a significant influence on blood cholesterol for most individuals (Leeds & Gray, 2001; Durrington, 2007). However, some individuals with inherited forms of raised cholesterol may benefit from additional restriction.

Carbohydrate

Carbohydrate intake has no direct effect on blood cholesterol levels; however, energy consumed from carbohydrates is inversely proportional to the energy derived from fat in the diet. Therefore, an increase in the proportion of energy derived from carbohydrate is often encouraged as a means of reducing the proportion of saturated fat in the diet. Increasing the total amount of dietary carbohydrate consumed, particularly if energy intake is excessive, can elevate endogenous production of triglyc-

eride by the liver as VLDL (Durrington, 2007). The quality of carbohydrate consumed is particularly important as rapidly absorbed refined carbohydrates can exacerbate hypertriglyceridaemia. Patients with raised triglycerides should be encouraged to choose wholegrains and carbohydrates with a low glycaemic index. Replacing fat energy with carbohydrate energy is associated with a decrease in HDL cholesterol of the order of 1 mmol/L per every 10% of energy from dietary fat that is replaced (Durrington, 2007).

Soluble fibre

Water soluble fibre (psyllium, guar, oat bran and pectin) reduces total and LDL cholesterol (Anderson & Hanna, 1999; Brown *et al.*, 1999; Truswell, 2002; Castro *et al.*, 2005), whereas insoluble fibre has no effect. An increase in soluble fibre intake of 5–10g/day can reduce LDL cholesterol by 5%. In the USA, the Adult Treatment Panel III guidelines recommend a daily intake of 5–10 g of viscous (soluble) fibres (NIH, 2002). In the UK, cereals are the most practical source of soluble fibre (especially whole oats and barley), followed by nuts and legumes. Some fruit and vegetables (okra, aubergine, citrus fruit, apples, bananas, cabbage, carrots, avocado and dried fruit) are good sources.

Obesity

Overweight and obesity are associated with elevated LDL cholesterol, hypertriglyceridaemia and decreased HDL cholesterol (Hecker *et al.*, 1999). Visceral obesity exaggerates lipid changes as a consequence of insulin resistance (Chan *et al.*, 2004; Carmena *et al.*, 2001). For every 1% above desirable body mass index (BMI), the risk of CHD increases by 3.3% for women and 3.6% for men (Anderson & Konz, 2001). Reviews of weight loss studies predict a drop in cholesterol of 0.23 mmol/L for every sustained 10 kg weight loss in obese and severely obese individuals (Poobalan *et al.*, 2004). Reductions in total cholesterol, LDL cholesterol and triglycerides of 1–1.3%, 0.7% and 1.6–1.9%, respectively, per kilogram of weight lost have also been reported (Anderson & Konz, 2001; Aucott *et al.*, 2011). A modest, sustained weight loss of 5–10% of body weight can therefore confer significant benefit (Aronne & Isoldi, 2007). Weight loss that is achieved through exercise is more effective at raising HDL levels than energy intake restriction (Rashid & Genest, 2007) (see Chapter 7.13.1).

Alcohol

Alcohol is a common cause of hypertriglyceridaemia and can also exacerbate existing hypertriglyceridaemia (Durrington, 2007). Complete alcohol avoidance over a month should bring about a significant reduction in triglyceride level and lifelong abstinence may be necessary. Moderate alcohol consumption produces a small increase in serum HDL cholesterol (0.03–0.05 mmol/L) regardless of its source and epidemiological studies have demonstrated a

reduction in CHD incidence (Durrington, 2007). The effect is insufficient to justify alcohol intake in those who currently abstain.

Plant sterols and stanols

Plant sterols are chemically similar to cholesterol and perform similar functions in plants (see Chapter 5.2). They are found naturally in vegetable oils, nuts, seeds and grains, with a typical diet containing 146–405 mg, although vegetarian intakes are significantly higher (Cassidy & Dalais, 2003). Both plant sterols and their hydrogenated form (stanols) decrease the absorption of dietary cholesterol and biliary cholesterol by displacing cholesterol within micelles. The unabsorbed cholesterol is eliminated in the faeces along with virtually all the plant sterols and stanols. This inhibition of cholesterol absorption results in a compensatory increase in cholesterol synthesis; however, the overall effect is a reduction in circulating LDL cholesterol of up to 10% within a 2–3-week period.

The effect is dose responsive, with an optimal intake of 2.0–2.5 g/day, but no significant additional effect on cholesterol reduction above 3.0 g/day (Katan *et al.*, 2003; Hallikainen *et al.*, 2000). The health claim '*Plant sterols and plant stanol esters have been shown to lower/reduce blood cholesterol. High cholesterol is a risk factor in the development of coronary heart disease,*' has been approved for fortified foods (fat spreads, yoghurts, milks, cheese) (EFSA, 2010). Since plant sterols and stanols work by mixing with foods within the gut, fortified foods should be taken at meal times.

Plant sterols and stanols can also reduce the absorption of fat soluble vitamins; however, this can easily be compensated for by a diet rich in fruit and vegetables. Foods fortified with sterols/stanols are not recommended in individuals without hypercholesterolaemia or in pregnant and breastfeeding women unless medically advised. Plant sterols are contraindicated in sitosterolanaemia, a very rare metabolic lipid condition estimated to affect only 80–100 people in the world.

Soya protein

Soya is low in saturated fat and cholesterol, is a good source of high quality vegetable protein, dietary fibre, vitamins, minerals and phytonutrients, and has a low glycaemic index. A number of systematic reviews have demonstrated that soya protein can reduce LDL cholesterol (Reynolds *et al.*, 2006; Harland & Haffner, 2008; Zhan & Ho, 2005, Anderson *et al.*, 1995) via two separate mechanisms. First, soya protein is thought to interfere with LDL cholesterol synthesis; second, the inclusion of soya protein alternatives in the diet can result in the displacement of both saturated fat and cholesterol from animal proteins. Together these effects have been estimated to lower LDL cholesterol by up to 10.3% (4.3% intrinsic and 6.0% displacement) (Jenkins *et al.*, 2010). A recent systematic review and meta analysis of 39 studies has shown that even modest intakes of soya proteins (15–25 g) can result in significant reductions in

cholesterol of approximately 6% (Harland & Haffner, 2008).

Nuts

Tree nuts (almond, Brazil, beechnut, cashew, hazelnut, macadamia, pecan, pistachio and walnut) and peanuts (a legume) are rich in energy, with approximately 75% of the energy from fat (predominately monounsaturated). The saturated fat contents are relatively low (approximately 10% of energy) and should not discourage consumption. Epidemiological studies have associated the frequency of nut consumption with a reduced risk of CVD. A pooled analysis of studies identified a dose–response effect with a 35% risk reduction for CHD for those eating the most nuts (Kris-Etherton *et al.*, 2008). Studies of almonds, peanuts, pecans and walnuts have shown a LDL cholesterol lowering effect of 2–19% (Mukuddem-Petersen *et al.*, 2005). The ability of nuts to lower cholesterol may only be partly explained by their favourable lipid profile (Mukuddem-Petersen *et al.*, 2005, Ros *et al.*, 2010, Nash & Nash, 2008). Concerns over the potential of nuts to cause weight gain could be misplaced as several studies have failed to identify weight gain as a consequence of regular consumption (St-Onge, 2005; Higgs, 2005).

Physical activity

Regular physical activity has beneficial effects on lipid metabolism in overweight and obese individuals, and these are independent of weight loss (Shaw *et al.*, 2006). Increasing aerobic activity has been shown to improve lipid profiles in overweight children and teenagers (Kelley & Kelley, 2007a), adults (Durstine *et al.*, 2001) and older adults (Kelley *et al.*, 2005). Beneficial effects have been shown in both primary (Karmisholt *et al.*, 2005) and secondary (Kelley *et al.*, 2006) prevention and in people with diabetes (Kelley & Kelley, 2007b).

Smoking

Smoking suppresses levels of HDL cholesterol and increases LDL oxidation.

Dietary regimens

Mediterranean diet

The Mediterranean diet describes a pattern of eating that is high in monounsaturated fatty acids (from olives and olive oil), rich in fruit, vegetables, whole grain cereals, low fat dairy products, fish, poultry, nuts and pulses with moderate alcohol consumption and is relatively low in red meat. This dietary pattern was first described in the 7 Countries Study when differences in mean age, blood pressure, serum cholesterol and smoking habits were shown to explain 80% of variance of death from CHD in a 15-year observational study of over 11,000 middle aged men (Keys *et al.*, 1986). Adherence to a Mediterranean style diet is consistent with a reduced prevalence and progression of metabolic syndrome, and favourable improvements in components of metabolic

syndrome, e.g. HDL cholesterol, triglycerides, blood pressure, blood glucose and waist circumference (Kastorini *et al.*, 2010).

Portfolio diet

A number of individual dietary components have been shown to have an additive cholesterol lowering effect. The portfolio diet combines specific daily quantities of these (14–23g of almonds, 1g of plant sterols, 22.5g of soya protein and 10g of soluble fibre per 4.2MJ (1000kcal), together with a low saturated fat diet (<7% energy), low dietary cholesterol (<200mg) and 5–10 portions of fruit, vegetables and pulses (Jenkins *et al.*, 2006). Reductions in cholesterol of up to 35% have been demonstrated in metabolic studies (Jenkins *et al.*, 2003a). In free living populations, average cholesterol reductions of 12–14% were observed. The percentage cholesterol reduction was linked to the degree of adherence to the diet (Jenkins *et al.*, 2006; 2011), with one-third achieving a >20% reduction in LDL cholesterol at 1 year (Jenkins *et al.*, 2006).

Ultimate Cholesterol Lowering Plan

The Ultimate Cholesterol Lowering Plan (UCLP) combines a step by step approach to cholesterol lowering with motivational interviewing techniques. It is a modified portfolio diet that encourages patient compliance through discussion, patient choice and commitment to a range of small dietary changes. The baseline diet (<10% of energy from saturated fat; five portions of fruit and vegetables, one of pulses and two of fish, one of which is oily) can be enhanced by including one or more of the four cholesterol lowering food types (15–25g of soya protein, 1.5–2.4g of plant sterols/stanols, 30g of nuts and 15–20g of soluble fibre).

Diagnosis, classification and management

Blood biochemistry

A full lipid profile, using venous blood serum, is necessary to aid diagnosis and management of lipid disorders. This should include the follow serum measurements:

- Total cholesterol (mmol/L).
- HDL cholesterol (mmol/L).
- LDL cholesterol (mmol/L) (by Friedwall calculation) or non-HDL cholesterol.
- Total to HDL cholesterol ratio (by calculation).
- Triglycerides – levels are raised following a meal so measurements should be made in a fasting state.
- Apolipoproteins – depending on the clinical circumstances.

Cholesterol targets are shown in Table 7.14.12.

Screening is often carried out at events, in primary care and pharmacies; however, this relies on trained staff using regularly calibrated portable point of care testing equipment and capillary samples of blood. Therefore, screening is only helpful to highlight those who may be at higher risk of dyslipidaemia and a full fasting lipid profile is still

Table 7.14.12 Cholesterol targets (NICE, 2010a; Joint British Societies, 2005)

	Individuals at low risk	Secondary prevention or individuals at high risk* of cardiovascular disease (CVD)
Total serum cholesterol	<5 mmol/L	<4 mmol/L (or a 25% reduction)
LDL cholesterol	<3 mmol/L	<2 mmol/L (or a 30% reduction)
HDL cholesterol		>1.0 mmol/L (men) >1.2 mmol/L (women)

*Individuals with CVD, diabetes, other atherosclerotic disease or an absolute risk of CVD of 20% or more over 10 years.

required to aid diagnosis and management. Home testing kits are not recommended due to their variable results.

Monitoring

Small variations in cholesterol and triglyceride resulting from changes in diet can be difficult to demonstrate due to the variability in many factors including:

- Normal variation in testing of approximately 7% (i.e. a mean total cholesterol of 6.5 mmol/L can fluctuate by ± 0.5 mmol/L).
- Menstrual cycle (cholesterol and triglycerides peak mid cycle).
- Seasonal variations (highest in winter and lowest in summer, perhaps reflecting changes in diet and body weight).
- Interlaboratory variations.
- Illness or trauma (can reduce cholesterol and raise triglycerides).

Clinical features

Dyslipidaemia is usually symptomless and can therefore go undiagnosed; a heart attack may be the first symptom. Specific signs and symptoms usually only occur if the increase in lipid level is severe over a prolonged period. Very high cholesterol levels may result in:

- *Xanthomata* – small soft deposits of cholesterol, sometimes seen as a uniform thickening of the Achilles tendon or as nodules in the tendons of the fingers (tendon xanthomata). Palmar xanthomata may be seen as yellow lines in the creases in the palm of the hand. Tuberoso xanthomata occur in the form of masses around the elbows or knees.
- *Corneal arcus* – a white ring visible around the iris of the eye.
- *Xanthelasma* – small soft yellow deposits of cholesterol and other fatty substances found in the skin, often on the eyelids.

Very high triglyceride levels may result in:

- *Small yellow papules with a faint red halo* – often found on the skin of the buttocks, thighs and elbows.

Table 7.14.13 Fredrickson classification of dyslipidaemia

Phenotype: Fredrickson type	I	Ila	Ilb	III	IV	V
Increased lipid fraction	Chylomicrons	LDL	LDL and VLDL	IDL	Triglycerides	VLDL and chylomicrons

LDL, low density lipoprotein; VLDL, very low density lipoprotein, IDL, intermediate density lipoprotein.

Table 7.14.14 Aetiological classifications of dyslipidaemia

Elevated cholesterol	Familial hypercholesterolaemia (FH) – single gene alteration Polygenic hypercholesterolaemia – influenced by several genes
Elevated triglycerides	Familial lipoprotein lipase deficiency (familial hypertriglyceridaemia) – single gene Polygenic hypertriglyceridaemia – influenced by several genes
Elevated cholesterol and triglycerides	Familial combined hyperlipidaemia (FCH) Familial dyslipoproteinaemia (broad beta disease) is an additional but rare type

- *Lipaeemia retinalis* – plasma lipids visible in the retinal veins and arteries.
- *Acute pancreatitis* – sudden onset inflammation of the pancreas.
- *Hepatosplenomegaly* – enlargement of the liver and spleen.

Classification of primary (familial) dyslipidaemia

The classification and definitions of dyslipidaemia vary. Historically, primary disorders of lipid metabolism were categorised on the basis of the type of lipoprotein fraction that is raised (Frederickson classification), as shown in Table 7.14.13. While this is still used occasionally, a method of classification based on aetiology (genetic cause and the type of lipid raised) is recommended (Table 7.14.14).

Elevated cholesterol

Familial hypercholesterolaemia

Familial hypercholesterolaemia (FH) has a prevalence of 1 in 500 people and is caused by an autosomal dominant gene. It dramatically increases the risk of premature CHD before the age of 50 years (and may be as early as 20–40 years), accounting for 5–10% of early CHD deaths (Holmes *et al.*, 2011). If untreated, sufferers are eight times more likely to die from CHD, but when treated early they will have a normal lifespan (Holmes *et al.*, 2011). It is usual for LDL cholesterol levels to be raised from birth and these are two to three times higher than normal.

Carriers of this gene have fewer LDL receptors, which normally take LDL out of the blood, on the surface of liver

cells, or their functionality is reduced. Most people have heterozygous FH but one in a million have a more severe form (homozygous or compound heterozygous FH). In the latter cases, plasma cholesterol levels may be as high as 20–30 mmol/L.

Familial hypercholesterolaemia is often accompanied by xanthomata and corneal arcus in undiagnosed individuals. Diagnosis of FH relies on the Simon Broome criteria and/or genetic testing (NICE, 2008). Children from affected parents should be tested early, ideally between 2 and 9 years of age. Treatment with a statin can be started as early as childhood, although some patients are not responsive to statins.

Polygenic hypercholesterolaemia

Polygenic hypercholesterolaemia is common and is characterised by raised total and LDL cholesterol levels (with normal HDL cholesterol and triglyceride levels). Clinical signs such as xanthomas are rare and LDL cholesterol is elevated to a lesser extent. Polygenic hypercholesterolaemia results from several genetic factors and their interaction with environmental, largely nutritional, factors (see Chapter 5.1). Treatment is based on overall cardiovascular risk.

Elevated triglycerides

Familial lipoprotein lipase deficiency

Familial lipoprotein lipase deficiency (LPLD) has a prevalence of 1 in 1000000. Severe hypertriglyceridaemia results from a congenital deficiency (autosomal recessive) of the lipoprotein lipase gene and is characterised by the presence of chylomicrons in fasting plasma. Levels of triglycerides are raised from childhood, but the condition may not be picked up until adulthood. Symptoms include recurrent abdominal pain, eruptive xanthomata and attacks of acute pancreatitis. Most medications have only modest benefits. The main treatment is a low fat diet (20–40 g/day) but occasionally restrictions to 10 g of fat or less may be required. Medium chain triglycerides (MCTs) should be consumed with caution as they can exacerbate triglyceride levels (Durrington, 2007). At very low fat intakes, supplements of essential fatty acids and fat soluble vitamins are required. Sufferers are at risk of developing type 1 diabetes.

Polygenic hypertriglyceridaemia

This is a group of disorders in which a genetic disposition interacts with environmental factors such as diet; the prevalence is 1 in 100. Plasma triglycerides are elevated with a normal to slightly elevated cholesterol. Reduction

of body weight is a key element of management; fish oils may also be prescribed.

Severe polygenic hypertriglyceridaemia (chylomicronaemia syndrome)

This is characterised by a gross accumulation of triglyceride rich VLDL and chylomicrons, and has a prevalence of 1 in 50–100 000; cholesterol is moderately elevated. Uncontrolled diabetes mellitus is often the precipitating factor in those who already have the genetic predisposition.

Elevated cholesterol and triglycerides

Familial combined hyperlipidaemia

Familial combined hyperlipidaemia (FCH) is a common disorder (prevalence 1 in 100) characterised by raised levels of VLDL triglyceride and LDL cholesterol, and low HDL cholesterol. The condition is associated with an increased risk of CHD and is usually diagnosed in adulthood. Environmental factors appear to play a significant

role in its expression as people with FCH are often hypertensive and overweight, and may be insulin resistant, have diabetes or gout.

Familial dysbetalipoproteinaemia (broad beta disease, remnant removal disease, floating beta disease, Fredrickson type III)

This is a rare polygenic disorder (prevalence is <1 in 5000) in which abnormal IDL accumulates. This results in the accumulation of broad beta-lipoprotein that carries roughly equal amounts of cholesterol and triglyceride. Intermittent claudication and CHD are equally common symptoms (Durrington & Sniderman, 2005).

Secondary (acquired) dyslipidaemias

Secondary dyslipidaemias can mimic primary dyslipidaemias and have similar consequences, resulting in increased risk of premature CVD or (in the case of high levels of triglycerides) pancreatitis (Table 7.14.15). Treatment of

Table 7.14.15 Conditions and drugs commonly associated with changes in lipid levels (Durrington & Sniderman, 2005)

Condition	Raised cholesterol	Raised triglycerides	Reduced HDL
Obesity	X	X	
Excess alcohol intake		X	
Diabetes, metabolic syndrome		X	X
Hypothyroid	X	X

Amiodarone (antiarrhythmic agent)	X		
Antipsychotic drugs, e.g. olanzapine, clozapine	X		

HDL, high density lipoprotein.

the underlying condition or discontinuation of the offending drugs usually leads to an improvement in the dyslipidaemia. Specific lipid lowering therapy may be required in certain circumstances.

Diabetes and metabolic syndrome

Patients with metabolic syndrome and diabetes are at increased CHD risk with insulin resistance resulting in increased lipid levels. Dyslipidaemia in diabetes and metabolic syndrome is characterised by raised triglycerides, low HDL cholesterol and increased small dense LDL particles. Dyslipidaemia is often present in type I diabetes but HDL levels may be increased or normal (Durrington & Sniderman, 2005).

Drug treatment

Lipid lowering drugs are being increasingly used in the treatment of dyslipidaemia, in patients with established CHD or those at significant risk of developing CHD. They include statins, fibrates and cholesterol absorption inhibitors.

Statins (HMG CoA reductase inhibitors)

Statins are now routinely prescribed for the management of dyslipidaemia and have been shown to significantly reduce the risk of vascular events in those at high risk (Durrington & Sniderman, 2005). Statin therapy is considered cost effective once the absolute risk of CVD exceeds 20% over a 10-year period (equivalent to a CHD risk of 15% or more over 10 years) (NICE, 2010b). Statins reduce LDL cholesterol levels by up to 60% by blocking the enzyme (HMG CoA reductase) in the cholesterol production pathway in the liver. Reduced endogenous cholesterol production causes the liver to take up more cholesterol from the blood by activating the LDL receptor genes. This increases the number of LDL receptors on the surface of the liver, which in turn increases uptake and consequently lowers LDL cholesterol levels. A reduction in blood cholesterol levels occur after 4–6 weeks and longer periods are needed to reduce tissue levels. Statins also help to stabilise atheroma, improve endothelial function and have anti-inflammatory, antioxidant and antithrombotic effects. They can increase HDL cholesterol by about 5% and moderately lower triglycerides.

Statins are generally well tolerated and relatively free of side effects. Occasionally, side effects such as muscle related pain (myopathy) have been reported at higher statin doses. This is usually related to an increase in the muscle enzyme creatinine kinase (CK); elevations of CK (over 10 times normal) should be investigated.

In the UK, atorvastatin, simvastatin, pravastatin, fluvastatin and rosuvastatin are available. Clients taking simvastatin or atorvastatin need to avoid or restrict their intake of grapefruit juice, respectively, as it reduces metabolism and therefore potentiates their effects.

Fibrates

These drugs, e.g. bezafibrate and gemfibrozil, are generally used for mixed dyslipidaemias, and are often used in conjunction with statins in diabetic patients where serum triglycerides are significantly raised. They are effective in reducing triglycerides (by reducing VLDL), improving LDL quality and increasing HDL cholesterol.

Cholesterol absorption inhibitors

Cholesterol absorption inhibitors, e.g. ezetimibe, act at the brush border of the small intestine and prevent the absorption of cholesterol; their cholesterol lowering ability is approximately 18% (Reckless & Morrell, 2005). They are often prescribed when statins are not tolerated or alongside a lower statin dose.

Other drug treatments

Other classes of lipid lowering drugs available include:

- *Nicotinic acid (niacin)* – inhibits triglyceride breakdown and the release of free fatty acids from adipose tissue. It is used to treat hypertriglyceridaemia and mixed dyslipidaemias.
- *Resins or bile acid sequestrants (cholestyramine, colestipol)* – used widely to treat hypercholesterolaemia before statins are prescribed, but were poorly tolerated. A non-absorbed lipid lowering polymer (olesevelam) is better tolerated.
- *Omacor (EPA and DHA)* – has beneficial effects on serum triglyceride levels, but may be poorly tolerated at the high dosage required (2–4 g).
- *Fish oil* – can be prescribed, but >10 mL is needed to provide sufficient EPA and DHA to lower triglycerides. This amount can lead to unacceptable intakes of other fatty acids and dioxins, as well as unpleasant fish odours.

Low density lipoprotein apheresis

Apheresis involves whole blood undergoing a procedure via an external machine, in a manner similar to renal dialysis, on a regular basis so that LDL cholesterol is extracted. It may be used where cholesterol levels remain high or are resistant to statins; however, this technique is not widely available in the UK.

Dietary treatment

A summary of dietary advice for the management of dyslipidaemias is shown in Table 7.14.16. Table 7.14.17 summarises the evidence for the use of dietary interventions.

Drug–nutrient interactions

Grapefruit juice reduces the metabolism of simvastatin and atorvastatin, and therefore potentiates their effects.

Table 7.14.16 Summary of dietary advice for the management of dyslipidaemia

Raised total and LDL cholesterol (with normal HDL cholesterol and triglyceride levels)	Moderately raised triglyceride levels (with normal total, LDL and HDL cholesterol levels)	Raised total and LDL cholesterol and raised triglyceride levels	Low HDL cholesterol
Reduce saturated fat intake Partial substitution of saturated with polyunsaturated and monounsaturated fats, to a level of energy intake appropriate for body weight Encourage the consumption of foods that actively lower cholesterol Moderate intake of dietary cholesterol only if excessive and in familial hypercholesterolaemia if failing to achieve target levels	If obese, weight loss is the overriding treatment priority Energy reduction should come from a reduction in saturated and total fat, and refined carbohydrate, and activity should be increased Remaining carbohydrates should be from more complex sources, especially those with a low glycaemic index Encourage oily fish Reduce or avoid alcohol intake	If obese, weight loss is the overriding treatment priority Reduce saturated and total fat intake Partial substitution with polyunsaturated and monounsaturated fats to a level of energy intake appropriate for body weight Encourage the consumption of foods that actively lower cholesterol Replace high intakes of refined carbohydrates with more complex sources of carbohydrate, especially those with a low glycaemic index Reduce or avoid alcohol Moderate intake of dietary cholesterol if excessive	Modest alcohol intake (1–3 units/day) is acceptable Ensure that total fat intake is not reduced too low, i.e. that some saturated fats are replaced with monounsaturated fats If polyunsaturated fat intake is high, partially substitute with monounsaturates Stop smoking (this depresses HDL cholesterol) Encourage physical activity

Table 7.14.17 Current scientific evidence to support dietary recommendations for total fat and fatty acid intake in adults (FAO/WHO, 2008)

	Convincing	Probable	Possible
Total fat		No relation with CHD events or fatal CHD	
Saturated fatty acids (SFAs)	Increases LDL and TC:HDL ratio when compared to PUFA and MUFA		Increases risk of diabetes
Monounsaturated fatty acids (MUFAs)	Decreases LDL and TC:HDL ratio when substituted for SFA		Reduces risk of metabolic syndrome
Total polyunsaturated fatty acids (PUFAs)	Decreases LDL and TC:HDL ratio when substituted for SFA Reduces risk of CHD events		Reduces risk of metabolic syndrome Increases lipid oxidation with high consumption especially if vitamin E intake is low
n-6 PUFA	Decreases LDL and TC:HDL ratio when substituted for SFA Reduces risk of CHD events	Reduces risk of metabolic syndrome	
n-3 PUFA	Reduces risk of CHD events (DHA and EPA)		Decreases risk of total CHD events and stroke
<i>Trans</i> fats	Lowers HDL and increases TC:HDL ratio in comparison to SFA, MUFA and PUFA Increases risk of CHD events	Increases risk of metabolic syndrome Increases risk of fatal CHD and sudden cardiac death	

CHD, coronary heart disease; TC, triglyceride; HDL, high density lipoprotein; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

7.14.4 Hypertension

Karin Harnden

Key points

- Hypertension is a major risk factor for cardiovascular disease; it greatly increases the risk of premature death from coronary heart disease and stroke.
- Over 29% of the adult UK population has hypertension or is on antihypertensive medication.
- Obesity, physical inactivity, high salt intake and excessive alcohol consumption are major contributory factors to the development of hypertension.
- Hypertension should be treated in the context of overall cardiovascular risk.
- Diet and lifestyle modification is an integral part of the management of all hypertensive patients, whether on drug therapy or not.

Hypertension (high blood pressure) is a major risk factor for stroke, myocardial infarction (MI), heart failure, chronic kidney disease, peripheral vascular disease, cognitive decline and premature death (NICE, 2011). Globally, about 51% of strokes and 45% of cases of coronary

heart disease (CHD) are estimated to be attributable to high systolic blood pressure (WHO, 2009). In people with diabetes, hypertension significantly increases the risk of both cardiovascular and microvascular complications, particularly diabetic nephropathy. Hypertension is one of

the most important preventable causes of premature morbidity and mortality worldwide (NICE, 2011). Hypertension is responsible for 13% of global mortality (WHO, 2009).

Definition

Blood pressure is a measurement of the force exerted by the blood circulating in the arteries. The force with which the heart pumps blood, the diameter of the blood vessels and the volume of circulating blood influence blood pressure. When taking a blood pressure reading two figures are recorded:

- Systolic pressure (SBP) – the force during contraction of the heart ventricles.
- Diastolic pressure (DBP) – the blood pressure during relaxation of the heart ventricles.

The pressures are measured in millimetres of mercury (mmHg) and expressed as systolic/diastolic. Readings vary from day to day, and repeated measurements on two or more separate occasions are necessary to establish the usual blood pressure for an individual. Twenty-four hour ambulatory blood pressure monitoring (ABPM) is increasingly being used to confirm the diagnosis of hypertension.

Definitions of normal and abnormal blood pressure are summarised in the British Hypertension Society Guidelines (Williams *et al.*, 2004) and updated in the National Institute for Health and Care Excellence (NICE, 2011) guidelines on the clinical management of primary hypertension in adults, as shown in Table 7.14.18. Similar guidance has been produced by European and WHO expert committees (Mancia *et al.*, 2007; Subcommittee, 1999). In healthy adults, optimal systolic blood pressure is considered to be below 120 mmHg and diastolic pressure below 80 mmHg (120/80). Hypertension is usually symptomless and often only discovered as a result of routine health screening or when overt signs of cardiovascular disease (CVD) develop.

Table 7.14.18 Blood pressure (BP) classification (Williams *et al.*, 2004; NICE, 2011)

Category	Systolic BP (mmHg)	Diastolic BP (mmHg)
Optimal blood pressure	<120	<80
Normal blood pressure	<130	<85
High normal blood pressure	130–139	85–89
Stage 1 Hypertension	140–159	90–99
Stage 2 Hypertension	160–179	100–109
Severe Hypertension	≥180	≥110

Ambulatory blood pressure measurement (ABPM) daytime average of >135/85 mmHg but <150/95 mmHg also required in the diagnosis of stage 1 hypertension (NICE, 2011).

Prevalence

Based on the criteria of SBP >140 mmHg and/or DBP >90 mmHg, in 2009 32.0% of men and 26.9% of women in England were hypertensive or on hypertensive medication (Health Survey for England, 2009). Prevalence rose steeply with age so that by the age of 75 years, 73.3% of men and 64.3% of women had high blood pressure. Prevalence was higher among men than women at all ages, except in the 65–75 year age group. The prevalence of hypertension in childhood is increasing (Din-Dzietham *et al.*, 2007). Raised blood pressure levels in childhood are associated with higher levels in adulthood (Chen & Wang, 2008).

There are genetic influences on blood pressure and the susceptibility to hypertension, and these may be particularly marked in some minority ethnic groups, particularly people of African-Caribbean origin (Agyemang & Bhopal, 2003). In the UK, the two main minority ethnic groups are African Caribbean and South Asian. Khan & Beevers (2005) found the prevalence of hypertension to be 2.6 times higher in the African-Caribbean population and 1.8 times higher in South Asians than in the white population. Mortality due to hypertensive complications in England and Wales is 3.5 times higher in the African-Caribbean population and 1.5 times higher in Asians than the national average (Raleigh, 1997).

Prognostic significance

Hypertension, smoking and raised blood cholesterol are the three main modifiable risk factors for CHD, and hypertension is the single biggest risk factor for stroke. People with hypertension are three times more likely to develop heart disease and stroke, and twice as likely to die from these diseases as people with normal levels (SACN, 2003). The increased risk of cardiovascular events is associated with both SBP and DBP. The risk increases progressively throughout the range of usual blood pressure, starting at about 115/75 mmHg (Chobanian *et al.*, 2003; Lewington *et al.*, 2002; Klag *et al.*, 1996). Meta analysis of prospective data from one million adults has shown that each 20 mmHg increase in usual SBP or 10 mmHg increase in DBP doubles the risk of death from CVD (Lewington *et al.*, 2002).

Reducing blood pressure, particularly SBP, significantly reduces the risk of coronary heart disease and stroke (Wang *et al.*, 2005; Turnbull, 2003; Neal *et al.*, 2000). Reducing blood pressure by 10 mmHg can reduce stroke by 41% and CHD events by 22% (Law *et al.*, 2009). In people with diabetes, treatment of hypertension also reduces the risk of diabetic microvascular complications as well as CVD (UKPDS, 1998).

Risk factors

Hypertension occurs when the vessels through which the blood flows become too narrow, or the volume of circulating blood becomes too high. Raised blood pressure increases the workload on the heart and can damage the endothelial lining of blood vessels. It also increases the

infiltration of blood components such as lipids into the arterial wall, exacerbating endothelial damage, enhancing atherosclerotic deposition and ultimately increasing cardiovascular risk.

Primary hypertension accounts for approximately 90% of cases. The remaining 10% of cases are secondary to a specific cause such as renal or liver disease, cardiac failure and pregnancy. The pathogenesis of primary hypertension remains unknown and probably results from the interaction of a number of factors, including the effects of the ageing process on renal function and peripheral resistance, genetic susceptibility and environmental influences, such as smoking, stress, diet and lifestyle. The most significant diet and lifestyle influences are considered to be (Williams *et al.*, 2004):

- Overweight and obesity.
- Excess salt intake.
- Excess alcohol intake.

Obesity

Obesity is well established as a risk factor for hypertension. The Framingham study found that hypertension is twice as likely in obese subjects (Hubert *et al.*, 1983). Blood pressures increased with increasing body mass index (BMI); SBP increased by 4 mmHg for each 4.5 kg increase in body weight (Higgins *et al.*, 1988). The Nurses' Health Study found that the incidence of hypertension was up to six times higher in those with a BMI of >29 kg/m² compared with those with a BMI of <22 kg/m² (Manson *et al.*, 1995). A more recent study showed that over half those with hypertension were obese (Ford *et al.*, 2008). Weight gain with age significantly contributes to the rise in hypertension with age (Burt *et al.*, 1995; Vokonas *et al.*, 1988; Yang *et al.*, 2007). Raised blood pressure is particularly linked to central adiposity and this association is more marked in men than women (Strazzullo, 2002; Poirier *et al.*, 2005; Benetou *et al.*, 2004; Canoy *et al.*, 2004).

Salt

Sodium, taken as dietary salt, is a major cause of raised blood pressure and the age related rise. Evidence comes from a variety of sources, including epidemiological, migration, intervention, treatment, animal and genetic studies (Sacks *et al.*, 1988; 2001; Elliott, 1991; Elliott *et al.*, 2007; Cutler *et al.*, 1997; Midgley *et al.*, 1996; Graudal *et al.*, 1998; He & MacGregor, 2010). The relationship between salt and blood pressure is direct and dose related (Denton *et al.*, 1995; Ezzati *et al.*, 2002; Sacks *et al.*, 2001). A recent meta analysis concluded that high dietary salt intake is associated with an increase in stroke and cardiovascular events; a 5-g higher daily salt intake is associated with a 23% increased risk of stroke and a 17% increased risk of total CVD (Strazzullo *et al.*, 2009).

Alcohol

Many epidemiological studies have shown a direct and linear association between alcohol consumption and

increased blood pressure, particularly with regular heavy consumption of alcohol or binge drinking (Puddey *et al.*, 1999; Klatsky *et al.*, 1977; Xin *et al.*, 2001). High levels of alcohol consumption are associated with a high risk of stroke, particularly for binge drinkers (Wannamethee & Shaper, 1996).

Management

Antihypertensive therapy can result in reductions in stroke, MI and heart failure of between 20% and 50% (Neal *et al.*, 2000). The management of hypertension has changed in recent years and blood pressure levels alone no longer determine treatment. Risk models should be used to predict likelihood of developing CHD or stroke over 10 years, taking into account gender, age, family history, diabetic status, smoking status, total cholesterol, high density lipoprotein (HDL) cholesterol and blood pressure (NICE, 2010). The NICE guidelines (2011) are:

- Pharmacological treatment should be initiated with SBP of ≥ 160 mmHg or DBP of ≥ 100 mmHg and a daytime average ABPM of $>150/95$ (stage 2 hypertension).
- When SBP is between 140 and 159 mmHg and/or DBP is 90–99 mmHg, pharmacological treatment (stage 1 hypertension) should be decided on the basis of established CVD, diabetes, target organ damage, (e.g. kidney, or an estimated CVD risk of $>20\%$ over 10 years).
- People with high normal blood pressure (130–139/85–89 mmHg) should be given diet and lifestyle advice and reassessed annually.

For most patients, optimal goals for blood pressure treatment are ≤ 140 mmHg SBP and ≤ 85 mmHg DBP. For patients with diabetes, renal impairment or established CVD, a lower target of $\leq 130/80$ mmHg is recommended.

Drug treatment

Classes of drugs that may be used include:

- *Thiazide diuretics* – inhibit sodium reabsorption from the distal tubules of the kidney, so increasing fluid loss and reducing blood volume.
- *Beta-blockers* – reduce the stimulating action of noradrenaline (noradrenaline) by blocking beta-adrenoreceptors in the heart and peripheral vasculature. Beta-blockers lower blood pressure primarily by reducing the force and rate of cardiac output.
- *Calcium channel blockers* – inhibit smooth muscle contraction in blood vessel walls.
- *Angiotensin converting enzyme (ACE) inhibitors* – reduce the production of the vasoconstrictor angiotensin II.
- *Angiotensin II receptor antagonists* – alternatives for people who cannot tolerate ACE inhibitors.
- *Alpha-blockers* – block alpha-adrenoreceptors and have vasodilatory effects.

Many of the drugs used to treat hypertension are also used in the management of CVD; therefore, the choice of drug will be influenced by the nature of any clinical

symptoms present as well as other factors such as age and renal function. Most people require more than one blood pressure lowering hypertensive drug in order to achieve optimal levels of control.

Diet and lifestyle

Guidelines on the management of hypertension emphasise the importance of diet and lifestyle changes (NICE, 2011). All people with high blood pressure should be given diet and lifestyle advice. If implemented, such measures have been shown to avoid the need for drug treatment or reduce the dosage of antihypertensive drugs required (Appel *et al.*, 1997; Whelton *et al.*, 1998). Diet and lifestyle measures may be the only form of treatment needed in people with stage 1 hypertension who have no other evidence of CVD. The effectiveness of lifestyle measures alone should be evaluated for up to 6 months.

People with borderline or high normal blood pressure should also be encouraged to adopt protective diet and lifestyle measures. These can reduce the age associated rise in blood pressure and hence delay or prevent the need for antihypertensive drugs in the future. Dietary advice should be given in the context of general cardio-protection and tailored to individual risk factors and nutritional priorities. Diet and lifestyle measures that should be strongly recommended to people with hypertension are given in Table 7.14.19.

Weight management

Weight loss, whether by dietary means or physical activity, can result in clinically significant reductions in blood pressure. A meta analysis (Neter *et al.*, 2003) concluded that a reduction in weight by energy restriction and/or increased physical activity of 1 kg would result in a fall in both SBP and DBP of 1 mmHg. The blood pressure lower-

ing effect of weight loss persists over longer periods, particularly if it is maintained (Harsha & Bray, 2008). Weight loss decreases blood pressure in both hypertensive and normotensive obese subjects, although the effect is greatest in hypertensive subjects (Staessen *et al.*, 1988).

Salt intake

A number of trials have shown the blood pressure lowering effects of salt restriction. A meta analysis by He & MacGregor (2002) of trials of more than 1-month duration showed that a reduction of 6 g of dietary salt lowered blood pressure by 7/4 mmHg in hypertensive individuals and by 4/2 mmHg in those who were normotensive; the reduction was dose responsive. The reduction in blood pressure in response to sodium restriction has been shown to be even more striking in patients with resistant (i.e. does not respond to medication) hypertension (Pimenta *et al.*, 2009). Dose–response trials have clearly demonstrated that the lower the salt intake, the lower the blood pressure (Sacks *et al.*, 2001; MacGregor *et al.*, 1989). Also, salt reduction blunts the age related rise in blood pressure (Sacks *et al.*, 2001). The fall in blood pressure with salt restriction is greatest in those of African origin, older people and those with hypertension (Vollmer *et al.*, 2001). This may partly be due to the diminished responsiveness of the renin angiotensive system in these individuals (He *et al.*, 1998).

Salt reduction can enhance the action of antihypertensive medication and reduce the need for drug therapy (Whelton *et al.*, 1998; MacGregor *et al.*, 1987). It is also additive to other dietary treatments, such as the Dietary Approaches to Stop Hypertension (DASH) diet (see later) (Sacks *et al.*, 2001) and weight reduction (Whelton *et al.*, 1998; The Trials of Hypertension Prevention Collaborative Research Group, 1997). Evidence that a reduction of salt intake has long term beneficial effects on cardiovascular outcomes has come from the 10–15 year follow-up of the Trial of Hypertension Prevention. The group that reduced their original salt intake by 25–30% (from an average of 10 g/day) had a 25% lower incidence of cardiovascular events (Cook *et al.*, 2007). A reduction of dietary salt from 10 g to 5 g/day would be expected to decrease stroke rate by 23% and CVD by 17% (Strazzullo *et al.*, 2009; Cook *et al.*, 2007; Karppanen & Mervaala, 2006).

The World Health Organization (WHO/FSA, 2010) encourages population sodium reduction strategies and has set a worldwide target for salt intake of no more than 5 g/day. A number of countries have salt reduction programmes and one of the most successful is the UK's programme. In 1994 the Committee on Medical Aspects of Nutrition (COMA) recommended a daily maximum salt intake of 6 g (Department of Health, 1994). A comprehensive review by the Scientific Advisory Committee on Nutrition (SACN, 2003) concluded that evidence for an adverse association between salt and blood pressure had strengthened, and endorsed the COMA recommendation. The National Diet and Nutrition Survey 2000/1 (Hoare *et al.*, 2004) assessed the UK average daily salt consumption to be 9.5 g, with 80% from processed foods and food eaten outside the home. The initial target was to encourage

Table 7.14.19 Lifestyle modifications to prevent and manage hypertension

Lifestyle modification	Approximate systolic blood pressure lowering (mmHg) (Aronow <i>et al.</i> 2011)
Lose weight if overweight or obese	5–20/10 kg weight loss
Reduce sodium intake to <6 g of salt/day	2–8
Limit alcohol consumption to <3 units/day for men and <2 units/day for women Less advisable if overweight Binge drinking must be avoided	2–4
Take regular aerobic physical exercise Ideally for >30 minutes/day on at least 5 days/week	4–9
Consume at least five portions/day of fruit and vegetables	
DASH diet	8–14

manufacturers to reduce salt content of processed foods on a voluntary basis. This has been successful, as the salt content of most of these foods has been reduced by 20–30%. The Food Standards Agency and Consensus Action on Salt and Health (a group of scientific experts aiming to reduce the UK salt intake) have conducted salt awareness campaigns and promoted front of pack food labelling to provide clear indications of salt content. By 2008 the average daily salt consumption in the UK had fallen to 8.5 g (Bates *et al.*, 2010). The NICE guidance (2010) on the prevention of CVD at the population level has set a target of UK daily salt consumption at <6g for adults by 2015 with a further reduction to 3g/day by 2025. Children younger than 11 years should consume substantially less than adults.

Potassium

High levels of potassium in the diet are associated with lower blood pressures (Intersalt Cooperative Research Group, 1988; Tunstall-Pedoe, 1999; Cappuccio & MacGregor, 1991; Whelton *et al.*, 1997; Geleijnse *et al.*, 2003; Dickinson *et al.*, 2006a). The blood pressure lowering effect of potassium is greater in those of African origin, in the presence of a high salt intake and in individuals with hypertension. Meta analyses do not support the use of potassium supplements (Dickinson *et al.*, 2006a). Increasing dietary potassium is recommended as treatment for high blood pressure, especially when a reduction in salt intake is not achieved (Whitworth & WHO, 2003; Williams *et al.*, 2004; European Society of Hypertension, 2003). At least five portions of fruit and vegetable should be eaten per day. Most healthy individuals can tolerate an increase in dietary potassium but care should be taken in those with certain conditions, e.g. chronic kidney disease.

Calcium and magnesium

Dietary calcium intake may have a small inverse effect on blood pressure, but studies are inconsistent (Cappuccio *et al.*, 1995). There is insufficient evidence to advocate calcium supplementation (Dickinson *et al.*, 2006b). A recent meta analysis showed that there is an inverse association between risk of elevated blood pressure and intake of low fat dairy foods, as well as with milk and yoghurt (Ralston *et al.*, 2012). The evidence linking dietary magnesium with a positive effect on blood pressure is inconsistent (Burgess *et al.*, 1999; Ma *et al.*, 1995; Mizushima *et al.*, 1998) and dietary supplementation is currently not advised (Dickinson *et al.*, 2006c).

Alcohol

In a meta analysis of 15 randomised controlled trials, Xin *et al.* (2001) found that reducing alcohol intake lowered SBP and DBP by an average of 3.3 and 2.0 mmHg, respectively. The effect was dose related with larger reductions in alcohol intake producing greater reductions in blood pressure. The effects of intervention were also greater in those with higher baseline blood pressure. Alcohol in small amounts has been shown to have cardioprotective properties and should be allowed in moderation (Power *et al.*, 1998). Alcohol should be restricted to no more

than 21 units/week in men and 14 units/week in women, with binge drinking being discouraged (Williams *et al.*, 2004). Alcohol should be taken with food as this seems to lessen the blood pressure raising effects (Stranges *et al.*, 2004).

Other dietary components

A number of other dietary components have been implicated in lowering blood pressure, although the evidence base is not strong enough for these to be incorporated into management guidelines. These include cocoa (Desch *et al.*, 2010), dietary fibre (Whelton *et al.*, 2005), fish oil (Appel *et al.*, 1993), protein (Altorf-van der Kuil *et al.*, 2010) and vitamin D (Geleijnse, 2011). There may be a U shaped relation between coffee and blood pressure levels. Coffee has been reported to lower blood pressure in both abstainers and in those with high coffee intake, and to slightly raise blood pressure (by about 2/1 mmHg) in those with medium (five cups/day) intake (Geleijnse, 2008). Liquorice consumption may raise blood pressure even at levels as low as 50g/day for 2 weeks (Sigurjonsdottir *et al.*, 2001).

Physical activity

As well as the benefits of physical activity in terms of energy balance and obesity, aerobic exercise may have direct hypotensive effects. A meta analysis of 54 randomised controlled trials found that aerobic exercise reduced SBP by an average of 3.8 mmHg, and DBP by 2.6 mmHg (Whelton *et al.*, 2002). These effects occurred in both normotensive and hypertensive individuals, and also in overweight and normal weight individuals. Aerobic exercise (brisk walking, jogging or cycling) three to five times/week can reduce SBP and DBP by 3 mmHg (NICE, 2011). However, the effect is variable, and only 30% of subjects have a reduction in SBP of 10 mmHg or more.

Isometric exercise, such as heavy weight lifting, is not recommended for hypertensive patients. However, in a recent, small meta analysis of five trials, isometric exercise of <1 hour/week lowered SBP by 10.4 mmHg and DBP by 6.7 mmHg (Owen *et al.*, 2010). Heavy physical exercise should not be recommended in severe or poorly controlled hypertension until pharmacological therapy is effective.

Multiple lifestyle interventions

In practice, advice is given to alter a number of factors to lower blood pressure. The additive effect of two or more lifestyle interventions will be less than the sum of each of the interventions applied separately (Appel *et al.*, 1997). A number of trials have incorporated multiple lifestyle interventions; the most widely studied and promoted are the DASH trials. The initial DASH diet was high in fruit and vegetables, low fat dairy foods, wholegrain cereals, nuts and seeds, with foods rich in saturated fat and refined sugar being restricted. Thus, the DASH dietary pattern increases intakes of potassium, calcium, magnesium, fibre and protein, while lowering saturated fat. When compared with a typical US diet, the DASH diet significantly lowered SBP and DBP in hypertensive and normotensive

individuals by 11.4 and 5.5 mmHg and 3.5 and 2.1 mmHg, respectively (Appel *et al.*, 1997). This reduction was achieved within 2 weeks and maintained for the remaining 6 weeks of the study. These dramatic effects were repeated in the DASH sodium trial (Sacks *et al.*, 2001), which demonstrated that restriction of dietary sodium had an additive effect on lowering blood pressure. The PREMIER trial demonstrated that the DASH diet is effective in lowering blood pressure over a longer time period and when subjects self select their food (Appel *et al.*, 2003). More recently, the ENCORE study showed that the addition of exercise and weight loss advice to the DASH diet for 4 months resulted in even greater blood pressure reductions (Blumenthal *et al.*, 2010); there was a 16.1/9.9 mmHg reduction in blood pressure with DASH and weight management, and a 11.2/7.5 mmHg reduction with the DASH diet alone. In USA (Chobanian *et al.*, 2003) and Canadian (Hackam *et al.*, 2010) national guidelines, the DASH diet is recommended for the treatment of hypertension. Harnden *et al.* (2010) have studied the use of the DASH diet in the UK.

Blood pressure response to dietary manipulation is modulated by genotype, particularly the sensitivity to sodium intake and response to the DASH diet (Svetkey *et al.*, 2011). Clear identification of the genotypes involved will have implications for focusing dietary advice.

Prevention

Reducing the prevalence of obesity and reducing salt intake would have the greatest impact on the prevalence of hypertension in the UK population; however, this will not be easy to achieve. Levels of obesity are currently increasing rather than decreasing, and the rising prevalence of childhood obesity heralds many future health problems. Designing and implementing public health strategies that lead to sustained lifestyle modifications to help prevent hypertension is an essential part of the overall strategy to meet national targets for the reduction of CHD and stroke.

7.14.5 Stroke

Fiona Jenkins

Key points

- Stroke is a major cause of morbidity and mortality in the UK.
- Malnutrition in stroke patients is associated with poor long term outcomes.
- Multidisciplinary management of stroke in designated units has been shown to improve long term survival and functional state.
- Nutritional concerns following a stroke can be broadly divided into two streams; risk of malnutrition in the acute phase and the need to provide secondary prevention advice.
- The neurological impairments of stroke can significantly impact on nutritional status and malnutrition can have a negative knock-on effect in terms of slowed recovery and capacity for rehabilitation.

Stroke is the third most common cause of death in the UK (Wolfe *et al.*, 1996) causing over 60 000 deaths each year (Allender *et al.*, 2006). Each year in the UK, over 130 000 people have a stroke (Carroll *et al.*, 2001) and a further 65 000 people will have their first transient ischaemic attack (TIA) (Scarborough *et al.*, 2009). More than 900 000 people in England are living with the effects of stroke; approximately half of these are left dependent on others for everyday living [National Audit Office (NAO), 2005]. The Stroke Association in Scotland estimates that there are 110 000 stroke survivors in Scotland living with the effects of stroke. At least 450 000 people are severely disabled as a result of stroke in England (NAO, 2005). Most strokes occur in people older than 65 years, but they can occur at any age. The mean age of men presenting with stroke is 72.6 years and of women was 78.8 years, with 49% of people who had a stroke being male and 51% female (Royal College of Physicians, 2010).

The Intercollegiate Stroke Working Party (RCP, 2008) estimated the economic impact of stroke on the English economy to be £7 billion/year, made up from:

- Direct costs to the NHS – £2.8 billion/year.
- Informal care – £2.4 billion/year.
- Lost productivity and disability costs – £1.8 billion/year.

Diagnostic criteria and classification

Strokes and TIAs are acute neurological events, presumed to be vascular in origin, that are caused by cerebral ischaemia, cerebral infarction or cerebral haemorrhage. Symptoms and signs are usually focal and can present as a sudden visual loss in a quarter or a half of the visual field,

or visual loss in one eye. Other signs that may be present include numbness, weakness or paralysis, slurred speech and visual disturbances that all develop rapidly. People with ischaemic stroke or TIA do not usually present with a headache.

When a stroke is diagnosed, the signs and symptoms remain beyond 24 hours. In a TIA, the symptoms and signs resolve within 24 hours; they can remain for a few hours but often resolve within minutes. Those with ongoing symptoms should be managed and treated on the assumption that they have had a stroke. The FAST (Face, Arm, Speech, Time) awareness campaign was launched in 2009 by the Department of Health to improve the recognition of the symptoms of stroke and TIA (www.nhs.uk/actfast).

Classification

Strokes are classified by their main causes. Nationally, the most common cause is ischaemic or infarct, occurring in 88% of cases, with the remaining 12% being primary intracerebral haemorrhage (RCP, 2010).

Ischaemic strokes

Ischaemic strokes are caused when a blood vessel in the brain becomes blocked and the cells in the part of the brain served by the affected blood vessel die from lack of oxygen and nutrients. There are two main types of ischaemic stroke:

- *Thrombotic ischaemic stroke* – caused by the interruption of blood flow to a part of the brain due to the slow formation of a blood clot along the lumen of an

artery. Such blood clots (thrombi) usually interrupt blood flow through arteries in the brain, causing damage.

- *Embolic ischaemic stroke* – part of the fatty material from an atherosclerotic plaque or a clot in a larger artery or the heart breaks off and becomes trapped in a narrower artery in the brain. Other causes of emboli are septic and air emboli. Embolic strokes are common complications of arterial fibrillation and atherosclerosis in the carotid arteries.

Haemorrhagic strokes

There are two main types of haemorrhagic stroke:

- *Intracerebral haemorrhagic stroke* – there is bleeding from a blood vessel within the brain. The main cause is high blood pressure.
- *Subarachnoid haemorrhagic stroke* – there is bleeding from a blood vessel between the surface of the brain and the arachnoid tissues that cover the brain.

Disease consequences

Immediate prognosis

The inpatient death rate for people admitted with a stroke was 24% in 2005 (NAO, 2005). The 30-day mortality rate showed a reduction from 20% in 2008 to 17% in 2010 (RCP, 2010). The risk of stroke recurring within 30 days of an ischaemic stroke was found to depend on the cause of the stroke and varied from 20% in the case of large vessel cervical or intracranial atherosclerosis with stenosis to about 1% for lacunar stroke (caused by a blockage of a small non-branching end artery deep in the brain).

Long term prognosis

Hardie *et al.* (2003) have shown that having survived 30 days after a stroke, the risk of dying in the next 10 years of a recurrent stroke was about 25%; this compared with 35% from a cardiovascular event (excluding stroke). The median survival time for people after an ischaemic stroke 6 months previously was shown to be longer in those who were previously independent in activities of daily living (Slot *et al.*, 2008). It must be remembered, however, that around half of stroke survivors are left dependant on others for everyday activities (NAO, 2005).

Diagnosis and treatment

Strokes are usually diagnosed from symptoms and the presence of risk factors. Brain imaging is important to determine whether an ischaemic or haemorrhagic stroke has occurred, as this will determine the treatment. One of the greatest advances in stroke improvement has been pharmacological. In the last decade, the use of a thrombolytic agent within the first few hours has been shown to significantly reduce the destruction of brain tissue in many cases. This consequently reduces the degree of long term disability and improves clinical outcome.

Following a cerebral infarction, the cells in the infarct core begin to die through lack of oxygen and as they do so, they release substances that damage the surrounding area. This zone of secondary damage is potentially salvageable and is known as the penumbra. The rapid destruction of the primary clot with the use of a thrombolytic agent results in the thrombus dissolving and the restoration of blood flow to the cerebral tissue that has not been irreversibly damaged, thereby preventing further evolution of the stroke and deterioration of brain tissue. Recombinant plasminogen activator (alteplase) is the only agent currently licensed in the UK for use in acute stroke. The main limitation with thrombolysis is the very short time available in which to perform the necessary tests and administer the drug. Alteplase is currently only licensed to be given within 3 hours of confirmed onset of symptoms (although in some areas this is being extended). During this time a brain scan needs to be performed and analysed; blood samples need to be analysed and results checked; and a safe environment identified in which to give the drug, which is not without complications.

In order to provide the drug in a timely manner, it is essential that there is a strict protocol involving many different organisations. The safe introduction of a thrombolytic service is only possible by promoting the rapid recognition of stroke symptoms in the community, prompt transport of patients to the acute setting and smooth efficient working within the different departments to enable early investigation, stabilisation and treatment. This high focus on stroke is essential not only for patients who receive a thrombolytic agent, but for all stroke patients. The rapid assessment of patients will facilitate all patients with a working diagnosis of stroke being transferred into the stroke care pathway. This will ensure that patients are able to access the multidisciplinary stroke specialist management found in designated units. These have been shown to improve long term survival and functional state (Department of Health, 2007). Thrombolysis should be given in accordance with the National Institute for Health and Care Excellence guidelines (NICE, 2008).

If the patient presents with a TIA and all neurological deficits have been resolved, diffusion weighted magnetic resonance imaging (MRI) or carotid imaging, bloods and electrocardiograph (ECG) should be requested and there should be referral to vascular surgeons as required. It is also important to ensure secondary prevention measures are in place (NICE, 2008), including discussion of individual risk factors. In some areas this timely access to stroke specialist assessment and imaging has been achieved via a number of different systems, including telemedicine, partnership on call rota systems across a number of organisations and the hub and spoke system. In the latter one hospital across a locality provides 24/7 hyperacute care, including thrombolysis, and the patient is then transferred to local hospitals or services for acute care and rehabilitation.

Multidisciplinary management of stroke in designated units has been shown to improve long term survival and

functional state (Department of Health, 2007). Patient centred goals, treatment and therapy plans agreed with the patient and developed in partnership with the multi-disciplinary team (MDT) will facilitate the rehabilitation of the patients post stroke. Close working within the MDT will increase the understanding of the impact of where the damage to the brain has occurred and the consequences of this with respect to the neurological impairments. For example:

- People with damage to the right side of the brain are more likely to:
 - Have perception problems – finding it difficult to recognise people, objects or their own body (visual agnosia).
 - Have spatial problems – finding it difficult to judge depth size, distance or position in space.
 - Exhibit impulsive behaviour.
 - Have left sided weakness or paralysis.
- People with damage to the left side of the brain are more likely to:
 - Have language problems.
 - Exhibit tearfulness and outbursts of anger.
 - Have right sided weakness or paralysis.

People with damage to the cerebella are likely to have problems with balance and swallowing.

Stroke can affect the patient in a number of ways and the MDT should work together to assess the impact on the individual patient, agree goals with the patient to address these and develop treatment/therapy plans to enable recovery, introduction of coping strategies or adaptations as required.

Nutritional consequences and management

Dysphagia is present in 64–90% of conscious patients in the acute phase of their stroke, with aspiration confirmed in 22–24% of cases (Mann *et al.*, 1999). Of stroke survivors, 15–20% will have significant dysphagia 1 week post stroke (Smithard *et al.*, 1997), and 1 month post stroke 2% will have persisting swallowing problems. Dysphagia can also lead to respiratory infection or pneumonia (Doggett *et al.*, 2001), undernutrition and dehydration (Whelan, 2001; Kidd *et al.*, 1995; Smithard *et al.*, 1997).

Up to 29% of patients recover their swallow and resume full oral nutrition, although this process may take up to 31 months (ESPEN, 2006). During this period of time it is important to utilise the skills of the dietitian and speech and language therapist to support the recovery and ensure that adequate intake of nutrition and fluids is maintained; considering the role of enteral nutrition and texture modification. Raising awareness of nutritional risk with all MDT members will support the recognition of malnutrition in a timely way that will enable its effective management.

Malnutrition is present in approximately 15% of cases with stroke admitted to hospital and this increases to 30% over the first week of recovery following a stroke (RCP, 2004). Gariballa *et al.* (1998) identified that malnutrition is common and worsens within the first 2 weeks after

stroke and this affects outcome. Malnutrition will impact on the patient's ability to participate in rehabilitation due to its impact on fatigue, strength and concentration, thus affecting recovery and long term outcomes.

Table 7.14.20 shows the potential complications or consequences following a stroke, the impact these may have on nutritional intake and how the dietitian can work with the patient and the other members of the MDT to reduce the impact.

Stroke quality markers

Stroke quality markers (QM) were developed as part of the National Stroke Strategy (Department of Health, 2007) as a means of raising the quality of stroke prevention, treatment, care and support, and to provide guidelines to measure the quality of stroke services. The following describes how these relate to the role of the dietitian.

QM1 Awareness raising

As part of their specialist role, staff working with stroke should be able to recognise the symptoms of stroke and know that the person should be treated as an emergency. They must ensure that this knowledge is passed on to other colleagues and members of the general public. Dietitians have a key role in primary prevention through public health nutrition.

QM2 Managing risk

Dietitians can help manage the risk of stroke by promoting healthy living by being able to assess and give information about smoking, diet, weight, alcohol and family history. Their role in secondary prevention is to provide advice with respect to diet and lifestyle, and to train other professionals. Dietitians have a key role in reducing the risk of further strokes and improving the management of conditions such as hyperlipidaemia, diabetes and hypertension as recommended in the RCP guidelines, British Hypertension Society Guidelines and Diabetes UK (see Chapters 7.14.3, Chapter 7.12 and Chapter 7.14.4). This can be delivered one to one, in group sessions, or by training other healthcare professionals to disseminate the information.

QM3 Information, advice and support

Dietitians should provide individual, specialised dietary advice and signposting to other services. In addition they should facilitate training other healthcare professionals, both in nutritional screening and the first line management of malnutrition. It is important that dietitians offer expert advice in team discussions around the ethics of artificial nutrition.

QM6 (TIA and minor stroke) Treatment

Dietitians provide information and advice for people who have had a stroke or TIA, as highlighted in QM2, and

manage other risk factors such as diabetes, hypertension and hyperlipidaemia or ischaemic heart disease.

QM8 Assessment

Patients diagnosed with stroke should receive early multidisciplinary assessment, including swallow assessment as this can impact on nutritional status, and nutritional screening to highlight those at nutritional risk and who require treatment. This includes patients who may be at risk of refeeding syndrome and treat accordingly.

By raising awareness of the impact of malnutrition on patient recovery it has been recognised for many years that malnutrition impacts on recovery of hospital inpatients. Patients with acute stroke often already exhibit a poor nutritional status on hospital admission, which negatively impacts on outcome and costs: length of hospital stay is extended; rehabilitation is delayed; and survival reduced (King's Fund, 1992; Age Concern, 2006; Axelson *et al.*, 1988; ESPEN, 2006). Dietitians can then undertake a more comprehensive assessment of a patient's nutritional status by assessing oral nutritional intake from food and fluids, thereby assessing nutritional adequacy.

Table 7.14.20 Complications and nutritional consequences of stroke, and their management

Complication and consequence of stroke	Potential nutritional impact	Dietetic and multidisciplinary team actions to reduce impact	MDT partnership working to facilitate implementation of actions
Neurological problems Balance, movement, tone, sensation	Can limit ability to self feed	Ensure appropriate seating/ positioning Adapted utensils Provide support at meal times	Physiotherapist Occupational therapist
Pain Neuropathic, shoulder pain and subluxation, musculoskeletal	Reduced appetite	Optimum pain control Use of appropriate moving and handling techniques	Medical team Nursing team Physiotherapist Occupational therapist
Mood and social interaction problems Depression, anxiety, emotionalism, disinhibition, aggression	Reduced participation in activities such as eating and drinking Reduced appetite	Complete mood assessment and ensure management plan is implemented as required	Occupational therapist Medical team psychologist Care management/social worker
Cognitive impairments Attention and concentration Memory Disturbance of spatial awareness – neglect Disturbance of perception – visual agnosia Apraxia – loss of the conceptual ability to organise activity to achieve a goal Planning, organising, initiating and monitoring behaviour, i.e. disturbances of executive functioning	Easily distracted when eating Forget to eat or what they have eaten Difficulty analysing the position of the plate Cannot recognise or define food on the plate Difficulties with self feeding or recognising cutlery Difficulty matching objects and action Food may be thrown around or played with rather than consumed	Reduce distractions as far as possible Keep food diary, written or pictorial Consider the position of the plate. Monitor and support meal times Consider adapted cutlery, plate and/or guards Errorless/kinaesthetic learning at meal times Behaviour modification techniques	Occupational therapist Psychologist Speech and language therapist Nursing team Assistants
Speech and communication difficulties Aphasia, dysarthria, apraxia of speech Acquired dyslexia	Difficulties filling out a menu or ordering food Difficulty requesting drinks Difficulty communicating thirst, hunger, food preferences	Use supported or facilitated communication, e.g. pictures, slowing down Reduce distractions Liaise with family regarding preferences	Speech and language therapist Nursing team
Visual impairments and hemianopias	Not all food will be seen, therefore not all food will be eaten	Consider where the food is positioned Support practice scanning especially at meal times	Occupational therapist Nursing team Assistants
Bladder and bowel problems Urinary incontinence, faecal incontinence, constipation	Reduced intake of fluids Reduced appetite	Monitor food and fluid intake, adapting as appropriate Support physical activity as much as possible Continence management plan developed	Nursing Physiotherapist Occupational therapist Assistants

(Continued)

Table 7.14.20 (Continued)

Complication and consequence of stroke	Potential nutritional impact	Dietetic and multidisciplinary team actions to reduce impact	MDT partnership working to facilitate implementation of actions
Swallowing and nutritional problems Oral health, malnutrition, dehydration	Poor appetite. Reduced food and drink intake (sore mouth) Reduced intake of fluids (distaste for thickened drinks) Reduced overall intake of food and drink (texture modification) Increased risk of aspiration pneumonia as a result of poor oral hygiene Difficulties in taking prescribed medication	Early multidisciplinary assessment including swallow assessment and nutritional screening to highlight those at nutritional risk and who require treatment Undertake a nutritional assessment Consider the need to achieve nutritional requirements via tube feeding, food fortification or supplementation Monitoring patients and adapting advice as required. If long term tube feeding is required, consider percutaneous endoscopic gastrostomy insertion Advise as to how to meet nutritional requirements on a texture modified diet Provide prompts to clear residue in the oral cavity and pharynx if appropriate Work with the pharmacist and medical staff to ensure that medication is prescribed in an appropriate form Reduce distractions and consider presentation of modified texture food and fluids	Speech and language therapist Nursing staff Dysphagia trained professional Pharmacist Medical staff
Sexual dysfunction	Low mood and appetite	Pharmacological interventions, counselling, advice	Occupational therapist Physiotherapist Nurse
Difficulties with activities of daily living Personal, social and vocational	Difficulties in the preparation of food and drink Reduced opportunities to purchase food and drink and go shopping Enteral feeding regimen could prevent normal activities being resumed	Assessment and treatment for remediation and adaptation as appropriate Review feeding regimen to ensure it does not adversely impact personal, social vocational activities, consider bolus feeding/overnight feeding	Occupational therapist Assistants Care management/social worker

MDT, multidisciplinary team.

QM9 (stroke) Treatment

Dietitians oversee the implementation and monitoring of nutritional screening processes and the actions arising from screening, incorporating a multidisciplinary approach to the management of dysphagia. This will ensure that patient receives in-depth assessment and appropriate treatment (Logemann, 1994). Dysphagia is a frequent and potentially serious complication of stroke (Smithard *et al.*, 1997) and in some cases may be the sole or overriding symptom (Celifarco *et al.*, 1990). All stroke patients should have access to dietetic services and be screened for their nutritional status. This includes ensuring patients

have their swallow screened within 4 hours of admission and have an ongoing management plan for the provision of adequate nutrition (NICE, 2010). There is mounting evidence, including from the FOOD Trial (Dennis, 2006) and evidence based guidelines, such as the dysphagia guidelines from the Scottish Intercollegiate Guideline Network (SIGN, 2004) and the adult nutritional support guidelines from NICE (2006) that in those patients for whom oral food and fluids are unsafe, alternative nutrition considered. If this plan includes the requirement for tube feeding, this needs to be initiated within 24 hours of admission (RCP, 2008). Dietitians advise patients

on achieving nutritional requirements via tube feeding, food fortification or supplementation, monitor patients and adapt advice as required, and advise staff, patients and carers on how to meet nutritional requirements on a texture modified diet. They also provide specialist diabetes education, especially to people who may have been undiagnosed until their admission onto the stroke unit.

QM10 High quality specialist rehabilitation

This includes rehabilitation of nutritional intake and swallowing by reviewing, monitoring and advising as clients return to oral feeding and weaning off artificial nutritional support. It may be useful to consider bolus feeding or overnight feeding to encourage patients to start eating and drinking during the day. It is also important to recognise the impact of therapy on nutritional requirements, taking into account the timing of therapy and nutritional support, the increased energy expenditure and the possible fatigue due to the therapy and the stroke. This is also the opportunity to provide secondary prevention dietary advice.

QM11 End of life care

This includes issues around oral and enteral feeding. There needs to be discussion within the MDT and with family/carers of issues at the end of life, possibly including restricting intake to keeping the mouth moist and clean, rather than other interventions.

QM12 Seamless transfer of care

This concerns the facilitation of seamless transfer of care by ensuring good communication and handover of information between colleagues working in different areas, e.g. from hospital to community, possibly across geographical boundaries.

This is especially important for those discharged from hospital on home enteral feeding in order to facilitate a safe seamless discharge. It is important to start discharge planning as soon as possible if a patient is going home on home enteral feeding. Howard & Bowen (2001) reported that for successful management of home enteral tube feeding (HETF), access to a dietitian was required to enable suitability of the feeding regimen to be monitored in the context of nutritional status. Similarly, Sayce *et al.* (2000) reported fewer feeding related complications when this was implemented. This was due in part to frequent monitoring by the dietitian. A study to assess HETF in everyday life (Liley & Manthorpe, 2003) showed that patients formed close relationships with the coordinating dietitian, with the process of HETF permitting practical and emotional support to coexist.

QM13 Long term care and support

Dietitians should provide advice and support to help individuals live as independently as possible; this includes

individuals on long term enteral feeding regimens and those with comorbidities such as diabetes.

QM14 Assessment and review

This should be a multidisciplinary review, which includes nutritional assessment.

QM17 Networks

Dietitians should be actively involved in any local, national or virtual stroke specific groups or neurodietitian groups, which will support sharing good practice, the provision of evidence based practice and clinical reasoning, and therefore the provision of high quality stroke care.

QM18 Leadership and skills

Nutrition and dietetic staff working within stroke care should have specialised skills and stroke expertise, as well as being a source of expert knowledge for others. Dietitians, like other members of the MDT, have a role in leading developments in stroke care at both local and national level, as well as providing professional support and leadership within the team.

QM19 Workforce review and development

Staffing levels for a 10 bedded unit vary between 0.3 and 0.5 whole time equivalent (WTE), with the requirement for an assistant, whether a specific dietetic assistant or stroke rehabilitation assistant, being equivalent to approximately 0.3 WTE (NAO, 2007).

QM20 Research and audit

Dietitians need to be involved in research and audit to influence the development of high quality services and measure how well their service is performing. One area to consider for research is the metabolic consequences of stroke. Dietitians are encouraged to use the British Dietetic Association (BDA) nutrition and dietetic stroke audit tool to evaluate their services and drive forward service improvements.

Stroke prevention

Risk factors

To prevent stroke or reduce the risk of further stroke it is important to moderate the risk factors where possible. These include:

- Smoking.
- Hypertension.
- Obesity.
- High cholesterol levels.
- Family history of heart disease or diabetes.
- Atrial fibrillation (which can be caused by high blood pressure, mitral valve disease, cardiomyopathy, pericarditis, hyperthyroidism, excessive alcohol intake and high caffeine intake).

The results of the national sentinel audit (RCP, 2010) gave the profile of risk factors for all strokes as:

- Vascular risk factors were present in 81% of patients.
- TIA occurred in 29% of patients.
- Hypertension was present in 57% of patients.
- Atrial fibrillation was present in 27% of patients.
- 21% of patients were on anticoagulants.
- 17% of patients were smokers.
- 8% of patients were documented as having excess alcohol consumption.

The most important causal risk factor for stroke is high blood pressure, causing about 50% of ischaemic strokes (Hankey & Warlow, 1994).

The main cause of haemorrhagic stroke is high blood pressure, the risks for which include:

- Overweight and obesity.
- Drinking excessive amounts of alcohol.
- Smoking.
- Sedentary life style.
- Stress, which may cause a temporary rise in blood pressure.
- Sometimes as the result of a traumatic head injury.

Ethnicity

Compared with the Caucasian population, African-Caribbean people are twice as likely to have a stroke. Their first stroke is also likely to occur at a younger age (Stewart *et al.*, 1999). The African-Caribbean and South Asian communities have particularly high rates of hypertension (Cappuccio *et al.*, 1997; Lane & Lip, 2001). In addition, there is variation in smoking between ethnicities that will influence risk.

Primary and secondary prevention

Measures to prevent stroke include following a healthy diet, particularly reducing salt intake and increasing fruit and vegetable intake. The result of a meta analysis of cohort studies (He *et al.*, 2006) supported the recommendation to consume more than five portions of fruit and vegetables per day. Moderating blood pressure through reducing salt intake and maintaining a healthy weight, and increasing exercise and the intake of n-3 fats through consumption of – one to two portions of oily fish per week are recommended.

Public health measures

Dietitians are working in public health projects and programmes across the community to promote a healthier lifestyle and in the longer term reduce stroke (See Chapter 4.2). It is important to address the risk factors for cardiovascular disease (CVD) both at population and individual level, working in partnership with a number of organisations including:

- Local and national government departments.
- Caterers.
- Food and drink producers.

- Food and drink retailers.
- Marketing and media industries.
- The farming sector.
- National as well as non-governmental organisations.

The NICE (2010) public health guidance on prevention of CVD is a national framework for action to address these issues. It includes the following aims:

- To reduce the population level consumption of salt, recognising that high levels of salt in the diet are linked to high blood pressure. Its recommendations include aiming for a maximum intake of 6g/day per adult by 2015 and 3g by 2025. More low salt products should be made available and low salt products should be sold more cheaply than their higher salt equivalents.
- To substantially reduce the population level consumption of saturated fats, as aiming for an average intake of 6–7% of total energy would greatly reduce CVD and deaths from CVD. This could be supported by ensuring it is viable for manufacturers and caterers to produce foods that are substantially lower in saturated fats.
- To ensure all groups of the population are protected from the harmful effects of industrially produced *trans* fatty acids (IPTFAs) by producing recommendations that include the development of UK validated guidelines and information for the food service sector and local government on removing IPTFAs from the food preparation process.
- To protect children from marketing and promotions in order to reduce the likelihood of them establishing poor eating and drinking practices. Its recommendations include the development of a comprehensive, agreed set of principles for food and beverage marketing aimed at young people based on a child's right to a healthy diet.
- To ensure dealings with government agencies and commercial sector are transparent to support public health agenda.
- To enable consumers to make informed choices by providing clear product labelling.

Drug–nutrient interactions

A number of drugs are used to prevent a stroke. Their main actions include reducing blood pressure, reducing the risk of developing blood clots and reducing lipid levels. These include statins and warfarin, which have known interactions with some foods:

- *Grapefruit and statins:*
 - Grapefruit juice can slow the breakdown of some medications. This causes an increase in the amount of the drug in the blood stream, which increases its effect. It is not clear how long this effect lasts or if it relates to grapefruit or grapefruit juice. This reaction is not associated with other juices.
 - Drinking grapefruit juice should be avoided when taking simvastatin. However, when taking another statin, such as atorvastatin, then grapefruit juice (or the grapefruit) can be taken in small quantities.

- *Fruit, vegetables, fruit juices and warfarin:*
 - Cranberry juice can increase the effect of warfarin, so should be avoided to reduce the risk of bleeding.
 - Foods high in vitamin K, e.g., brussels sprouts, broccoli and liver can stop warfarin from working. It is advised that these should not necessarily be avoided, but large quantities should only be eaten infrequently. This will have a more consistent impact on warfarin levels.

17.15.1 General aspects

Clare Shaw

Key points

- Diet is both a causative or protective environmental factor that may influence cancer development.
- Development of cancer may increase the individual's risk of becoming malnourished due to disease or treatment effects.
- Weight loss may increase morbidity and mortality associated with cancer treatment.
- Appropriate nutritional advice and/or artificial nutrition support should be an integral part of the cancer patient's treatment plan.

Cancer has been recognised as a disease for hundreds of years; it was mentioned in ancient Egyptian text. A third of the UK population will be diagnosed with cancer during their lifetime, but as treatments have been developed survival rates have increased significantly. The term *cancer* describes a wide range of malignant tumours that affect virtually every organ and tissue in the body. Cancer is a major cause of mortality and morbidity throughout the world. In Britain, approximately 309 500 new cases occur every year [Cancer Research UK (CRUK), 2011a].

In the UK, the most common cancer sites are the breast, lung, large bowel and prostate, which account for over 50% of cancer diagnoses (CRUK, 2011b). Cancer is generally a disease of increasing age with 64% of cancers occurring in those aged over 65 years. Worldwide survival rates vary greatly; this is largely dependent upon access to diagnostic and treatment services. Although incidence rates of some of the less common cancers are increasing, overall mortality rates from cancer in middle aged people are falling due to improvements in treatment (CRUK, 2012). Many cancers are also treatable if detected at an early stage and increasingly people are living with cancer; it is now recognised as a chronic disease. In the UK, for example, there are approximately 2 million cancer survivors (Maddams *et al.*, 2009). The number of people surviving has improved and for all cancers combined 5-year survival has reached 50% (CRUK, 2011c).

Definition of cancer

Cancer is essentially a consequence of genetic mutations within a cell, which result in the production and prolifera-

tion of abnormal cells. This can occur when healthy cells are damaged and undergo replication that is outside the usual control. Some of these genetic mutations are inherited, but most simply occur and accumulate over time as the result of lifestyle and environmental factors. The development of cancer is a complex, multistage process that can be summarised as:

1. *Initiation* – exposure to substances or influences (mutagens) that are capable of initiating genetic mutations. Any DNA damage caused may or may not lead to cancer.
2. *Promotion* – under the influence of promoters, damaged DNA begins to be expressed, resulting in cellular changes. Promoters thus enhance tumour development following exposure to mutagens.
3. *Progression* – a complex process leading to the development of malignant cells that have the capacity to invade other tissues.

A carcinogen is the term for a substance that may influence one or more of these stages. Only a few carcinogens can affect all three.

Cancers spread by invading surrounding tissue until they reach a blood or lymph vessel. Small groups of cells may then break off from the original tumour and be carried to other parts of the body where they may settle and grow. The new cancers that develop are called secondary cancers or metastases. Cancer is therefore not a single disease but a group of diseases; there are over 200 different types of cancer arising from different cells of the body.

Development of cancer

Much remains to be learned about the complex interplay of factors that lead to cancer development, particularly hereditary influences. About 5% of cancer cases are thought to result from inherited genetic mutations, e.g. the *BRCA1* and *BRCA2* genes in breast cancer, but even the aetiology of this form of cancer is not straightforward; not everyone with a cancer predisposing genotype develops the disease (see Chapter 5.1). Ninety-five per cent of cancer cases are defined as sporadic, meaning that it is the unpredictable consequence of a combination of genetics, environment and chance. Since little can be done to alter the influence of genetics and chance, efforts to prevent cancer have to focus on identifying and minimising the risk from factors that are modifiable, i.e. environmental influences. The main environmental factors implicated in the causation of cancer are:

- **Tobacco** – more than a quarter of all cancer deaths in the UK are thought to be tobacco related. Cigarette smoking causes nine in 10 cases of lung cancer and increases the risk of many other types of cancers, particularly those in tissues most exposed to tobacco carcinogens, i.e. cancers of the head and neck, oesophagus, stomach, kidney and bladder.
- **Diet** – can have either harmful or protective influences on cancer development depending on its composition in terms of foods, nutrients and food contaminants (see later).
- **Infection** – certain viruses can cause genetic mutations that may result in cancer development, e.g. the Epstein – Barr virus is associated with some types of lymphatic cancer and human papilloma virus appears to be closely linked with cancer of the cervix. Infection with *Helicobacter pylori* is thought to be a major factor in the development of gastric cancer.
- **Industrial pollutants** – exposure to toxic substances such as asbestos or vinyl chloride can rapidly lead to cancer. This is more of a problem in less developed parts of the world where environmental safety controls are often poor.
- **Ionising radiation** – over exposure to X rays, nuclear emissions or some other sources of radioactivity increases the risk of leukaemia.
- **Sunlight** – most skin cancers are caused by the action of radiation from sunlight on the skin.

Diet and causation of cancer

Although there is a common underlying aetiology, different factors influence the development of each type of cancer. For this reason, relationships between diet and cancer are complex and variable; dietary factors may be involved in the initiation of tumour growth (carcinogens), the promotion of growth or be protective against the development of cancer. It is thought that about half of cancer related deaths are preventable, many of them by diet and lifestyle measures.

It has long been known that many components of the diet have carcinogenic potential. Some of these result

from food contamination, e.g. aflatoxin, a potent carcinogen causing liver cancer that is produced by a mould that can grow on grain stored under inappropriate conditions. Other carcinogens such as alkaloids, benzene derivatives or N-nitroso compounds occur naturally in foods or are created during cooking or preservation processes. Alcohol may act as a carcinogen, e.g. when in contact with the tissues of the head, neck or oesophagus.

Diet may have a role to play in the promotion of tumour growth by encouraging replication of cells. This action may be caused by dietary components such as alcohol, or a high fat or high energy diet. Diet and body weight may also influence the growth of cancer cells through the promotion of hormones in the body, e.g. oestrogens in the promotion of breast cancer.

The human body has many defence systems to protect it from potentially harmful agents in its environment – both dietary and non-dietary – and to a large extent can withstand their continuous onslaught. However, the body's ability to do so depends on factors such as immune competence, integrity of mucosal barriers and levels of detoxifying enzymes, all of which are affected by diet. It is therefore not unreasonable to expect that diet is likely to be one of the factors enhancing or diminishing the risk of cancer.

In 1981 Doll & Peto suggested that about one-third of cancers in westernised countries may be attributable to dietary factors, and that as many as 70% of cancers in sites such as the large bowel, breast and prostate may be preventable by dietary modification. The evidence for this has since been comprehensively reviewed in a major report from the World Cancer Research Fund (WCRF) in conjunction with the American Institute for Cancer Research (AICR) (WCRF/AICR, 2007). The report confirmed that there are many links between diet and cancer, both causal and protective. The relationships are complex and, given the quality of the available evidence, difficult to ascertain. The effect on reducing cancer risk if dietary recommendations (Table 7.15.1) are followed is unclear, although a study of 29 564 women showed that following –six to nine of the WCRF recommendations over a 17-year period resulted in a 22% reduction in cancer risk compared with women who did not follow any recommendations (Cerhan *et al.*, 2004).

Nature of the evidence for relationships between diet and cancer

Most of the suggested associations between diet and cancer in humans are based on data from epidemiological studies, which comprised the following types of study (see Chapter 1.1, Research section):

- **Cross sectional studies** compare differences in diet and cancer prevalence, either between or within populations. These observations can provide valuable pointers but are not in themselves evidence of cause and effect as many other relevant factors, e.g. socioeconomic, demographic, genetic, cultural and environmental factors, will also differ.

Table 7.15.1 Dietary recommendations for cancer prevention [based on the World Cancer Research Fund (WCRF) report on Food, Nutrition, Physical Activity and the Prevention of Cancer: a Global Perspective (WCRF/AICR, 2007)]

Recommendation	Public health goals	Justification
Be as lean as possible within the normal range of body weight	Median adult body mass index (BMI) to be 21–23 kg/m ² depending on the normal range for different populations Level of overweight/obesity to be no more than the current level, or preferably lower, in 10 years	Maintenance of a healthy weight throughout life may be one of the most important ways to protect against cancer
Be physically active as part of everyday life	The proportion of the population that is sedentary to be halved every 10 years Average physical activity levels >1.6	Most populations, and people living in industrialised and urban settings, have habitual levels of activity below levels to which humans are adapted
Limit consumption of energy dense foods Avoid sugary drinks	Average energy density of diets to be lowered towards 125 kcal/100 g Population average consumption of sugary drinks to be halved every 10 years	Consumption of energy dense foods and sugary drinks is increasing worldwide and is probably contributing to the global increase in obesity
Eat mostly foods of plant origin	Population average consumption of non-starchy vegetables and of fruit to be at least 600 g (21 oz)/day Relatively unprocessed cereals (grains) and/or pulses (legumes), and other foods that are a natural source of dietary fibre, to contribute to a population average of at least 25 g/day of non-starch polysaccharide	An integrated approach to the evidence shows that most diets that are protective against cancer are mainly made up from foods of plant origin
Limit intake of red meat and avoid processed meat	Population average consumption of red meat to be no more than 300 g (11 oz)/week, very little if any of which to be processed	An integrated approach to the evidence also shows that many foods of animal origin are nourishing and healthy if consumed in modest amounts
Limit alcoholic drinks	Proportion of the population drinking no more than the recommended limits to be reduced by one-third every 10 years	The evidence on cancer justifies a recommendation not to drink alcoholic drinks. Other evidence shows that a modest amount of alcoholic drinks is likely to reduce the risk of coronary heart disease
Limit consumption of salt Avoid mouldy cereals (grains) or pulses (legumes)	Population average consumption of salt from all sources to be <5 g (2 g of sodium/day) Proportion of the population consuming >6 g of salt (2.4 g of sodium)/day to be halved every 10 years Minimise exposure to aflatoxins from mouldy cereals (grains) or pulses (legumes)	The strongest evidence on methods of food preservation, processing and preparation shows that salt and salt preserved foods are probably a cause of stomach cancer, and that foods contaminated with aflatoxins are a cause of liver cancer
Aim to meet nutritional needs through diet alone	Maximise the proportion of the population achieving nutritional adequacy without dietary supplements	The evidence shows that high dose nutrient supplements can be protective or can cause cancer. The studies that demonstrate such effects do not relate to widespread use amongst the general population, in whom the balance of the risks and benefits cannot confidently be predicted. A general recommendation to consume supplements for cancer prevention may have unexpected adverse effects. Increasing the consumption of the relevant nutrients through usual diet is preferred
Mothers to breastfeed: children to be breastfed	The majority of mothers to breastfeed exclusively for 6 months	The evidence on cancer as well as other diseases shows that sustained, exclusive breastfeeding is protective for the mother as well as the child
Cancer survivors: follow the recommendations for cancer prevention	All cancer survivors to receive nutritional care from an appropriately trained professional. If unable to do so, and unless otherwise advised, aim to follow the recommendations for diet, health weight, and physical activity	Subject to the qualifications made in the WCRF report

- **Case control studies** look for differences between the diet of people with a particular type of cancer and that of carefully matched healthy controls. This has the advantage of creating more homogeneous study populations, but at the same time, such homogeneity in terms of age, social class, occupation, etc. also means

that dietary differences between the two groups are likely to be small, or not readily detectable given the limitations of dietary assessment methodology. Alternatively, if dietary differences are observed, it is difficult to know whether they existed in the early stages of cancer development, perhaps many years before, or

whether they are a consequence of having the disease. Any attempt to get round this problem by retrospective dietary assessment is fraught with difficulties; most people cannot remember with any accuracy what they ate 5 or 10 years previously.

- *Prospective (cohort) studies* followed people until cancer develops, thus enabling dietary comparison between those who do with those who do not develop the disease, and are particularly informative. However, they are also the most difficult and costly studies to carry out, requiring large numbers of subjects to be monitored for 10–20 years or more. The European Prospective Intervention into Cancer and Nutrition (EPIC) is a major study of this type, investigating the effect of diet, lifestyle, and genetic and environmental factors on the incidence of different forms of cancer.
- *Intervention trials* evaluate the effects of dietary change in a randomised, controlled prospective trial and can provide the clearest evidence of dietary benefit or risk. However, for reasons of cost, they are unlikely to be carried out on a sufficiently large scale, or for long enough, to evaluate the effect of major dietary manipulations, e.g. encouraging a high consumption of fruit and vegetables, on a disease such as cancer.

Animal studies are a valuable supplement to human studies to help explain the mechanisms of carcinogenesis and provide pointers to dietary influences on those mechanisms. However, animal studies ultimately cannot predict dietary risk in free living human populations where many other factors will operate.

Complexity of the relationship between diet and cancer

The interrelationship between diet and the development of cancer is complex and multifactorial. The relationships between diet and cancer are hard to unravel because of the great variability of both the disease and the dietary influences on it. Different cancers are influenced by diet to a different extent. Although all cancers stem from DNA damage, the causes and effects of that damage are very variable. Some cancers, e.g. colorectal and breast, may be strongly linked with diet and body composition; others e.g. leukaemia, have no relationships with diet at all.

Some dietary factors, e.g. non-starch polysaccharide, may be protective against one type of cancer but have no influence at all on another. Also, observed dietary relationships do not always operate in the same direction; energy intake is positively associated with the development of some cancers, e.g. breast and endometrial, but negatively with others, e.g. stomach and oesophageal. A dietary influence may be heightened or diminished by non-dietary factors, e.g. a dietary component may only become a risk factor in certain circumstances, such as a person smoking. The risk or benefit from one dietary component may be affected by the presence or absence of other dietary components, e.g. the level of risk from meat may depend on the level of consumption of protective fruit and vegetables. For these reasons, attempts to

assess whether one particular dietary component is beneficial, harmful or neutral in effect are fraught with difficulty and open to misinterpretation. Few dietary risk factors operate in isolation and it seems increasingly likely that it is the combination of harmful and protective influences from both dietary and non-dietary sources that determines the level of cancer risk. The relationships between diet and cancer are therefore based on judgement as to what the research evidence means, as reviewed by the WCRF (2007).

Diet and cancer care

Nutrition is an important aspect of the care of the person with cancer from diagnosis onwards. Many aspects of cancer can affect nutritional status, and impaired nutritional status can in turn affect the response to treatment, the amount of treatment required and the quality of life (NICE, 2004; Henry, 2011). Dietitians working in oncology have a vital role in ensuring that nutritional aspects of patient management are an integral component of multidisciplinary care and that all cancer patients receive the dietetic support they need. The National Institute for Health and Care Excellence (NICE, 2004) recommends that dietitians working in oncology are basic or advanced level practitioners, who have knowledge of the impact of the disease and treatment, and the complex needs of such patients to be able to provide the high level of care required. This criterion is subject to peer review in the NHS (NCAT, 2008). Dietitians need to work in close collaboration with other team members to meet patient needs.

Nutritional implications of cancer

People with cancer are at high risk of nutritional depletion because of the physical and psychological effects of both the disease and its treatment for the following reasons:

- A prolonged catabolic response to the presence of a tumour may occur in some cancer patients, resulting in muscle wasting and weight loss (Laviano *et al.*, 2011).
- Physical symptoms, e.g. pain, dysphagia, vomiting and diarrhoea, may impair food intake or nutrient absorption, or increase nutrient losses.
- The psychological effects of being diagnosed with cancer can result in anxiety and/or depression and impair appetite.
- Cancer treatments often result in pronounced and debilitating side effects. Gastrointestinal consequences such as anorexia, nausea, vomiting, diarrhoea, bloating, pain or cramping inevitably have an adverse effect on nutritional intake, and additional problems such as taste changes, dysphagia, infections and fistulae may further compromise nutritional status.

The risk of weight loss and undernutrition is therefore high. About 40% of cancer patients have been found to have significant protein energy malnutrition (Ravasco

et al., 2003; Bozzetti & SCRINIO Working Group, 2009) and in some high risk groups, such as head and neck cancer patients, up to 80% may have some degree of malnutrition. The adverse consequences of this in terms of postoperative recovery time, prevalence of complications and prognosis are well documented (see Chapter 6.2). In cancer patients, undernutrition may also have implications for cancer treatment because chemotherapy dosages are based on body weight and underweight patients may not be given optimum dosages (Andreyev *et al.*, 1998). A patient with muscle wasting is also less likely to be able to withstand the side effects of treatment and will develop more toxicity (Prado *et al.*, 2009).

Preventing and correcting nutritional depletion in order to maintain physical strength and quality of life for as long as possible are therefore important objectives in the care of the cancer patient. The ways in which this is achieved will vary according to the individual clinical circumstances, but primarily comprise:

- Ensuring nutritional and hydration needs are met in an acceptable and appropriate way for each individual throughout the course of the disease.
- Restoring any nutritional inadequacies that occur.
- Minimising the nutritional consequences of the symptoms and side effects of treatment.
- Instituting additional nutritional support measures if dietary intake is inadequate.
- Reviewing the effectiveness of nutritional interventions and adjusting them as necessary.

Close interaction with other members of the multidisciplinary team is essential if these objectives are to be achieved effectively (NICE, 2004; Fearon, 2008).

General aspects of the dietary care of cancer patients

Dietary care of cancer patients may range from offering healthy eating guidance for people who have successfully recovered from treatment, to the provision of total artificial nutritional support for those who are critically ill or unable to manage their full nutritional requirements. In practice, most people will require varying degrees of nutritional intervention throughout the treatment and progression of the disease. It is important to consider the whole treatment plan for the cancer patient as this may involve many weeks or months of a range of different treatments. Assessment of individual needs and problems is therefore the cornerstone of dietary management and should consider:

- *Current nutritional intake* – whether this is sufficient to meet nutritional needs.
- *Current nutritional problems* – the extent to which food and fluid intake is impaired by the physical or psychological effects of the disease or its treatment.
- *Degree of any nutritional depletion* – although to some extent compounded by the cancer process itself, the extent and rapidity of recent weight loss is an important indicator of nutritional depletion (see

Chapter 2.2). Other markers of nutritional status such as anaemia or poor immune function may also be indicative when considered in conjunction with dietary intake.

- *Likelihood of further (or future) nutritional depletion* – surgery will incur significant metabolic costs as a result of pre- and peri-operative starvation and postoperative trauma. Radiotherapy and chemotherapy often result in general disinclination to eat, as well as causing specific problems with eating or swallowing, or exacerbating pre-existing problems. The risk of nutritional depletion is particularly high in those who are already in a malnourished state.
- *Nutritional implications of specific types of cancer, consequences of surgical procedures, e.g. dumping syndrome following gastric resection, and consequences of treatment, e.g. diarrhoea or steatorrhoea following pelvic radiotherapy.* These are discussed in more detail in other chapters.

Even if no nutritional problems are identified, the importance of good nutrition should still be stressed and people encouraged to continue to meet their needs via a healthy well balanced diet. If nutritional intake is inadequate, the dietetic objectives are to:

- Increase energy and nutrient intake to meet nutritional requirements in ways that are acceptable to the patient.
- Tackle general and specific problems inhibiting food and fluid intake.
- Identify when further nutritional support measures are necessary in the context of current and future planned anticancer treatment.

In many people, energy, nutrient and fluid intake can be increased by relatively simple dietary measures which increase the frequency and the energy/nutrient density of foods and beverages consumed (see Chapter 6.3). Food enrichment measures, e.g. the addition of milk powder to milk, and adding cheese, butter or cream to foods, can also be an effective way of boosting nutrient intake. Remedial measures to help alleviate treatment side effects affecting food intake, such as mucositis, taste changes, nausea, vomiting or diarrhoea, should also be suggested (see Chapter 6.3 and the later specific cancer chapters). Adequate symptom control is also paramount for these patients.

If oral intake remains inadequate, additional supplementation in the form of sip feeds or other supplements may need to be considered. Artificial nutritional support (enteral and parenteral nutrition) may be necessary following some types of surgery or cancer treatment or in those with severe or worsening malnutrition (see Chapter 6.4 and Chapter 6.5). If the cancer progresses, then palliative measures may become the primary consideration (see Chapter 7.16).

Some oral nutritional supplements are specifically aimed at patients with cancer cachexia. They contain n-3 fatty acids, which due to their anti-inflammatory properties aim to reduce the metabolic element of cancer

cachexia whilst also providing additional energy and protein as a drink. A randomised trial in patients with pancreatic cancer failed to show that eicosapentaenoic acid (EPA) supplemented drinks were any better at slowing down weight loss than conventional high energy, high protein drinks (Fearon *et al.* 2003). Poor compliance with n-3 fatty acid supplemented drinks was a factor in the study. Additional studies in different patient groups have also failed to confirm any benefit, although the principles supporting a reduction in the inflammatory reaction produced by cancer are attractive in the management of cachexia (Murphy *et al.*, 2011).

At all stages of the disease, the dietitian has a crucial role in identifying when additional support measures are appropriate and what form these should take in order to optimise nutritional status without impairing quality of life. Social factors must also be considered in assessing nutritional needs. Those who live alone are particularly vulnerable to malnutrition when they are unwell, in pain and find it an effort to shop, cook and eat. People should be encouraged to make use of any help offered by friends and neighbours or other support services available in their community.

It is essential to provide written guidance for patients and carers, together with contact details of a dietitian or another member of the healthcare team. Patients often feel unwell at the time they talk to a dietitian and may find it difficult to remember the advice given, or later think of other questions they wanted to ask. Providing appropriate dietetic support and guidance not only helps patients feel physically better, but often also psychologically better equipped to cope with what is inevitably a traumatic phase in their lives.

Maintaining nutritional status may improve tolerance to treatment in terms of less medication needed for symptom control, a shorter period of chemotherapy induced nausea and vomiting, better tolerance of chemotherapy and fewer treatment delays (Bozzetti, 2001). All cancer patients should therefore be encouraged to regard eating well as an important component of medical care, and a positive step they can take to help maintain their health. Some patients may be at increased risk of gaining weight with treatment, e.g. breast cancer patients, and therefore may require advice on weight maintenance.

Specific aspects of dietary management during cancer treatment

Treatment for cancer usually involves surgery, radiotherapy or chemotherapy (including hormonal treatment), and sometimes a combination of all three.

Surgery

A high proportion of patients undergoing curative treatment will have surgery at some point in their treatment. Surgical removal of a tumour has a number of nutritional implications:

- Preparation for surgery involves a period of nil by mouth.

- Surgery incurs a significant metabolic cost as a result of the response to trauma.
- In all cases, there will be some delay before normal feeding is resumed. If the surgery is major or involves any part of the gastrointestinal tract, there may be considerable delay before feeding is possible via an enteral route. Surgery to the mouth, throat or digestive tract may result in prolonged problems with oral feeding (see Chapter 7.15.2).
- Surgery may result in temporary or permanent side effects that affect food intake, digestion or absorption, e.g. dumping syndrome, intestinal failure, ileostomy.

In addition, some cancer patients will undergo surgery in an already malnourished state and be particularly at risk of severe nutritional depletion. All the above factors need to be taken into account when nutritional care is being planned and may influence the following:

- Whether preoperative nutritional support is indicated, whether this is feasible and, if so, what form it should take. This may include the consideration of immunonutrition, which has been demonstrated to reduce postoperative infection in upper gastrointestinal cancer patients (Gianotti *et al.*, 2002).
- Whether peri- and post-surgical nutritional support is likely to be needed, either at an early stage or if there are delays in resumption of oral feeding or complications.
- Whether support should be total or partial.
- The extent to which the oral route will be accessible.
- Whether support is likely to be short or long term.

Practical aspects of pre- or post-operative nutritional support can be found in Chapter 6.4 and Chapter 7.17.5. As recovery progresses, every effort should be made to restore and maintain good nutritional status, if necessary by means of oral support to optimise nutritional intake. Some patients will require specific guidance to alleviate the postsurgical consequences of gastric or intestinal resection, such as dumping or intestinal failure. Arrangements should be made to ensure that after discharge from hospital the progress of any nutritionally vulnerable patient, particularly in terms of body weight and dietary intake, is monitored at either the primary or secondary care level.

Radiotherapy

This involves the use of ionising radiation within a treatment field to destroy cancer cells. Radiotherapy damages tissue because energy dissipated from ionising radiation generates a series of biochemical events inside the cell. Free radicals are formed and these disrupt DNA, preventing replication, transcription and protein synthesis. When given in combination with chemotherapy, the risk to healthy tissues may be enhanced. Individual radiation treatments, known as fractions, are usually given once daily, sometimes more often (known as hyperfractionated) or less often (hypofractionated); the radiation dose is measured in Gray (Gy). The length of treatment can

vary from a single fraction to a 7-week course of five fractions/week. Radical treatment is given with curative intent, whilst palliative treatment is usually given for symptom control, e.g. pain or shortness of breath. Common general side effects of radiotherapy include:

- Anorexia.
- Nausea.
- Fatigue.
- Reduced mood, often related to physical symptoms.

Combinations of these, together with travelling for treatment each day, can have a devastating effect on food intake. Some people will find the fatigue makes shopping, food preparation and eating particularly difficult.

The site at which the radiotherapy is targeted will determine the severity of side effects. Specific side effects of radiotherapy to particular areas of the body can further impair food intake. Radiation to the head and neck often affects the ability to eat or swallow; radiation to the pelvic area often results in abdominal cramps and diarrhoea. If steps are not taken to alleviate them, the nutritional consequences can be severe. The side effects of radiotherapy may also change during the course of treatment, e.g. patients initially experiencing dry mouth may develop a sore mouth at a later stage. Regular dietetic assessment of this patient group is therefore essential to ensure that appropriate and timely advice is given as patients may experience progressive dysphagia. The effects in particular diagnoses are considered in the following chapters. As patients proceed with radiotherapy treatment, there is a high risk of worsening morbidity and quality of life. Patients undergoing radiotherapy should have regular nutrition screening and identification of any difficulties with eating identified at an early stage in order for these to be addressed.

Chemotherapy

Chemotherapy has a systemic effect; the aim is to destroy cancer cells but normal tissue will also be affected. The consequences, and hence side effects, are worst in rapidly dividing tissues such as the lining of the mouth and gastrointestinal tract. Chemotherapy may be given with other targeted therapies, e.g. drugs that affect the growth of cancer cells by different actions. These include monoclonal antibodies that target vascular epidermal growth factor (VEGF), thereby preventing it from stimulating the growth of new blood vessels. Chemotherapy can be administered as oral tablets, a bolus, continuous infusion or combinations of these.

The number of cytotoxic drugs used to treat cancer is continually increasing and each drug has different side effects. When drugs are used in combination, the aim is to increase toxicity to the cancer cells while minimising the side effects. Nevertheless, side effects are common and those that may affect appetite and food intake include:

- Nausea and vomiting.
- Taste changes.
- Stomatitis.

- Mucositis (resulting in sore or painful mouth).
- Oesophagitis.
- Diarrhoea.
- Constipation.
- Neutropenia.

In addition to the impact on nutritional status, cytotoxic drugs may also influence certain nutrients as a result of drug–nutrient interactions. For example, methotrexate is a folate antagonist so its use may need to be accompanied by folic acid rescue; the administration of folic acid to speed recovery from methotrexate induced mucositis or myelosuppression. Pyridoxine is used to treat palmar plantar erythrodysesthesia (a painful condition affecting the hands and feet) caused by capecitabine or 5-fluorouracil chemotherapy.

Good symptom management is essential to minimise the impact on nutritional intake and nutritional status. Dietary measures that may help alleviate effects of chemotherapy, such as nausea, taste changes or sore mouth, are described in Chapter 6.3, and these should be available to patients undergoing treatment to ensure that their dietary intake and quality of life is maximised.

Endocrine therapies

Hormonal manipulation is used in the treatment of hormone sensitive cancers, e.g. breast and prostate. Cells may vary in their sensitivity to hormones such as oestrogens and progesterones, and sensitivity can be determined by the presence of cellular receptors (oestrogen receptor and progesterone receptor). Treatment interventions may include surgery, e.g. oophorectomy, or more commonly medication that blocks hormone action. For example, some endocrine therapies will block at the receptor level (receptor antagonist) or block part of the process of hormone manufacture, e.g. aromatase inhibitors or luteinising hormone releasing hormone agonists. Endocrine therapies can influence mood and cause a decrease in appetite however, in some patients weight gain may occur after diagnosis (Harvie & Howell, 2005; Parry, 2011).

Monitoring progress of cancer patients

Nutritional assessment should be an integral part of patient monitoring following cancer treatment. Some patients with complex nutritional problems will need ongoing specialist dietetic follow-up. It is essential that all members of the healthcare team are aware of the need to look for and identify emerging nutritional problems so that they can be rectified at an early stage. Appropriate guidance should be given for identified problems or patients referred for dietetic assessment and advice. Patients who are unable to maintain an adequate dietary intake may need nutritional supplementation or artificial nutritional support.

Enteral feeding may be indicated for patients with severe anorexia, dysphagia or mucositis or who have become nutritionally debilitated. In the short term, this

is usually achieved by nasogastric or nasojejunal tube, sometimes on an overnight basis. In the long term (for 4 weeks or more), it is more likely to be via gastrostomy or jejunostomy. Parenteral nutrition should only be used when use of the gastrointestinal route is contraindicated, usually for reasons such as bowel obstruction, uncontrollable vomiting or severe malabsorption.

Post recovery dietary guidance

Cancer patients are usually anxious to consume a diet that minimises the chance of disease progression or recurrence. Some may be tempted to follow one of the complementary or alternative dietary regimens promoted for cancer patients (see Chapter 5.4). People should be assured that current evidence suggests that a diet based on the principles of healthy eating, i.e. a well balanced diet relatively high in starch and fibre and low in fat, will offer the most protection. Particular emphasis should be placed on the importance of plentiful consumption of fruit and vegetables and wholegrain cereal foods. In the UK, the NHS Choices website provides appropriate up to date information on healthy eating (see Chapter 4.2) and the WCRF provides dietary guidance for cancer survivors who are able to eat well and have a normal body weight. However, this advice does not apply to patients who have eating difficulties or are losing weight. Dietary guidance for cancer protection is summarised in Table 7.15.1.

Some patients may choose to take vitamin and mineral supplements with the aim of influencing cancer growth or risk of recurrence. Some studies have indicated that such high dose supplements may increase risk, e.g. beta-carotene in lung cancer, or decrease risk, e.g. calcium in colorectal cancer, of disease or recurrence. Studies can be difficult to interpret with conclusions being dependent on the particular dose given, dietary intake, chemical form of the supplement and the combination of any other drugs or nutrients. At present there is insufficient evidence to recommend the use of vitamin or mineral supplements as an adjunct to conventional therapy apart from their use to ensure an adequate dietary intake or to correct a detected deficiency. High doses of vitamins are to be avoided as they may interact with medication, including chemotherapy.

Palliative care

Sometimes cancer cannot be cured and treatment becomes palliative, i.e. focusing on the relief of symptoms rather than treating their cause. As the disease progresses, eating and swallowing difficulties become increasingly likely. The patient's food intake is often a great concern to relatives and carers, and can even be a source of conflict. Patients become increasingly cachectic (see Chapter 7.15.9) and the extent to which nutritional and hydration support should be used to sustain life may eventually need to be discussed. The nutritional care of people who are terminally ill is discussed in Chapter 7.16. Some of the ethical issues involved are discussed in Chapter 1.1.

Alternative diets

Many people with cancer are tempted to try unconventional remedies, including alternative and complementary diets, in the hope of cure or remission (Downer *et al.*, 1994). Alternative diets claim to treat or cure cancer; they are followed instead of conventional cancer treatment. Complementary diets constitute any unusual or unorthodox change to a normal diet and claim to benefit people with cancer; they are followed in association with accepted cancer treatments.

The rationale for trying these diets is understandable; faced with the prospect of a life threatening condition, people will try anything that they think might improve their chances of survival. Patients may also use complementary and alternative therapies to address the emotional and spiritual aspects of the disease and to boost their immune system (Parker *et al.*, 2010). No randomised controlled trials have been carried out to evaluate the benefit of such diets and many healthcare professionals remain sceptical about their value (Cassileth *et al.*, 1991). In addition, cancer patients may not be aware of the potential risks of using complementary and alternative medicines or may not always inform their doctor of their use (Werneke *et al.*, 2004), often because the healthcare professional does not ask the patient if they are taking such therapies. Alternatively, patients may choose to make lifestyle changes with the aim of managing the negative impact that cancer treatment can have on health related quality of life (Ashing-Giwa *et al.*, 2010). These lifestyle changes include eating a healthier diet, increasing exercise, use of complementary or alternative medicine and stress reduction.

The problem with many alternative and complementary diets (see Table 7.15.2) is that they are more likely to worsen nutritional status than improve it. Such diets tend to share a number of common features such as:

- Being vegetarian or vegan.
- Containing large amounts of raw food.
- Advocating the use of organic foods.
- Being low in fat.
- Being low in sugar or sugar free.
- Being low in salt.
- Restricting intake or avoiding dairy products.
- Avoiding processed foods and beverages containing caffeine.
- Encouraging the use of vitamin and mineral supplements.

As a result, these diets often have a low energy density due to their high bulky fibrous food content and low content of fat and carbohydrate. People may therefore find it difficult to eat enough to meet their needs, particularly if they have eating or swallowing problems associated with the disease or its treatment. Restrictions on food choice may cause dietary imbalances. Use of mega doses of vitamins and minerals can create other nutritional distortions and may even be hazardous. Safe upper limits for vitamins and minerals are described in the Food Standards Agency report on this subject (EVM, 2003).

Table 7.15.2 Examples of alternative and complementary dietary regimens used by cancer patients

Dietary regimen	Philosophy	Main dietary principles
The Bristol Cancer Centre Diet (complementary)	The Centre believes that, as part of an holistic approach, diet and nutritional supplements can be important and may well have an influence on recovery by enhancing the effectiveness and reducing side effects of cancer treatment, improving wellbeing and in some cases prolonging survival	Wholefoods Fresh fruit and vegetables Organically grown foods Whole grains Organic poultry, eggs, game and fish in moderation Beans and pulses Freshly made fruit and vegetable juices Supplements of vitamin C, beta-carotene, vitamin B complex, selenium, zinc
Macrobiotics (complementary)	Foods are classified as Yin foods, representing feminine, dark and negative principles, and Yang foods, representing masculine, light and positive principles. The aim is to balance these for each individual in order to obtain a healthy mind and body	Mainly based on cereal grains Vegetables, sea vegetables and fruit Bean and bean products Nuts and seeds Fish Soup made with vegetables, beans and grains Sea vegetables seasoned with sea salt, soy sauce or miso
Dairy free diets (complementary)	Milk and dairy foods promote the growth of cancer, particularly breast and prostate cancer	Soya foods, including soya milk, are substituted for dairy foods Increase consumption of fruit and vegetables (preferably organic) Avoid processed foods, including meats, oils, refined starchy foods, alcohol and fizzy drinks
Gerson therapy (alternative)	Aim is to stimulate the body's own defence system to overcome cancer. Both the nutritional and detoxification parts of the therapy are required	Vegan Fresh fruit and vegetables Freshly made fruit and vegetable juices Supplements of digestive enzymes, niacin, liver capsules, iodine, thyroid extract, potassium compound and vitamin B ₁₂ injections Coffee enemas

Such regimens may also be expensive, unpalatable and time consuming to prepare. Patients accept this because they have high expectations of their success, but may then suffer feelings of anger and frustration if these are subsequently not met. They may also feel guilty if they have to abandon the diet for any reason. While there is no evidence that these regimens offer any benefit over conventional therapies, and in some instances make matters worse, some cancer patients do claim to feel better on these regimens (Werneke *et al.*, 2004; Cassileth & Deng, 2004). The reason for this is unclear, but may be associated with *doing something positive* to take control of the disease and treatment, and also because of the often excellent psychological support offered along with dietary advice as part of holistic therapy.

It is important that dietitians are aware that patients may be tempted to try, or are already following, alternative or complementary diets. In this situation, the role of the dietitian is to explore whether the patient would like to discuss their dietary intake and change any aspect of their diet:

- If patients ask whether they should try a particular alternative diet, encourage them to find out all they can about the regimen and openly discuss the potential benefits and hazards.
- If the patient wants to try one of these diets, encourage them to follow it for a short period of time, such as a month, and then return for further assessment and discussion.
- If an alternative diet is already being followed, discuss any obvious dietary shortcomings and suggest positive measures that the patient can take to improve nutritional intake. Some patients may be prepared to compromise and will incorporate some aspects of their alternative regimen into a better balanced nutritional programme.
- If alternative or complementary medicines are being taken, refer to the pharmacy to check the supplement, dosage and any possible interaction with conventional medicines that are being prescribed (Werneke *et al.*, 2004).

Ultimately, the patient is responsible for making the decision to follow a complementary or alternative dietary regimen. However, it is the responsibility of the dietitian to ensure that the patient has been given sufficient balanced information and advice on which to base that decision. In order to do this, it is important that dietitians keep up to date with the types of diets being suggested for cancer and their nutritional implications. The progress and dietary intake of patients following alternative diets

should be monitored in order to try and ensure that good nutritional status is maintained.

Drug–nutrient interactions

Drug–nutrient interactions may occur with chemotherapeutic agents, drugs used to manage symptoms and additional medication that is being taken to manage comorbidities. These interactions can potentially occur with food, nutritional supplements and herbal preparations. Patients should be encouraged to discuss all additional over the counter supplements with a pharmacist before consuming them to check for any potential adverse reactions.

7.15.2 Head and neck cancer

Bella Talwar

Key points

- The dietitian is a key member of the head and neck cancer care team, providing nutritional assessment, advice and support from diagnosis onwards.
- Early referral is crucial to provide nutritional support tailored to the patient's needs. Appropriate and timely intervention aims to overcome the physical, social and psychological challenges.
- Prophylactic tube placement is recommended if oral intake is inadequate, not possible or likely to be restricted during treatment and rehabilitation over a prolonged period of time. Appropriate decision making around prophylactic tube feeding should be discussed at diagnosis as part of the treatment management plan.
- Multifactorial high risk selection criteria for enteral tube feeding, including patient demographics, tumour site and staging, treatment modalities, placement technique and associated morbidity, should be considered on an individual basis.

Cancers of the head and neck are the sixth most common cancers worldwide and constitute 5% of malignancies in the UK (Quinn *et al.*, 2001). The majority of these cancers arise from the surface layers of the upper aerodigestive tract and include a variety of histological types of which squamous cell carcinomas make up 95% of cancers (Argiris *et al.*, 2008). The mouth, lip and tongue (oral cavity), the upper part of the throat and respiratory system (pharynx), and the voice box (larynx) represent 90% of head and neck malignant tumours. Cancers of the salivary glands, nose, sinuses, middle ear and those that originate in the nerve and bone of the head and neck are relatively rare (NICE, 2004).

The age distribution of newly diagnosed patients is in the fifth to seventh decade of life, but it is increasing in the middle aged adult population, and the 3:1 ratio for the prevalence in men and women is decreasing (NICE, 2004).

Tobacco exposure and high alcohol consumption are the two strongest aetiological factors, both independently and synergistically, in the development of primary and secondary head and neck cancers (Marron *et al.*, 2010). Certain tumour sites are associated with specific risk factors. The chewing of beetle nut is linked to cancers of the oral cavity (Proia *et al.*, 2006). Epstein–Barr virus is associated with nasopharyngeal cancers in individuals of oriental origin. Human papilloma virus (HPV 16) is an

increasingly recognised causative factor in oropharyngeal and oral cancer, particularly in individuals who are non-smokers or non-drinkers, and in people aged 30–50 years (BAO-HNS, 2011).

The aims of treatment are to eliminate the disease and achieve long term survival. However, the 5-year mortality rate from head and neck cancer has not improved significantly over the last 40 years, despite advances in diagnostic tools and treatment modalities. Therefore, locoregional control (disease recurrence at the primary site or the neck), quality of life and organ function are critical outcome considerations in describing and evaluating treatment (List & Bilir, 2004; BAO-HNS, 2011).

Nutrition is a fundamental long term prognostic factor (Brooks, 1985) and has become an increasingly important quality of life issue surrounding the psychosocial and rehabilitation needs of head and neck cancer patients (BAO-HNS, 2011).

Nutritional implications

Head and neck cancer patients present a significant nutritional challenge due to their risk of malnutrition associated with lifestyle choices, site of their cancer, the disease process and treatment. It is estimated that approximately 50–75% of diagnosed patients experience moderate to severe malnutrition (van Bokhorst-de van der Scheuren

Table 7.15.3 Factors contributing to malnutrition in head and neck cancer (source: Talwar 2010. Reproduced with permission of Wiley-Blackwell Publishing)

Contributory factors	Cause
Poor dietary habits	Consumption of unbalanced meals can lead to energy, protein and micronutrient deficiency
Excessive alcohol intake	Associated with appetite suppression, inadequate nutrient intake and micronutrient deficiency
Depression and anxiety	These can result in aversion to food and/or loss of appetite with reduced quality of life
Difficulty with chewing	Lack of teeth, ill fitting dentures and physical problems with jaw movement can markedly affect food choice in favour of a limited range of soft or liquid foods
Difficulty with swallowing	Presence of the tumour mass, pain on eating, ulcerated mouth and fear of choking can compromise the safety of swallowing and result in the consumption of a diet restricted in variety, texture and nutritional content
Cachexia	Altered nutritional and metabolic response due to the presence of the tumour can result in symptoms such as anorexia, loss of appetite, early satiety and marked weight loss associated with muscle wasting and increased production of acute phase protein
Changes in body composition	Disturbance in energy balance with changes in resting energy expenditure, glucose uptake, mobilisation of fat and protein stores, and muscle protein release
Halitosis	Anaerobic respiration with the production of lactic acid and subsequent build-up of ammonia released via the mouth
High risk of refeeding syndrome	Combined effect of the causes and consequences of malnutrition in this patient group, leading to risk of starvation for longer than 7–10 days and unintentional significant weight loss
Limited support network	Patients who live alone or have no family can be less motivated and often find it more challenging to maintain adequate nutrition
Impaired wound healing	Increased risk of infection due to decreased muscle, respiratory, gut and immune functions
Higher risk of hospital admission	Nutritional deterioration requiring feeding management with greater length and cost of hospital stay
Poor functional status and quality of life	Increased lethargy and decreased ability to mobilise, work and socialise
Increased morbidity and mortality	Poor nutritional status at presentation combined with malnutrition and its associated consequences, limiting the options and choice of cancer therapy due to tolerance and therefore contributing towards poorer tumour control and survival

et al., 1997; Hammerlid *et al.*, 1998), and 80% will lose weight during multimodality treatment (BAO-HNS, 2011). Malnutrition is discussed in more detail in Chapter 6.2. However, the causes and consequences of malnutrition in head and neck cancer patients at presentation are multifactorial (Table 7.15.3). It is evident from the above that nutrition influences patients' functional, oncological and quality of life outcomes, which have an impact on health economics.

Nutritional effects of treatment

Treatment options for head and neck cancers involve single- or multi-modality regimens with surgery, radiotherapy and, more recently, the advances that have been made with the use of chemotherapy and biological targeted treatment (BAO-HNS, 2011). The International Union Against Cancer (2007) TNM classification of head and neck tumours describes the anatomical extent of disease based on the size of the primary tumour (T1–4), the absence or presence and extent of regional lymph node metastasis (N1–3), and the absence or presence of distant metastasis (M site). The main anatomical sites in the head and neck region are shown in Figure 7.15.1.

Curative treatment options differ according to the staging and primary tumour site with stage I or II disease

managed with single modality treatment using surgery or radiotherapy, and stage III and IV disease requiring multimodality therapy with surgery, radiotherapy and chemotherapy (Argiris *et al.*, 2008). The different combination treatments have led to several competing management strategies, each with different advantages and disadvantages, and initial treatment can vary significantly between institutions (BAO-HNS, 2011).

Over the past decade there have been significant advances in treatments. Surgical resection and reconstruction techniques have evolved and now include minimally invasive approaches such as trans oral laser. Radiotherapy fractionation schedules have been modified to promote organ preservation with induction and/or concurrent chemotherapy sparing healthy tissue by targeted coverage (BAO-HNS, 2011). Chemoradiotherapy results in an absolute survival improvement of 8% at 5 years and is currently recognised as the gold standard treatment for advanced cancers requiring combined modality treatment. These chemotherapeutic agents are platinum based, with the dose, delivery method and timing varying between institutions (Pignon *et al.*, 2009). Cancer treatments delivered as single or multimodality therapy to the head and neck region have a permanent effect on organs essential for normal human activities like breathing, speaking, eating and drinking (NICE, 2004). This creates further nutritional problems and increases

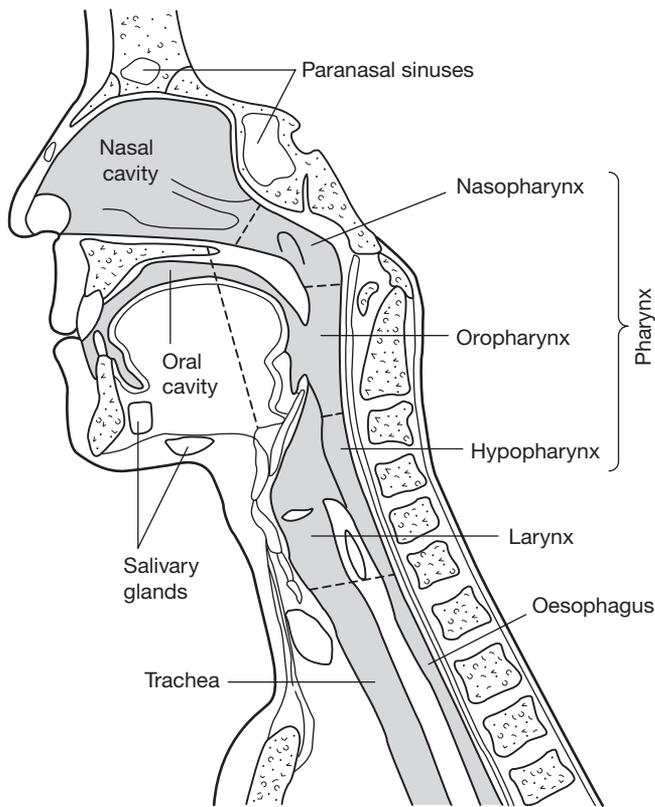

Figure 7.15.1 Main sites of head and neck cancers (adapted from Talwar 2010. Reproduced with permission of Wiley-Blackwell Publishing)

the risk of nutritional depletion requiring appropriate and timely intervention (Talwar, 2010).

Surgery

Surgical resection can severely restrict or even eliminate the patient's ability to consume oral nutrition. Van Bokhorst-de van der Schueren *et al.* (1997) assessed a variety of malnutrition parameters in patients undergoing major surgery for advanced cancer and identified weight loss as the most significant. Patients with a weight loss of >10% during the 6 months presurgery had a greater risk of postoperative complications, with an incidence of between 20% and 50% (Bertrand *et al.*, 2002). A follow-on study to evaluate nutritional status as a prognostic value found no influence of any of the investigated nutritional parameters for the whole group. However, preoperative weight loss and occurrence of major postoperative complications showed a marked negative influence on the survival of male patients with head and neck cancers (van Bokhorst-de van der Schueren *et al.*, 1999).

Based on the above findings, the same researchers conducted a randomised controlled trial to study the effect of perioperative nutritional support on nutritional status, immune status, postoperative outcome and survival in severely malnourished patients undergoing major surgery. Although the trial concluded that 7–10 days preoperative feeding did not improve nutritional status, it did find that preoperative enteral nutrition in patients with head and

Box 7.15.1 High risk selection criteria for preoperative feeding of head and neck cancer patients (Weimann *et al.*, 2006)

- Weight loss >10–15% in 6 months
- Body mass index <18.5 kg/m²
- Subjective Global Assessment Grade C
- Serum albumin <30 g/L
- Unable to maintain intake above 60% of recommended intake for >10 days

neck cancer improved their functional and emotional status in the preoperative period, although this was not evident at 6 months (Van Bokhorst-de van der Schueren *et al.*, 2000). This raised the question of whether preoperative enteral feeding should commence at clinical presentation when there is a strong suspicion that the diagnosis is likely to be a malignancy, to evaluate if there is a beneficial effect on nutritional status (Bradley & Donaldson, 2000).

Immunonutrition is supported by limited evidence in the literature and therefore is recommended in this patient group, with some benefit observed if administered in the pre- or post-operative period to reduce fistulae rates and length of stay, and improve 10-year survival (Findlay *et al.*, 2011). Further research is required. However, there is consensus guidance at an international level for best practice, recommending preoperative nutrition in patients at severe nutritional risk (BAO-HNS, 2011; Findlay *et al.*, 2011) as identified in Box 7.15.1. Consequences of surgery are outlined in Table 7.15.4.

Radiotherapy

Side effects of radiotherapy are due to the direct effect of radiation upon the tumour, or because of involvement of healthy tissue within the field of treatment in the head and neck region (Figure 7.15.1). The severity of the reaction depends on the radiation schedule, volume and cumulative dose given to the anatomical structures in the treatment field. This treatment can be given as a single or cumulative dose, and a radical course involves the patient attending daily treatments for up to 6–7 weeks and receiving a total dose of 60–70 Gray (Kelly, 2007). Radiotherapy side effects impact on the patient from the second week of treatment, peaking during the fourth to fifth week and continuing for on average 3 weeks after completing the course (Polisena, 2010). Radiotherapy can further compromise the patient's nutritional status and make the management particularly challenging. The treatment side effects can occur in the acute stage with permanent changes, or as a late reaction during the patient's follow-up and rehabilitation (Talwar, 2010). These side effects are summarised in Table 7.15.5. Prior to starting radiotherapy, it is estimated that 44% of patients present with common symptoms associated with eating, including difficulty with mastication, swallowing and odynophagia, loss of appetite and nausea, and by the third week of

Table 7.15.4 Effects of surgery and nutritional consequences (source: Talwar 2010. Reproduced with permission of Wiley-Blackwell Publishing)

Effects of surgery	Nutritional consequences
Loss of taste	Surgery to the tongue, salivary glands or olfactory nerve negatively influence taste acuity, leading to reduced appetite and gustation
Loss of smell	Loss of nasal airflow via the olfactory receptors in the nasal cavity leading to reduced enjoyment of meal times and social interaction
Difficulty chewing	Partial or total inability to masticate due to loss of bony supporting structure (mandible), exacerbated by dental extraction, misalignment of the jaw and trismus, leading to the requirement for texture modification, increased effort and reduced enjoyment of food, and social isolation
Drooling and pocketing of food and fluid	Reduced pressure to move the bolus into the pharynx occurs due to surgery or nerve damage, and can be embarrassing and isolating, causing anxiety and depression
Reduced peristalsis	Prolonged meal times with risk of avoiding food and fluid, leading to inadequate diet, dehydration, constipation and weight loss
Oral regurgitation	Due to reconstruction or gastric transposition (pharyngolaryngo-oesophagectomy) requiring small frequent meals, remaining upright for 1 hour post meal, and lying down with the head elevated
Nasal regurgitation	Functional impairment of the soft palate or motor activity of the graft can be embarrassing and distressing, and require to be maintained whilst eating and drinking
Dumping syndrome (pharyngolaryngo-oesophagectomy)	Causes nausea, bloating, abdominal cramps and explosive diarrhoea; fear of food and eating is common and changes in eating habits are required due to prolonged meal times and early satiety
Poor wound healing	Examples include flap failure, dehiscence at anastomosis, necrosis and infection. Contributing factors include previous radiotherapy, malnutrition and increased nutritional requirements, necessitating assessment for vitamin and mineral supplementation
Fistulae	Occur in the oral cavity, pharynx or larynx, caused by previous radiotherapy and affect tissue healing and swallowing, requiring alternative feeding
Risk of wound infection	At wound site or chest with extensive or revision surgery and lengthy operations when entering into or resecting part of the upper aerodigestive tract, increasing nutritional requirements
Nerve injury	Damage to the trigeminal, facial, glossopharyngeal, vagus, accessory, hyoglossal and recurrent laryngeal nerves affect swallowing coordination, chewing and taste, increasing the risk of aspiration and fatigue during meals, as well as facial disfigurement
Aspiration	Can be a silent or reactive cough with food or fluid entering the lungs, requiring the patient to be nil by mouth and needing alternative feeding
Chylous fistulae	Tumour invasion or surgical trauma of the thoracic duct with <500 mL/day lymphatic drainage, requiring conservative management or >600 mL/day over a prolonged period and suggesting surgical repair
Strictures and stenosis	Complete or partial obstruction of the food bolus, requiring dilatation with texture modification, and smaller size food bolus with plenty of fluid and multiple swallows
Patient comorbidity factors	Diabetes, renal impairment, malnutrition, previous surgery or radiotherapy, anaesthetics for procedure and duration of the surgery

treatment patients report three or more eating problems (Larsson *et al.*, 2005).

In a small study (Larsson *et al.*, 2003) using qualitative measures to examine patient experiences during radiotherapy, the following symptoms were reported to affect quality of life:

- Ability to chew and swallow.
- Will and desire to eat.
- Changes in saliva quantity and consistency.
- Narrowing in the throat and pain.
- Nausea.
- Taste changes.

Patients felt their way of life was disturbed as a result of having to cope with the effects of their symptoms at meal times, leading to loss of togetherness with family and friends. Additionally, they experienced extreme fatigue and loss of self confidence (Larsson *et al.*, 2003).

Up to 57% of head and neck cancer patients experience weight loss before starting radiotherapy, 95% of whom report this as being unintentional weight loss. Radiotherapy treatment may result in a further loss of approximately 10% of body weight (Lees, 1999).

Chemoradiation

Chemotherapy is particularly likely to affect the rapidly dividing cells of the buccal and gastrointestinal mucosa, causing damage to the mucosal lining of the mouth (Van Cutsen & Arends, 2005). Chemotherapy alone is not used widely, but is administered as a neoadjuvant (before radiotherapy) and/or concurrently with radiotherapy; although it has been shown to improve survival, this is at the cost of increased toxicity (Pignon *et al.*, 2009). Chemoradiation results in more severe acute adverse effects than radiotherapy alone, and the long term effects of

Table 7.15.5 Side effects of radiotherapy and nutritional consequences (source: Talwar 2010. Reproduced with permission of Wiley-Blackwell Publishing)

Side effect	Nutritional consequences
Taste changes	Diminished, distorted, abnormal and/or loss of taste (described as cardboard, metallic or sandpaper) leading to food aversion and reduced intake
Mucositis	Oral mucosal reaction that can result in pain, infection or retching
Xerostomia	Requires good oral hygiene, artificial saliva and food texture modification
Dysphagia	Pre-existing or post treatment with tissue damage impairing wound healing
Swallowing impairment of oral phase	Reduced range of lingual motion and strength, impaired bolus formation and transport through the oral cavity, prolonged transit time and increased residue occur in floor of mouth resections, causing difficulty with chewing, taste changes and fatigue during meals
Swallowing impairment of pharyngeal phase	Impaired tongue base movement, delayed trigger of the swallow, reduced pharyngeal contraction, reduced laryngeal function, reduced opening of the oesophageal sphincter, resulting in impaired bolus clearance and aspiration
Aspiration	Silent or reactive coughing on food and fluid associated with fear of eating; can be due to lethargy, weakness and reduced alertness secondary to malnutrition
Trismus	Restricted ability to open the mouth, which can be due to pre-existing tumour obstruction, radiation induced or reduced mastication over a prolonged period
Osteoradionecrosis	Mandible incapable of healing itself or fighting infection due to poor blood supply, resulting in reduced ability to masticate and limited mouth opening
Impaired wound healing	Permanent tissue damage increasing risk of poor wound healing
Fatigue	Apathy and severe tiredness limiting physical function, as well as motivation with swallowing increasing time and effort at meals with an overall reduced nutrient intake
Dental caries	Due to poor oral hygiene or exacerbated in the presence of xerostomia as food and fluid stick to the teeth, there is no flushing effect from saliva and the teeth rapidly decay
Dehydration	Decreased salivary flow resulting in altered colonisation of the oropharynx, impaired bolus preparation due to lack of saliva and increased thickness of sputum

radiation are also increased and can profoundly affect nutritional intake and swallowing physiology, causing significant morbidity and diminished quality of life (Shiley *et al.*, 2006). In head and neck cancer the chemotherapeutic agents most commonly used are platinum based and where patient comorbidities present a risk for administering systemic agents, an alternative monoclonal epidermal growth factor receptor (EGFR) inhibitor is used (cetuxmab) (BAO-HNS, 2011).

Chemoradiation is known to exacerbate weight loss during treatment by >5% of pretreatment weight (Nugent *et al.*, 2010b). Odynophagia (pain on swallowing food and fluids) caused by severe mucositis and nausea can markedly impair the intake and enjoyment of food, and are thought to be significant factors associated with the weight loss and difficulties experienced with eating (Kelly, 2007).

Poor symptom control during radiotherapy and/or chemotherapy will result in dehydration, lethargy and severe weight loss if nutrition support is inadequate, and contribute to inadequate treatment delivery and efficacy for local regional control and survival (BAO-HNS, 2011; Findlay *et al.*, 2011). The side effects of chemotherapy on nutritional consequences are listed in Table 7.15.6.

Current treatments for head and neck cancer have an adverse effect on many nutritional aspects. A prospective cross sectional study, taking account of the stage of disease and therapeutic intervention, evaluated quality of life, nutritional status and dietary intake, and found that

reduced energy and protein intakes, together with weight loss, were independent determinants of quality of life (Ravasco *et al.*, 2004). Patients at risk of severe weight loss at diagnosis and during treatment can be identified with health related quality of life questionnaires (Karin *et al.*, 2005), although there is no nutrition specific module to assess the relationship between malnutrition, nutritional status, dietary counselling and nutrition support in this patient group (Talwar, 2010).

New treatments for head and neck cancer currently being examined include robotic surgery, photodynamic therapy and biological targeted therapy focussing on tumour suppression genes and EGFRs using cetuximab (Argiris *et al.*, 2008). The nutritional consequences have yet to be evaluated.

Principles of nutritional management

The organisation and structure of nutrition and dietetic services should aim to provide a quality centred, seamless service at all stages of the patient pathway, with access to site specific dietitians throughout the patient journey and recognising that they are core members of the multidisciplinary head and neck cancer team (BAO-HNS, 2011). The publication of evidence based practice guidelines based on a systematic review of literature across the entire nutritional care pathway sets the benchmark for quality rated nutritional interventions and outcomes (Findlay *et al.*, 2011). Best practice nutritional care should

Table 7.15.6 Side effects of chemotherapy and nutritional consequences (source: Talwar 2010. Reproduced with permission of Wiley-Blackwell Publishing)

Side effect	Nutritional consequences
Severe mucositis	Although radiation induced, this can be exacerbated by the systemic effects of the drug and can impair wound healing
Nausea and vomiting	Systemic or anticipatory; triggered by taste, smell and anxiety
Anorexia	Reduced appetite accompanied by reduced intake
Taste and smell alterations	Diminished, distorted, abnormal and/or loss of taste (described as cardboard, metallic or sandpaper), leading to food aversion and reduced intake
Diarrhoea	Risk of dehydration and distressing to the patient
Stomatitis	Sore mouth significantly affecting food intake
Nephrotoxicity/ototoxicity	Renal impairment can lead to nausea and loss of appetite
Metabolic abnormalities	Can lead to increased energy expenditure and micronutrient deficiency

incorporate implementation of appropriate validated tools for routine malnutrition screening, early referral to the dietitian, and regular comprehensive nutritional assessment and monitoring to optimise nutritional status (Talwar & Findlay, 2012). The patient pathway and dietetic clinical model of care is shown in in Box 7.15.2.

Nutritional screening

It is crucial that all head and neck cancer patients undergo nutritional screening to identify those who have, or are at risk of developing, malnutrition at any stage of the patient pathway, and it should be an integral part of multidisciplinary clinical practice (NICE, 2004; BAO-HNS, 2011; Findlay *et al.*, 2011). Nutritional screening tools should be validated in oncology patients and where used for head and neck cancer patients should be able to identify the following groups who may benefit from full nutritional assessment (BAO-HNS, 2011; Findlay *et al.*, 2011):

- Patients who are not nutritionally compromised at diagnosis, but who are at risk of malnutrition during treatment. These patients would benefit from a dietetic assessment during the planning of their cancer treatment in order to recommend an appropriate nutritional management plan.
- Patients who are disease free post treatment, but who present with late side effects from both surgery and radiotherapy that may impact on their oral intake and increase the patients' risk of developing malnutrition.

Nutritional assessment

Effective nutritional management is dependent upon appropriate nutritional assessment. Useful factors to con-

sider include clinical observation, dietary history, and calculation of requirements, proposed treatment, anthropometry, biochemistry and social information. The specific parameters for this patient group are summarised in national clinical guidance (BAO-HNS, 2011) with key reflective questions that should be considered as part of the assessment. These should include the following.

Nutritional aspects

- What is the nutritional status of the patient? Consider the percentage energy intake from alcohol, percentage body weight loss in the previous 6 months, and body mass index (BMI).
- Is the patient at risk of refeeding syndrome?
- How many cups of fluid is the patient drinking during the day?
- How long is it taking the patient to consume a meal?
- Is the patient feeling hungry or thirsty after a meal?
- Which types of food is the patient finding easy/difficult to manage?
- Is the patient chewing food for longer before swallowing?
- Consider the effort and time taken to eat or drink and how this is impacting on the patients quality of life.
- Does drinking sips of liquids between bites of food make it easier to swallow?
- Has the patient adapted their eating habits to make it easier to swallow? If so, how?
- Is it taking more time and effort to eat and drink throughout the day?
- Are there any problems with the patient's dentition?

Clinical aspects

- What is the size of the tumour?
- What part(s) of the anatomy does the tumour involve?
- What are the aims of treatment – cure, symptom control, palliation?
- Does the treatment plan involve combined modality treatment?
- Has the patient had previous oncological treatment?
- What is the extent of any surgical resection and is reconstruction planned?
- What are the risk factors for postoperative complications?
- What is the radiotherapy dose and treatment field?
- What is the patient's performance status?
- Does the patient have comorbidities or contraindications if considering alternative feeding?
- What is the patient's social support network?
- What are the patient's lifestyle choices for smoking, drinking and recreational drugs?

Dietetic management

Dietetic input throughout the patient pathway is needed to assess and correct nutritional deficiencies, evaluate how different treatment modalities will impact on a patient's nutritional status, and recommend the most appropriate short and long term nutritional interventions to meet the nutritional needs of the patient and/or achieve

Box 7.15.2 Patient pathway and dietetic clinical model of care (Talwar, 2010)**Diagnosis***Intervention*

Assess risk factors for patient compliance
 Negotiate feeding options with team and patient
 Assess need for artificial feeding to include screening for suitability and method of insertion
 Screening of nutritional status

Outcome

Improve or maintain nutritional status
 Identify need and determine timing and type of prophylactic tube placement

Pretreatment*Intervention*

Discuss outcomes of intensive nutritional counselling with dietary intake, oral and enteral nutrition support
 Assess presenting symptoms from previous treatment
 Discuss effects of treatment and possible impact on ability to eat and drink in the short and long term
 Discuss method of feeding options and types of feeding tubes using visual aids, psychosocial aspects relating to body image, feeding in public, physical activity

Outcome

Assess need for pretreatment reconditioning
 Provide realistic expectations of eating and feeding issues
 Establish rapport to promote patient motivation and compliance
 Support consent process for placement and use of feeding tubes, timelines for oral and enteral nutrition and rehabilitation programme to ensure timely and appropriate tube removal

Treatment: Surgery*Intervention*

Discuss effects of surgery on ability to eat and drink
 Advise patient on how to overcome dietary problems and use the feeding tube
 Tailor feeding regimen to meet patient's individual requirements
 Adjust feeding regimen accordingly following introduction of oral diet so that optimum intake is maintained
 Prepare patient for discharge on enteral feeding, including necessary training of patient and carers, practical feeding tube management
 Liaise with all relevant community staff and feed company to ensure that discharge home on enteral feed is safe and efficient

Outcome

Improve or maintain nutritional status to reduce risk of developing postoperative complications
 Prepare patient for safe and effective discharge, allaying any anxieties
 Adequate preparation for discharge reduces likelihood of readmission for feeding tube related problems

Treatment: Radiotherapy and/or chemoradiation*Intervention*

Discuss any presenting or ongoing problems with eating and drinking, and potential impact of further treatment
 Advise patient on overcoming problems associated with chemoradiation
 Monitor dietary adequacy and tolerance to treatment

Outcome

Optimise nutritional status to minimise risk of treatment interruptions (and subsequent admission)
 Provide support and advice to enhance motivation and compliance with oral nutrition support and appropriate use of enteral feeding to prevent tube reliance

Post treatment*Intervention*

Assess/monitor post treatment effect on ability to eat and drink
 Adjust dietary feeding regimen accordingly with oral diet to maintain adequate nutritional intake
 Provide advice on modifying texture of diet and symptom control for side effects
 Negotiate feeding tube removal as appropriate

Outcome

Maintain adequate nutritional status
 Maximise patient motivation and compliance
 Assist patient to re-establish eating and drinking, thus improving quality of life

Long term care/survivorship*Intervention*

Provide ongoing nutritional care with dietary advice for oral nutrition support and enteral nutrition
 Provide psychosocial support for enteral feeding

Outcome

Establish goals for weight management and maintaining adequate nutrition support
 Support the patient and carers living with the effects of treatment

outcomes (BAO-HNS, 2011; Findlay *et al.*, 2011). Key questions that need to be asked in order to determine the nutritional management:

- Is it safe for the patient to consume oral nutrition and/or does the patient need to be referred to a speech and language therapist?
- Is the patient maintaining their nutritional status with oral intake alone or is an alternative system of feeding required?
- Do the patient's symptoms and/or treatment plan indicate the need for alternative feeding in the short or long term?
- If the patient requires enteral feeding, what is the type of tube and safest technique for placement to meet the patient nutritional needs?
- If the patient requires tube feeding, is there continuity with dietetic support and management until it is appropriate to remove the feeding?

Dysphagia can lead to an inadequate energy, nutrient and fluid intake, and can have a severe adverse effect on the patient's health, nutritional status and quality of life unless the cause is identified and appropriately managed. If unrecognised over a prolonged period of time, dysphagia can place the patient at risk of malnutrition or dehydration and their associated complications (Table 7.15.7).

The speech and language therapist will assess the degree of dysphagia, including the risk of aspiration, and recommend management that may include alternative texture modification and the use of swallowing techniques or postures where appropriate (RCSLT, 2002) (see Chapter 7.3). The dietitian should be part of the dysphagia team, providing nutrition information to support

the diagnosis of swallowing problems and subsequent management (Lundy *et al.*, 2009).

Nutritional support

Choice of cancer treatment will influence the need for preoperative nutrition, and may also increase the nutritional requirements for postoperative recovery and hence the need for nutritional support during radiotherapy or chemoradiation. Recently there have been a number of systematic reviews to evaluate the outcomes of dietary counselling and methods of nutritional support in patients receiving treatment for head and neck cancer (Garg, 2010; Nugent *et al.*, 2010a; Findlay *et al.*, 2011).

First line nutritional support intervention is often food fortification, but it is imperative to evaluate the appropriateness of this given the intensity of treatment regimens and the consequences on the patient's ability to consume and sustain adequate oral nutrition. Each patient should be individualised to receive nutritional support that is tailored to their diagnosis and treatment plan, including early oral nutritional support and enteral nutrition (BAO-HNS, 2011).

Oral nutritional support

It is challenging for patients to remain motivated and committed to sustaining adequate nutrition whilst experiencing side effects of treatment (Cady, 2007; Mayre-Chilton *et al.*, 2011). It is important that patients maintain an intake as close as possible to a normal diet in order to maintain muscle function for swallowing and minimise feelings of loss of control with oral nutrition during their cancer care (BAO-HNS, 2011). However, a patient's ability to sustain an adequate oral intake over an extended period of time is underestimated (Talwar, 2010). Randomised controlled trials evaluating the impact of dietary counselling demonstrated improvements in patients' nutritional status, dietary compliance and quality of life (Isenring *et al.*, 2004; Ravasco *et al.*, 2005). (see Chapter 6.3).

Enteral nutritional support

If oral nutrition is inadequate or not possible, enteral feeding should be considered without delay as otherwise the patient's nutritional status will be compromised, leading to poor patient centred, clinical and financial outcomes (Findlay *et al.*, 2011). Assessing the need for early instigation of partial or total artificial support should be included when treatment options are being considered for head and neck cancer patient (Grobbelaar *et al.*, 2004; BAO-HNS, 2011). Details of the principles and practice of artificial nutritional support are given in Chapter 6.4.

The benefits of increased energy and protein intake, and reduced weight loss in patients receiving enteral nutrition compared with oral nutrition has been known for decades from randomised controlled trials (Daly *et al.*, 1984; Hearne *et al.*, 1985). Early referral to the

Table 7.15.7 Consequences of malnutrition and dehydration in head and neck cancer patients

Consequences of malnutrition	Swallowing impairment and increased risk of aspiration due to lethargy, weakness and reduced alertness Reduced strength of the cough and mechanical clearance in the lungs Impaired wound healing and increased risk of infection due to decreased muscle, respiratory, gut and immune functions Higher risk of admission to hospital and greater length and cost of hospital stay Poor functional status and quality of life due to lethargy and decreased ability to mobilise, work and socialise Increased morbidity and mortality
Consequences of dehydration	Decreased salivary flow resulting in altered colonisation of the oropharynx Impaired bolus preparation due to lack of saliva and increased thickness of sputum Increased risk of aspiration due to lethargy and mental confusion

dietitian within a nutritional support programme and dietary counselling have also been shown to improve outcomes for enteral nutrition, with less weight loss, and fewer treatment interruptions and unplanned hospital admissions (Wood, 2005; Mangar *et al.*, 2006; Paccagnella *et al.*, 2010).

Early studies showed gastrostomy feeding to be more advantageous than nasogastric tube feeding, with patients experiencing increased mobility, reduced anxiety with altered body image, higher energy intakes and improved quality of life scores with the former (Lees, 1997; Mekhail *et al.*, 2001; Piquet *et al.*, 2002). Patients and their carers need to be supported to establish a feeding pattern and to improve their confidence with tube care before having to cope with the debilitating effects of the treatment (Scopapio *et al.*, 2001).

The relative advantages of gastrostomy placement have been challenged over the past 5 years, with much debate regarding the optimal timing and route of enteral tube feeding (Talwar & Findlay, 2012). Prophylactic placement is gastrostomy insertion before treatment and differs from interventional gastrostomy, which refers to placement as required during treatment. In a non-prospective randomised controlled trial, nasogastric tubes were compared with non-prophylactic gastrostomy placement (Corry *et al.*, 2009). The gastrostomy group used tubes for longer and had better weight outcomes compared with the nasogastric group who experienced greater tube dislodgement and increasing patient and carer dissatisfaction as the study progressed. These findings have been supported in a large retrospective review that showed weight loss was less with prophylactic gastrostomy placement compared with placement as an intervention during treatment (Nugent *et al.*, 2010a). In a randomised controlled trial, improved quality of life scores at 6 months have also been reported with prophylactic gastrostomy placement compared with interventional gastrostomy placement (Salas *et al.*, 2008). A Cochrane review concluded that the method of enteral feeding remains unclear in patients receiving radiotherapy or chemoradiotherapy, but this review only included one study and this study had a high degree of bias (Nugent *et al.*, 2010b). However, another systematic review that included 10 randomised controlled trials concluded that both dietary counselling and prophylactic gastrostomy maintained or improved nutritional status (Garg, 2010). All of these studies used weight as a nutrition outcome, but more recently a prospective longitudinal case series evaluated other anthropometrical measures and found improvements with prophylactic tube placement before, during and after treatment (Silander *et al.*, 2010).

Despite the evidence supporting the benefits of prophylactic tube feeding, mainly with gastrostomy placement, there are no consensus guidelines and decision making is based on the clinical expertise and experience of the institution (Talwar, 2010). The optimal timing for decision making is at diagnosis and all factors impacting on nutrition should be considered, including patient demographics, tumour site and staging, treatment modalities, nutritional status, type and placement technique of

feeding tube, and associated morbidity (Talwar & Findlay, 2012).

Careful consideration needs to be given to the timing and method of gastrostomy placement, with appropriate screening and selection for endoscopic, radiological or surgical placement based on comorbidities and contraindications. Organisational needs include a coordinated approach across the head and neck, gastroenterology and radiology services for appropriate screening and selection of placement method. Close monitoring to minimise the risk of morbidity or mortality from postoperative complications and accountable services for insertion and removal of the feeding tube are essential (Talwar, 2010; BAO-HNS, 2011; Findlay *et al.*, 2011; Talwar & Findlay, 2012).

Practical and psychosocial aspects of gastrostomy feeding

The emotional, psychological and physical stresses associated with the diagnosis and treatment of head and neck cancer can be substantial for patients and their partners (Vickery *et al.*, 2003). Patients and carers reported that the gastrostomy improved nutritional status, provided relief from the pressure of coping with the side effects of treatment during periods of extreme fatigue, and was a lifesaver; they would confidently make the same decision regarding gastrostomy placement (Mayre-Chilton *et al.*, 2011). However, a gastrostomy is not without a burden in day to day living and negative experiences have also been reported (Silver *et al.*, 2004; Jordan *et al.*, 2006; Brotherton & Judd, 2007; Mayre-Chilton *et al.*, 2011). These studies found the following key elements to influence the patient and/or carers' daily activities, lifestyle choices, relationship dynamics and quality of life (Talwar, 2010):

- *Practical limitations* – imposed physical restrictions on going out or staying at home during the day, as well as disturbed sleep at night.
- *Lifestyle restrictions* – restricted choice of clothing and going on holiday.
- *Social adjustments* – difficulties finding a place to feed, effect on eating patterns and interference with family life.
- *Psychological issues* – avoiding or missing meal times with others; dealing with the negative attitudes of others towards feeding; changes in body image; effect of setting up the feeds; confidence with feeding in front of others; inability to act affectionately; understanding of why the tube is necessary.
- *Impact on carers* – interaction at meal times; burden of care, with an estimated 15–30 hours/week dedicated to feeding issues.
- *Feeding tube management* – limited knowledge of and support for technical difficulties, leading to complications and hospital readmission.

The above findings have been confirmed in a quality of life study that also identified the importance of effective gastrostomy counselling in the pretreatment phase, with the use of appropriate literature and visual aids, and ongoing support until the tube is removed (Rogers *et al.*, 2007). A specialist dietitian should undertake this role

from the point of deciding on tube placement until tube removal (Talwar, 2010).

Nutritional monitoring

Continuous feeding can markedly restrict a patient's independence but may be necessary to meet nutritional requirements when experiencing treatment related side effects. Patients established on a feeding regimen should be encouraged to bolus feed during the day with or without overnight pump feeding. This will prevent nutritional inadequacy, e.g. when attending radiotherapy on a daily basis, encourage a normal eating pattern, help the transition to oral feeding and, most importantly, release the patient from being attached to a pump and thus improve their sense of being in control over feeding issues (Talwar, 2010).

Nutritional intervention post treatment improves and maintains nutritional status and quality of life (Findlay *et al.*, 2011). The majority of patients continue to experience eating difficulties after treatment (Pauloski *et al.*, 2006) and places them at risk of ongoing weight loss; therefore, dietary manipulation and optimisation of nutritional support should continue as a priority (Schattner *et al.*, 2005). Weight loss and functional status are important predictors of quality of life in head and neck cancer patients (Karin *et al.*, 2005). Patient weight should be monitored weekly during treatment, or on admission and at each outpatient appointment (BAO-HNS, 2011). It should be routine practice to use anthropometric tools that measure functional muscle status in this patient group, especially in those on long term nutritional support (see Chapter 2.2). The specialist dietitian and speech and language therapist should set collaborative goals to optimise nutrition and swallowing outcomes, dispelling the misinterpreted concept of gastrostomy dependency and optimising safe transition with swallowing from enteral to oral nutrition without compromising the patient's quality of life in the presence of side effects from treatment (Talwar & Findlay, 2012).

Palliative care issues

The incidence of distant metastasis at initial diagnosis is 10%, with the lung, mediastinal lymph nodes, liver and bone being the most common sites of presentation (Argiris *et al.*, 2008). The incidence of developing a second primary is 3–5% on a yearly basis (Khuri *et al.*, 2006) and the 5-year survival for all stages combined is 60% (Ries *et al.*, 2006). Mortality is usually associated with recurrent disease from the primary site. The patient's ability to consume oral intake can be severely restricted or eliminated due to the progressive nature of the disease causing swallowing difficulties. This can lead to malnutrition and its associated consequences, and is further exacerbated by tumour induced metabolic changes (cancer cachexia) for which the incidence in this patient group is not known (Talwar, 2010). The treatment options at this stage are the same as for curative intent, with the aim of

symptom control and the goal of improving quality and quantity of life (BAO-HNS, 2011).

Oral and/or artificial supportive nutrition should be offered as part of palliative care for symptom control. The specialist dietitian should discuss nutritional support and facilitate the decision making process for appropriate nutritional management with other members of the head and neck cancer care team (NICE, 2004; Findlay *et al.*, 2011; BAO-HNS, 2011) (see Chapter 7.16).

7.15.3 Cancer of the gastrointestinal tract

Eva Glass, Linda Murray, Lindsey Bottle

Key points

- Cancers of the gastrointestinal tract (GIT) are associated with nutritional risk factors, including obesity.
- A range of symptoms, which greatly affect food intake and utilisation, accompany GIT cancer.
- Nutritional problems can be further exacerbated by treatment interventions such as major surgery, radiotherapy or chemotherapy.
- Nutritional intervention may involve dietary counselling and nutritional support at all stages of cancer treatment, including palliation.

This chapter discusses cancer of the gastrointestinal tract (GIT) apart from hepatocellular carcinoma (liver cancer), which is discussed in Chapter 7.4.12.

Carcinoma of the oesophagus

Eva Glass

Oesophageal cancer is the ninth most common cancer in the UK, accounting for nearly 8000 new diagnoses/year (CSR, 2011; NHS Scotland, 2011; NISRA, 2008; 2010; Welsh CISU, 2010). The incidence is much higher in males, with a 2:1 male to female ratio. The World Health Organization (WHO) describes more than 20 histological subtypes of oesophageal carcinoma, although adenocarcinoma, arising from the glandular epithelium, and squamous cell carcinoma, arising from the epithelial cells, represent the majority of the diagnoses. In the western world, adenocarcinoma is on the rise, whereas the inci-

dence of squamous cell carcinoma is stable or even decreasing. However, adenocarcinoma remains the most dominant subtype in the developing world (Vizcaino *et al.*, 2002). Environmental factors for which there is convincing evidence of an increase in the risk of oesophageal cancer include reflux disease, consumption of tobacco and alcohol, and greater body fatness. There is probable evidence that non-starchy vegetables, fruit, foods containing beta-carotene and vitamin C decrease the risk of developing oesophageal cancer (WCRF, 2007).

Patients may present with loss of body weight, dysphagia and retrosternal pain on eating. The extent of weight loss tends to be related to the degree and duration of the dysphagia.

Cancer of the oesophagus is diagnosed by endoscopy, endoscopic ultrasound, computed tomography (CT) and positron emission tomography CT. Biopsy is required to confirm the histological diagnosis. By the time patients

present with symptoms, the disease may be advanced and deterioration may occur rapidly. Treatment may involve chemotherapy, radiotherapy and surgery, depending on patient choice, fitness, location and stage of disease, and whether there is spread to adjacent lymph nodes or distant sites in the body. Endoscopic techniques such as dilatation or the insertion of a stent may also be required depending on the progression of disease or symptoms following treatment. If the cancer is advanced, palliative chemotherapy and/or supportive care may be appropriate.

Upper gastrointestinal (UGI) cancer patients present many dietetic challenges, as discussed in Chapter 7.15.2 and later in this chapter. The reported incidence of malnutrition in UGI patients ranges from 35% to 100% (Isenring *et al.*, 2003; Ravasco *et al.*, 2003). This reported variance is due to differences in the definition of malnutrition and in subjects included in studies. The highest incidences of malnutrition are normally found in those with advanced disease, with the majority of studies reporting an incidence of approximately 30–50% (Bozzetti & SCRINIO Working Group, 2009; Deans *et al.*, 2009; Khalid *et al.*, 2007).

Management

Oesophageal resection

Endoscopic mucosal resection is mainly used in severe dysplasia, but its use in treating very early carcinomas is increasing. Surgical treatment of carcinoma of the oesophagus may be by partial or total oesophagectomy or oesophagogastrectomy, depending on the site and extent of the cancer. Patients who are severely nutritionally depleted will require nutritional support prior to surgery. Patients who are able to swallow will require dietary advice, often with nutritional supplements. Those undergoing preoperative chemotherapy may experience an improvement in dysphagia during this time, which enables an improved dietary intake prior to surgery.

The Enhanced Recovery Programme is mainly used in other surgical areas, e.g. orthopaedics, but there is increasing usage in the UK with oesophagectomies and gastrectomies; this area is being developed. The main nutritional areas of this programme are:

- Preoperative assessment and education.
- Carbohydrate loading.
- Late nil by mouth status preoperatively.
- Early oral or enteral feeding postoperatively.

The programme has been shown to have positive benefits, including a lower lean body mass loss, decreased complications and decreased length of hospital stay (Varadhan *et al.*, 2010) (see Chapter 7.17.5).

Early postoperative nutritional support is essential. Enteral feeding by a route that bypasses the oesophagus and stomach is usually appropriate, e.g. jejunostomy feeding. Once the integrity of the anastomosis has been confirmed, oral feeding can resume, starting with oral fluids followed by gradual phasing in of solid foods (see Chapter 7.3) as enteral nutrition is phased out.

Ongoing dietetic supervision is essential, both during hospitalisation and following discharge. Persistent postoperative nutritional problems can include:

- Poor appetite.
- Early satiety.
- Fear of eating, particularly foods that were difficult to eat preoperatively.
- Difficulty in regaining or maintaining body weight.
- Nausea.
- Reflux.
- Dysphagia (due to anastomotic stricture or recurrence of disease).

Dietary management should aim to prevent further nutritional deterioration and weight loss, and attempt to restore good nutritional status, which may have been severely compromised prior to surgery.

Practical guidance should focus on:

- Eating small, frequent meals.
- Taking time at meal times and chewing foods well.
- Drinking fluids separately from meals.
- Good choices of nutrient and energy dense foods, and useful food enrichment strategies (see Chapter 6.3).
- Good choices of nutrient rich beverages.
- Avoiding foods that cause discomfort or gastrointestinal symptoms.
- Adopting strategies that reduce the likelihood of reflux, e.g. not eating late at night, not lying down soon after eating and avoiding strong tea, coffee and alcohol.

Additional support measures, such as oral sip feed supplementation, may be indicated if nutritional needs cannot be met by these measures alone.

Radiotherapy

Radiation therapy, external beam radiation therapy (EBRT) or, occasionally, intraluminal radiation (brachytherapy) may be used to treat oesophageal carcinoma. One of these may be the sole treatment or used in combination with chemotherapy or surgery. During a course of radiotherapy, the tissues will become oedematous, inflamed and swollen, and it is therefore likely that dysphagia will worsen before it improves. These effects are usually temporary but, as these patients are often already severely malnourished and have suffered marked weight loss, it may be important for the dietitian to raise with the medical team whether enteral feeding is indicated prior to or during treatment. The need for enteral feeding is even more imperative in those patients presenting with an already high degree of dysphagia due to the anticipated side effects experienced with radiotherapy. Nutritional support at this stage via nasogastric tube, gastrostomy or jejunostomy may prevent further deterioration of an already poor nutritional status. If such support is implemented, it is important to explain to the patient why such intervention is advisable at this stage, i.e. to avert possible problems and not a sign that their condition has worsened.

During radiotherapy treatment, patients may experience a sore throat and/or an increase in dysphagia. Therefore,

they may find that bland foods (avoiding strong flavours, artificial or natural acidity, and spices) are best tolerated. Foods may need to have a smooth consistency, e.g. liquidised meals, strained thickened soups, custard and milk pudding, or of a crumbly texture, e.g. crackers, crisp bread or savoury cheese snacks.

Reintroduction of a normal diet should be gradual. Meals will need to be well moistened and accompanied by frequent sips of drinks to assist the passage of food past the inflamed area. Sip feed supplements may be necessary to maintain adequate energy and nutrient intake. Most patients will continue with a soft diet for some time as some difficulties with swallowing often persist. Some will also be afraid to try foods they associate problems, particularly meat and bread. Patients may find that such foods can be well tolerated if consumed with plenty of sauce or gravy.

Chemotherapy

Side effects, such as nausea, vomiting and taste changes, commonly associated with this form of therapy, may have an additional impact on oral intake. General remedial measures to help alleviate these effects are discussed in Chapter 6.3 and Chapter 7.15.1.

Other treatment strategies

When radical surgery is contraindicated because of surgical risk due to medical history, metastatic spread or the patient being considered unfit or too weak to withstand its effects, endoscopic techniques such as dilatation, laser therapy or the insertion of a stent can be used as palliative procedures to relieve dysphagia. Intubation with an oesophageal stent is carried out under general anaesthesia or sedation. Often this will be a permanent self-expanding metal stent, although it may be removed if the patient proceeds to surgery. These procedures have a high rate of complications, such as perforation or haemorrhage, and there is an increased risk of mortality. However, insertion of the device does usually bring about an immediate improvement in dysphagia and, with appropriate guidance, many patients are able to resume a fairly normal diet comprised of soft normal foods. The main complication is that of stent migration or overgrowth of tumour, which leads to a recurrence of dysphagia. If this occurs, laser therapy or placement of a further stent is required. A temporary (around 3 months) biodegradable stent is sometimes the preferred to a permanent stent or enteral feeding. This is a measure for those who are dysphagic, but who will be receiving treatment that may ultimately improve their swallow without the need for a permanent stent.

Guidelines for the dietary management of patients who have an oesophageal stent in place vary according to the type of device inserted and local policy. There is little evidence in the literature of the best advice for such patients. The British Dietetic Association's Oncology Group (2008) has constructed a consensus statement based on the available literature and current practice (Table 7.15.8).

Table 7.15.8 Professional consensus statement of dietetic advice post oesophageal stent placement (British Dietetic Association's Oncology Group, 2008)

Fluids	Fluids only for 24 hours post insertion of stent. Local policy needs to be agreed, as many areas extend this to 48 hours Role of fluid thereafter is to wash away debris. There is no evidence base to support the advice to use fizzy fluids. Fizzy fluids may cause problems if acid reflux is experienced. A stent positioned at the distal end of the oesophagus may result in reflux Advise frequent consumption of any type of fluid after consuming food
Food	Education will depend on extent of tumour, ability to chew, continuing dysphagia and position/posture of patient Gradual introduction of small amounts of liquid/soft foods may be required Importance of chewing well needs to be emphasised
Caution with certain foods	Dietitians should be aware of any limitations on food intake. Literature provided should reflect individual need for texture modification. Patients should be advised to chew all food well, to sit upright, not to rush eating and to drink plenty of fluids. They should also be aware of foods that are most likely to cause a problem. Controversy remains about the use of a standard list of foods to avoid, but observational reports point to risk from: <ul style="list-style-type: none"> • Bread and toast • Egg • Fish with bones • Stringy, pithy fruit • Stringy/hard raw vegetables • Chips
Nutrition support	Required by the majority of patients to some extent

Guidance on texture modification may be helpful in some cases (see Chapter 7.3). However, tolerance of different foods does vary between patients, and may even vary on a day to day basis in the same patient. It is therefore difficult to give precise guidance as to which foods will or will not cause problems, but the dietitian should give advice on ensuring small mouthfuls, positioning and chewing food well. Many patients establish a diet of suitable texture by a process of trial and error.

Nutritional support

Whether the treatment plan is for surgery, chemotherapy with or without radiotherapy or supportive care, many patients will be nutritionally compromised. A common complaint is reduced appetite, often accompanied by dysphagia and other issues already outlined (Khalid *et al.*, 2007). Consumption of a nutrient dense diet via appropriate food choice, food enrichment strategies and, if necessary, use of proprietary supplements should be

encouraged (see Chapter 6.3). However, patients may present with cancer cachexia that cannot be fully reversed with an improvement in energy intake alone (Fearon *et al.*, 2011) (see Chapter 7.15.9).

The use of enteral nutrition in oesophageal cancer varies depending on the treatment planned and its expected outcome, i.e. radical or palliative treatment. As already discussed, patients with total dysphagia will often receive enteral nutrition (normally via a jejunostomy or radiologically placed gastrostomy), particularly if they are to undergo radical treatment with chemotherapy and surgery, or chemotherapy and radiotherapy. Those who undergo palliative chemotherapy may also receive enteral nutrition if a stent is not in place. There is much debate on the ethics of enteral nutrition in the palliative care setting for oesophageal cancer patients who are unable to meet their nutritional requirements for reasons other than dysphagia. The multidisciplinary team may decide it is in the patient's best interest to have stent placement in order to improve their swallow, allow them to eat and improve their quality of life.

Gastric carcinoma

Eva Glass

The incidence of gastric cancer is on the decline, mainly due to the decrease in *Helicobacter pylori*; however, it is the seventh most common cause of cancer death in the UK (ISD, 2011; NISRA, 2008; 2010; ONS, 2010a; Welsh CISU, 2010). There is evidence to suggest the probability of salt and foods with a high salt content being implicated in gastric cancer. In contrast, it is probable that non-starchy vegetables, allium vegetables, e.g. garlic, and fruit protect against gastric cancer, although the exact way in which they do this has not been confirmed (World Cancer Research Fund, 2007). Gastric carcinoma is closely associated with *Helicobacter pylori* infection, which leads to chronic atrophic gastritis and eventual gastric neoplasia (Bonenkamp *et al.*, 2002). In populations where infection occurs at an early age the prevalence of gastric carcinoma is 100% in early adulthood. This is probably related to poor socioeconomic conditions.

Gastric carcinoma is often diagnosed late because its early symptoms may be dismissed as indigestion or heartburn. By the time patients present with anorexia, nausea, vomiting, pain on eating and severe weight loss, the disease may be well advanced, possibly with metastatic spread. If the condition is operable (usually assessed by CT scanning and endoscopic laparoscopy), the preferred treatment is perioperative chemotherapy followed by partial or total gastrectomy as appropriate (Cunningham *et al.*, 2006) (see later). If a gastrectomy is contraindicated in patients with pyloric obstruction, then a gastroenterostomy may be performed or the pylorus stented, to allow the patient to eat foods that can be tolerated. If a stent is used, then patients will require dietary advice on a suitable soft diet with sufficient fluids. The additional use of supplements or other support measures is usually necessary to make up the shortfall in energy and

nutrient intake. However, if pyloric obstruction occurs in patients with a poor prognosis, medical management is normally conservative, involving medications such as prokinetics and end of life care. Jejunal feeding may be used for a small number of patients receiving palliative treatment for gastric outlet obstruction if their prognosis is not as poor as the aforementioned and a stent is not placed.

Gastric resection and reconstruction

Gastric surgery can have a considerable negative impact on subsequent food intake, weight recovery and quality of life. Gastric replacement with various enteric reservoirs has been used to improve the postprandial symptoms and nutrition of patients after total gastrectomy. To improve quality of life postoperatively, pouch and Roux en Y reconstructions have been shown to be the most useful of the commonly performed procedures (Gertler *et al.*, 2009). Increasingly, laparoscopic techniques are being used for the removal of early gastric cancers.

As a result of the combination of cancer related cachexia and chronic symptoms such as nausea, vomiting or discomfort on eating, patients with gastric carcinoma often present in a significantly malnourished state and therefore nutritional support measures should be instigated as early after diagnosis as possible, preferably before surgery or as soon as possible afterwards and preferably using the enteral rather than parenteral route.

Early postoperative enteral nutritional support (within 24 hours of surgery) can be safely established via a jejunostomy catheter or nasojejunal tube placed intraoperatively. However, some hospitals do not provide this routinely, keeping patients nil by mouth postoperatively with or without the provision of parenteral nutrition until oral diet can be commenced (Baker *et al.*, 2011). Standard feeds are commonly given, although the use of immunonutrition is on the rise; there is increasing evidence for the benefit of this following gastric resection, some debate on its use remains (Shrikhande *et al.*, 2009).

Disturbances in gastrointestinal function following gastric resection and reconstruction are common, and may affect nutritional intake and subsequently nutritional status. Gastrointestinal consequences of gastric resection and reconstruction include:

- Rapid emptying of the stomach remnant.
- Reduced secretion of intrinsic factor.
- Reduced secretion of pancreatic enzymes.
- Inadequate mixing of food with enzymes and bile.
- Reduced absorption of certain food substances, especially protein and fat.
- Rapid absorption of glucose.
- Abolition of the normal pH gradient in the small intestine.
- Increased intestinal motility.

Some of these problems occur soon after eating; others result from the long term consequences of disturbed gastric function. Early symptoms may include the following.

Small stomach syndrome

The majority of patients experience early satiety and may feel distended and uncomfortable during or after eating. This is particularly common after total or partial gastrectomy, but may also occur after vagotomy and pyloroplasty. Small, frequent meals should be eaten and fluids should be consumed separately from solid food (see Chapter 6.3).

Dumping syndrome

Early dumping

This occurs soon after eating and causes symptoms such as sweating, dizziness, faintness, rapid weak pulse and hypotension as a response to the rapid and early delivery of a hyperosmolar meal into the jejunum. The symptoms usually recede by 2–3 months after surgery, but in the meantime may be relieved by consuming small meals, limiting the consumption of refined carbohydrates and avoiding the consumption of liquids with meals.

Late dumping

Some patients may also experience symptoms similar to hypoglycaemia around 2 hours after a meal as a result of overproduction of insulin in response to the rapid absorption of glucose. Patients typically experience weakness, light headedness, and feelings of cold and sweating, and these symptoms can be minimised by following the advice for early dumping, with emphasis on the regular consumption of starchy carbohydrate foods.

Diarrhoea

Diarrhoea frequently occurs following vagotomy or total gastrectomy, but may reduce with increasing time after surgery. Antidiarrhoeal agents such as codeine phosphate or loperamide may alleviate the problem.

Vomiting bile

Pancreatic and biliary secretions may accumulate in the afferent loop and, after food has left the stomach, can enter the gastric remnant, causing nausea and vomiting. Prokinetics, e.g. metoclopramide, domperidone or erythromycin, may be useful, although surgical correction may be needed if vomiting bile is refractory to medical management.

Long term consequences

Weight loss and malnutrition

Weight loss and nutritional inadequacy are common occurrences after gastric surgery, and nearly always reflect poor food intake. Problems such as early satiety or dumping syndrome tend to make people reluctant to eat, and side effects of treatments such as radiotherapy or chemotherapy may further affect appetite and food consumption. Dietary guidance should focus on the improvement of meal frequency and nutrient density via appropriate food choice and enrichment measures (see Chapter 6.3). Additional oral nutritional supplementation may also be indicated. Patients should be monitored regularly so that progress can be assessed and nutritional support measures adjusted as necessary.

Malabsorption

Malabsorption, particularly of fat, may result from a number of alterations in gastrointestinal function following gastrectomy as listed earlier. If this occurs, it is important to ensure that energy intake is increased to compensate for faecal energy losses and that micronutrient intake does not become compromised, particularly that of calcium, iron and fat soluble vitamins. Treatment of steatorrhoea by dietary fat restriction alone is not recommended as the resultant dietary energy content will be too low to meet energy needs. If symptoms of steatorrhoea are particularly troublesome, a proportion of dietary fat can be isocalorically substituted by either glucose polymers or medium chain triglycerides (MCTs). Medical management involves the use of antidiarrhoeal medication, bile acid binders and possibly pancreatic enzyme replacements.

Anaemias

Iron deficiency anaemia is a common and particular risk following gastrectomy as a result of the combination of poor iron intake and poor absorption. Haematological status should be regularly assessed and treated if necessary. Pernicious anaemia can be a secondary consequence of gastrectomy as a result of the loss of intrinsic factor (produced by gastric parietal cells) and other local conditions necessary for the absorption of vitamin B₁₂. Vitamin B₁₂ should be given by injection at intervals to those considered to be at risk. Megaloblastic anaemia may also result from folate deficiency, particularly if dietary intake is poor and malabsorption is present. Oral folate supplementation may be necessary.

Dietetic management

Dietary guidance following gastric reconstruction should focus on the need for:

- Small, frequent, regular meals.
- Avoiding large quantities of fluid.
- Consuming fluids between meals rather than with them.
- Eating a variety of nutrient dense foods, e.g. milk, dairy products, lean meat and eggs. Non-bulky, i.e. not high fibre, cereal foods and small amounts of fruit and vegetables should also be included in the daily diet.
- Boosting nutrient intake via food enrichment strategies if food intake is, or has been, particularly poor.
- Taking recommended nutritional supplements (either energy/nutrient supplements or vitamin /mineral preparations) if indicated.
- Advising remedial dietary measures for dumping syndrome or malabsorption if present.

Cancer of the pancreas

Linda Murray

Pancreatic cancer is the tenth most common cancer in the UK, but the fifth most common cause of cancer death. The prognosis is very poor; >80% of pancreatic cancers

are unresectable at diagnosis, with only 3% of patients surviving 5 years (ISD, 2010; NISRA, 2008; 2010; ONS, 2010b; Welsh CISU, 2010). The disease is often diagnosed at a stage when neither surgery, chemotherapy nor radiotherapy will prolong survival time for more than a few weeks.

Pancreatic cancer is accompanied by a range of symptoms that can affect food intake or utilisation, including pain, nausea, anorexia, early satiety and pancreatic insufficiency (Davidson *et al.*, 2004). Due to the retroperitoneal site of the pancreas and symptoms that are usually vague, delay in presentation and diagnosis is common. All too often the patient presents with features of advanced disease. Common modes of presentation include weight loss (70–90% of cases), pain (often relieved by sitting forward), jaundice (presenting feature in 75% of pancreatic head tumours) and diabetes mellitus (sudden onset in middle age with no family history). Only around 16% of patients survive for 1 year from diagnosis, which reflects the fact that most cases of pancreatic cancer are not suitable for potentially curative treatment (ONS, 2010b).

Curative resection

Curative resection, when possible, usually takes the form of a pancreaticoduodenectomy (Whipple's procedure). The extent of this resection ranges from preservation of the pylorus to radical surgery, combining Whipple's procedure with extensive lymph node dissection. Extensive surgery of this nature may be undertaken in patients who are already nutritionally compromised, and early nutritional assessment and intervention both pre- and post-operatively are essential. Postoperative nutritional problems vary and can include pancreatic fistulae, abdominal chyle leaks, delayed gastric emptying, diabetes mellitus and steatorrhoea. Early dietetic intervention from diagnosis and staging, through surgery and possible chemotherapy, is essential to maintain good nutritional intake, promote recovery and help improve quality of life. It is increasingly recognised that pre- and post-operative nutritional support via the enteral or parenteral route may make a considerable difference to recovery time and outcome (see Chapter 7.15.5). This aspect of care has often been overlooked in the past (Ulander *et al.*, 1991). Postoperatively, nutritional monitoring on a frequent basis remains important. Since enzyme supplementation and insulin are commonly required following pancreatic resection, dietary guidance on these aspects is also likely to be needed. Dietary fat should be included to tolerance as some patients, despite commencing pancreatic enzyme supplementation after surgery, often report symptoms of steatorrhoea. Recovery after major resective surgery of this type may take up to a year.

Palliative treatment

The aim of management in palliative care is to improve quality of life via pain and symptom control, such as malabsorption. Surgical treatments include biliary stenting to

relieve jaundice and accompanying symptoms of anorexia and poor intake. Gastric or duodenal obstruction, evident by intractable vomiting, is common in pancreatic cancer and is relieved by palliative bypass procedures such as gastrojejunostomy, or a stent. However, as in gastric cancer, if the patient has a very poor prognosis and neither of these procedures is appropriate, then management is conservative. Where there is hepatic or biliary obstruction, biliary bypass procedures may be possible, but as with above, the surgical risk needs to be measured against the benefit. Ascites can often be a problem in this group of patients and they may require regular paracentesis.

Nutritional support should be sufficient to prevent unnecessary nutritional debilitation while not being over-invasive. Proprietary supplements may be useful to help maintain adequate energy and nutrient intake. Davidson *et al.* (2004) have shown that weight stabilisation with intensive nutritional intervention is associated with improved survival duration and quality of life in unresectable cancer patients. There has been evidence demonstrating the benefits of fish oil supplements in this group of patients to reverse the effects of cancer cachexia (Barber, 2001). Yet, a recent Cochrane review showed that there is currently insufficient evidence to support the use of supplement drinks containing eicosapentaenoic acid (EPA) (Dewey *et al.*, 2007) (see Chapter 7.15.9). Multidisciplinary team input is essential to improve symptoms of pain, nausea, steatorrhoea and early satiety. Good compliance with enzyme replacement therapy and pain control is required. The overall nutritional objective is to ensure that eating remains a pleasurable aspect of life for as long as possible, while preserving as much of the patient's strength and wellbeing as is practicable.

As well as these consequences, patients with pancreatic cancer also have to cope with the psychological effects of the diagnosis itself and its poor prognosis. The resulting depression and anxiety can profoundly impair the desire to eat. Since the rapid advancement of the disease can also result in high nutrient losses and poor nutrient intake if symptoms are not adequately controlled, the risk of debilitating malnutrition is high.

Colorectal cancer

Lindsey Bottle

Colorectal cancers include those that affect the colon, rectum (including the anus) and appendix. These are the third most common cancers in the UK, after breast and lung cancer, with approximately 40 000 new diagnoses/year (ISD, 2010; NISRA, 2008; 2010; ONS, 2010a; Welsh CISU, 2010). Incidence increased by 33% in men and 14% in women between 1971 and 2009 (ONS, 2011). Diagnosis is strongly related to age, and although three-quarters of all new cases are found in those aged over 65 years (NICE, 2011), it is not uncommon to encounter much younger patients. The introduction of the NHS Bowel Screening Programme in 2006 has led to earlier diagnosis, and is predicted to reduce mortality rates by 16% (NHS Bowel Screening Programme, 2011).

Aetiology

A number of risk factors have been implicated in the development and progression of colorectal cancer. These include genetic predisposition, inflammatory bowel disease, smoking, excess alcohol, lack of physical activity, obesity and diet (WCRF/AICR, 2011). Most (95%) cases are adenocarcinomas that develop from adenomatous polyps; many of these can be detected early prior to molecular changes that can result in malignancies (Manne *et al.*, 2010). Obesity has been associated with increased risk (Harriss *et al.*, 2009) and there is conclusive evidence to show that increased levels of physical activity lower risk (Boyle *et al.*, 2012). A positive association between intake of red and processed meat and colorectal cancer has been established (Xu *et al.*, 2013) and there is evidence to show that dietary fibre can have a protective effect (Murphy *et al.*, 2012), in particular wholegrain intake (Larsson *et al.*, 2005). The effect of lifestyle factors has become more convincing over the past few years and in theory some cancers could be theoretically avoidable if these factors are addressed (WCRF, 2007).

Diagnosis

Colorectal cancer usually presents with symptoms of a persistent change in bowel habit (including unresolved diarrhoea for several weeks), rectal bleeding, abdominal pain, a lump in the abdomen, unexplained tiredness, anorexia and loss of weight. If the disease is detected at an early stage, it can be completely cured by surgery. One-year survival rates have significantly improved over the past 40 years from 39% to 73% in men and 40% to 72.2% in women (Coleman *et al.*, 1999; ONS, 2011).

Management

The prognosis and treatment modality depend on the type and grade of tumour and its degree of spread. This is determined by the Duke's clinicopathological classification as well as the Royal College of Pathologists TNM5 staging (see Chapter 7.15.1).

Surgical resection is the principal first line treatment for the majority of patients. It is undertaken either as a curative treatment or as a palliative measure to improve quality of life in those with bowel obstruction. Carbohydrate loading as part of Enhanced Recovery Programmes is now common practice (see Chapter 7.17.5) will involve end to end anastomoses or stoma formation (ileostomy or colostomy), depending on the degree of tumour infiltration.

Chemotherapy and/or radiotherapy can be used neoadjuvantly to reduce the tumour burden prior to surgery, and chemotherapy is used adjuvantly postoperatively to prevent the risk of recurrence. In the case of advanced metastatic disease, palliative chemotherapy is routinely offered. New surgical techniques and treatment modalities, including targeted therapies, e.g. cetuximab and bevacizumab, are being developed and it is now recognised that optimum outcomes for patients with colorectal

cancer require specialised multidisciplinary care (NICE, 2011).

Dietary management

People with colorectal cancer may present in a nutritionally depleted state as a result of chronic symptoms, side effects from treatment and the cancer process itself. In such patients, appropriate nutritional support should be instituted as soon as possible to help manage the effects of treatment. An appropriate nutritional screening tool and dietetic referral system should be in place to identify at an early stage those who are malnourished (NICE, 2006).

Nutritional support should aim to prevent weight loss during treatment as undernutrition and cachexia are indicators of poor prognosis (Dewys *et al.*, 1980) and can increase the risk of treatment related toxicity (Andreyev *et al.*, 1998). Side effects experienced by colorectal cancer patients undergoing chemotherapy can include diarrhoea, nausea, taste changes and anorexia. In the first instance, it is essential to ensure that such symptoms are controlled with medication. Diet should then be manipulated accordingly to ensure that patients maximise their intake (see Chapter 7.15.1). Dietary counselling during chemotherapy has been shown to improve nutritional status (Dobрила-Dintinjana *et al.*, 2012), and the use of oral nutritional supplements may be necessary if intake remains suboptimal and weight loss is ongoing. Supplements can result in increased energy intake and improved quality of life (Ravasco *et al.*, 2005).

Pelvic radiotherapy related symptoms can include diarrhoea, faecal incontinence, increased urgency and pain. Approximately 70% of patients experience acute small intestinal changes that can lead to gastrointestinal symptoms both during and after treatment (Andreyev *et al.*, 1998). Nutritional support is essential to prevent weight loss and manage these effects. Various approaches have been investigated, including elemental diets, probiotic supplementation, low fat diets and reducing insoluble fibre in the form of raw vegetables, but more research is recommended (McGough *et al.*, 2004). Late onset of symptoms is not always initially linked to previous cancer treatment, and dietetic input may be required for up to 6 months after radiotherapy finishes. If a definitive cause cannot be established and symptoms persist, referral to a gastroenterologist for further investigation is advisable.

If the tumour or peritoneal metastases are causing a partial obstruction, a trial of a low fibre diet may be effective in reducing symptoms in the short term, but no research is available to support this approach. Patients undertaking such dietary restrictions should be advised, monitored and reviewed regularly by a dietitian. The aim is to maintain nutritional status whilst the obstruction is treated or palliated. This may involve placement of a colonic stent or insertion of a stoma if the patient is well enough to undergo surgery.

Patients who are undergoing colorectal surgery do not routinely require artificial nutritional support postoperatively. Oral fluids and diet should be initiated at an early stage (see Chapter 7.17.5). Nevertheless, as with all

patients, nutritional status during the recovery period should be monitored, particularly if patients were malnourished preoperatively or experience postsurgical complications, or if resumption of oral food intake is slow. In such cases, appropriate nutritional support should be instigated (see Chapter 6.3, Chapter 6.4 and Chapter 6.5). Symptom control, including adequate pain relief, is important as part of the overall management plan because continuous pain, discomfort or nausea can markedly suppress appetite.

Specific dietary measures may be required during the initial phase of adjustment to the effects of intestinal resection and possible creation or reversal of a stoma (see Chapter 7.4.9).

In the palliative care setting, if nutrition is highlighted as an issue for either the patient or family and carers, this should be addressed as for advanced cancer of any site (see Chapter 7.16). Dietary advice for colorectal cancer survivors should be to increase dietary fibre, limit red and processed meat, maintain a healthy body weight and be regularly physical active (WCRF/AICR, 2011).

7.15.4 Breast cancer

Michelle Harvie

Key points

- Breast cancer is the most common malignancy amongst women.
- Increasing rates of breast cancer are linked to trends in overweight and obesity, sedentary lifestyle and increased alcohol intakes.
- Weight control and exercise are recommended to improve survival after a diagnosis of breast cancer.

Breast cancer accounts for a third of cancer cases in women in the UK. In 2008, 47 693 women and 341 men were diagnosed in the UK, and 12 047 died from the disease. Earlier detection and improved adjuvant treatment has reduced breast cancer mortality by 37% in the past 20 years. The most recent, and undoubtedly conservative, estimates indicate there are approximately 550 000 women living with a history of breast cancer in the UK. This equates to almost 2% of the total female population and nearly 10% of the population aged 65 years and older. The long term health and wellbeing of breast cancer patients is therefore an increasingly important consideration for researchers and healthcare professionals [Cancer Research UK (CRUK), 2011b].

Risk factors and prevention

Estimated lifetime risk of breast cancer in the UK is 1 in 8 for women and 1 in 1014 for men. Female UK breast cancer rates doubled between 1979 and 2008, with similar increases globally, particularly within Asian and developing countries that traditionally have had low rates (Bray *et al.*, 2004). These increases have been linked to adverse trends in a number of lifestyle, hormonal and reproductive risk factors.

Hormonal and reproductive risk factors

The majority of breast cancers (81%) occur in postmenopausal women. Both earlier age of menarche (20% risk

reduction for 5-year delay) and later age of menopause (3% for each year older at menopause) increase risk. The average age of menarche in developed countries has fallen from 16–17 years in the mid 19th century to 12–13 years today. Risk of breast cancer reduces by 7% with each full term pregnancy and by 4% for every 12 months of breastfeeding. Women currently taking hormone replacement therapy (HRT), particularly combined oestrogen–progestogen therapy, have a two-fold increased risk of breast cancer compared with non-users. Once HRT use ceases, a woman's risk returns to that of a never user within 5 years.

Lifestyle risk factors

Observational data consistently link overweight and obesity, adult weight gain, sedentary lifestyle and alcohol intake to increased risk amongst women; excess weight is linked to post-, but not pre-menopausal, breast cancer. A weight gain of 20 kg during adulthood doubles the risk of postmenopausal breast cancer (Vrieling *et al.*, 2010). Alcohol and sedentary behaviour increase the risk of both pre- and post-menopausal breast cancer. An additional 10 g of alcohol (1 unit) on a daily basis increases risk by 10% (Key *et al.*, 2006), whilst each additional hour of moderate exercise (65–80% maximum heart rate) per week can reduce risk by 6% (Monninkhof *et al.*, 2007). Observational studies and recent bariatric data suggest cancer risk reduction with weight loss and energy restriction, even with modest weight loss (5–10%) (Christou *et al.*, 2008; Eliassen *et al.*, 2006; Harvie *et al.*, 2005a). Energy restriction appears to be more important for prevention of breast cancer compared with modification of dietary composition (Brennan *et al.*, 2010). Weight is the only identified lifestyle risk factor amongst men, where a body mass index (BMI) of $>30 \text{ kg/m}^2$ doubles risk (Johansen Taber *et al.*, 2010).

The proportion of breast cancer cases estimated to be preventable with weight control, exercise and limiting alcohol is contentious, but has recently been cited to be between 18% and 40% in the UK (Department of Health, 2007; WCRE, 2007).

Genetic factors

Fifteen per cent of breast cancer cases occur in women with a family history of the disease, and 2% occur in women with mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2*. These mutation carriers have a 45–65% chance of developing breast cancer in their lifetime. As with the general population, excess weight and lack of exercise increase the risk of developing postmenopausal breast cancer amongst women with a family history and known *BRCA* mutation carriers (Begum *et al.*, 2009; Manders *et al.*, 2011).

Treatment

In countries with breast screening, approximately 60% of cancers are localised to the breast at the time of diagnosis

(stages 1 and 2), 30% have local lymph involvement (stage 3) and 10% are metastatic (stage 4) (CRUK, 2011a). Patients with early breast cancer (stage 1–3) generally have some form of breast and axillary lymph node surgery, followed by 15 or 19 daily sessions of radiotherapy for women who have had conservation surgery, i.e. not a mastectomy. Three-quarters of breast cancers in the UK are oestrogen receptor positive (ER positive) and these patients receive adjuvant endocrine (hormone) therapy. Standard treatment is a 5-year course of the selective ER receptor modulator tamoxifen. Aromatase inhibitors (anastrozole, exemestane and letrozole) are increasingly prescribed after surgery instead of tamoxifen for women at high risk of recurrence, or after 2–5 years on tamoxifen.

Approximately 25% of breast cancer patients receive adjuvant chemotherapy (after breast surgery) and 3% receive neoadjuvant chemotherapy (before breast surgery). The 20% of patients with cancers that express the human epidermal growth factor receptor 2 (HER 2) receive a targeted monoclonal antibody therapy, e.g. trastuzumab or lapatinib. Women diagnosed with advanced metastatic disease receive either endocrine therapy or chemotherapy.

Most men diagnosed with breast cancer undergo mastectomy with axillary lymph node clearance or sentinel node biopsy, where fewer than five lymph nodes are generally removed. Indications for radiotherapy are similar to those for female breast cancer. The majority of male breast tumours are ER positive and are treated with either tamoxifen or aromatase inhibitors, whilst some individuals receive chemotherapy. Men with metastatic disease typically receive endocrine treatment.

Body weight

An estimated 50–65% of breast cancer patients are overweight or obese at the time of diagnosis, whilst 60–75%, including those with previous healthy weight, gain weight during adjuvant treatment. Gains in fat mass are usually accompanied by a loss of fat free mass (sarcopenic obesity) (Irwin *et al.*, 2005). Excess weight at diagnosis has been consistently linked to poorer outcome (Vance *et al.*, 2010), whilst weight gain has been linked to increased risk of recurrence and poorer overall survival in many (Chen *et al.*, 2010; Nichols *et al.*, 2009); however, not all studies are consistent (Caan *et al.*, 2006; 2008). Gains in body fat are greater during adjuvant chemotherapy compared with endocrine therapy (3–7 kg versus 1–4 kg, respectively) (Harvie *et al.*, 2004; Irwin *et al.*, 2005). Gains occur both during and after chemotherapy due to increased energy intake and decreased energy expenditure linked to treatment (chemotherapy and steroids), hormonal (chemotherapy induced menopause), psychosocial and anxiety related factors. Part of the adverse effects of adiposity is linked to increased levels of insulin; therefore, the insulin sensitising drug metformin is currently being tested as a potential treatment for breast cancer (Goodwin, 2008).

Unlike other cancer patients, women with advanced breast cancer do not generally develop weight loss and cachexia, i.e. hypermetabolism and anorexia. These

metastatic patients often maintain good energy intakes, which lead to gains in body fat of 2%, but do not prevent declines in lean body mass (Harvie *et al.*, 2005b).

Evidence based diet and exercise recommendations after diagnosis

As for breast cancer prevention, weight control, energy restriction and exercise rather than specific dietary constituents influence outcome after diagnosis. The randomised Women's Intervention Nutrition Study (WINS) reported a 23% reduction in breast cancer relapse in women losing modest amounts of weight compared with a control group who had gained weight (3% difference in weight between the groups) (Chlebowski *et al.*, 2006). The weight losing women had consumed a low fat diet (30g of fat/day; 20% of energy as fat) compared with control women consuming on average 50g of fat/day (30% of energy as fat). The lack of effect on outcome of a comparable low fat intervention in the Women's Healthy Eating and Living study (WHEL), in which women did not lose weight (Pierce *et al.*, 2007), suggests energy restriction and weight loss are more important than fat restriction for outcome. Moderate fat diets (30–35% of energy from fat) are likely to be superior to low fat eating plans (20% of energy from fat) for breast cancer patients, as in other settings they are better for limiting calorie intake and weight, improving insulin sensitivity and reducing risk of cardiovascular disease (Shai *et al.*, 2008) (see Chapter 7.14.1).

There is much interest in the potential anticancer effects of fruit and vegetables, specifically carotenoids and brassicas. However, a recent large randomised trial of a high fruit and vegetable diet (13 servings/day) and low fat diet plan (20% of energy from fat) amongst 3088 early breast cancer patients did not find beneficial effects in terms of breast cancer recurrence or mortality (Pierce *et al.*, 2007). Alcohol is consistently linked to risk, but not with survival after diagnosis (McTiernan *et al.*, 2010). Exercise alone does not control weight amongst breast cancer survivors (Markes *et al.*, 2006). However, exercise is a vital part of energy restricted weight control programmes. Exercise has been associated with greater disease free survival, quality of life, cardiovascular fitness and bone density (McTiernan *et al.*, 2010).

Popular dietary practices

Soya and phytoestrogens

Many breast cancer patients deliberately increase their intake of soya foods or phytoestrogen supplements, i.e. black cohosh, agnus castus and red clover, in the belief that this will either reduce their risk of breast cancer recurrence or reduce hot flushes. However, soya has no proven benefits for hot flushes (Lethaby *et al.*, 2007). There have been concerns that soya may limit the efficacy of antioestrogen therapies such as tamoxifen (van Duursen *et al.*, 2011). Recent Asian population studies report 10–15g of soya protein/day to be safe as part of a healthy lifestyle amongst patients taking tamoxifen (250mL of soya milk = 7.5g of soya protein) (Guha *et al.*, 2009; Shu *et al.*, 2009) and aromatase inhibitors. These

studies do not however conclusively suggest soya has benefits for patients (Kang *et al.*, 2010).

Dairy free diets

An estimated 20% of UK breast cancer patients avoid or limit dairy foods after diagnosis (Breast Cancer Care, 2005). This populist approach is not supported by evidence. A recent meta analyses including 24 187 cases and 1063 471 participants found 15% fewer breast cancers amongst high (>3 servings/day) versus low dairy consumers (<1 serving/day). Likewise, a prudent diet that includes low fat dairy foods has been linked to reduced recurrence and all cause mortality amongst breast cancer patients (Kroenke *et al.*, 2005; Kwan *et al.*, 2009).

High dose vitamin supplements

An estimated 10% of breast cancer patients self prescribe high dose antioxidant supplements (beta-carotene, vitamins C and E, and selenium). There are concerns that antioxidants may protect tumour cells from the targeted oxidative damage during radiotherapy and chemotherapy, and potentially reduce the effectiveness of these treatments. Studies to date have not resolved this issue and further research is required (Greenlee *et al.*, 2009; Nechuta *et al.*, 2011).

Late treatment effects

Lymphoedema (arm swelling) is an undesirable complication following axillary clearance or radiotherapy to the axilla, which can have negative physical and psychological effects on women. Obesity is a risk factor for the development of lymphoedema and recent data suggest weight loss may reduce arm swelling and is likely to increase overall wellbeing and quality of life (Shaw *et al.*, 2007).

Bone health

Bone density is an important consideration amongst patients with chemotherapy induced menopause or for those prescribed aromatase inhibitors. Lifestyle recommendations to limit reduction in bone density include increasing weight bearing exercise, reducing alcohol intake, smoking cessation and supplementation with vitamin D (400–800 IU/day). Calcium supplementation is only advised if dietary intake is less than the requirement of 1g/day (Reid *et al.*, 2008).

Associated conditions and diseases

Both postmenopausal and menopausal breast cancer patients have obesity related comorbidities such as hypertension (18–50%), hyperlipidaemia (25%) (Manjer *et al.*, 2000), coronary heart disease (15–27%), vascular disease (3–5%) and type 2 diabetes mellitus (5–10%) (Yancik *et al.*, 2001). Comorbidities are a major cause of mortality amongst women diagnosed with localised breast cancer, particularly amongst older women in whom cardiovascular disease can account for over half of deaths (Schairer *et al.*, 2004). The consistent adverse effect of

comorbidities on overall survival highlights the importance of managing comorbid conditions alongside breast cancer treatments (Barone *et al.*, 2008).

7.15.5 Lung cancer

Mhairi Donald

Key points

- People with lung cancer should always be managed as part of a multidisciplinary team.
- Patients experience a wide range of nutritional problems and require a full nutritional assessment at diagnosis.
- Dietary adaptations should be implemented to help minimise specific nutritional symptoms and support quality of life.

Lung cancer is the most common type of cancer worldwide and in the UK it is the most frequent cause of cancer mortality death and the second most common cancer. Currently, it is more common in men than in women, although the incidence in men is falling as fewer men are smoking, while the incidence in women is rising as the number of women smoking has increased. The incidences are 58.8 and 39.3 per 100 000 population in men and women, respectively [Cancer Research UK (CRUK), 2011]. Cigarette smoking causes approximately 90% of lung cancers. Other factors thought to contribute are poor diet (lack of fruit and vegetables in particular), industrial carcinogens and air pollutants.

The symptoms of lung cancer may include:

- Continuing cough or change in a long standing cough.
- Chest infection that does not improve.
- Increasing breathlessness and wheezing.
- Coughing up blood stained phlegm.
- Hoarse voice.

- Dull ache or sharp pain on coughing or taking in a deep breath.
- Loss of appetite and weight loss.
- Difficulty swallowing.
- Excessive tiredness (fatigue) and lethargy.

There are two main types of primary lung cancer:

- Non small cell lung cancer (NSCLC), which accounts for 80% of cases.
- Small cell lung cancer (SCLC), which accounts for 20% of cases; this is more aggressive than NSCLC and can spread widely to other organs, including the brain.

The early stages of lung cancer do not usually produce symptoms, so the disease is generally at an advanced stage by the time it is diagnosed. It has one of the lowest survival outcomes of any cancer. Many patients are older, with 87% of those diagnosed being over 60 years old, and because of the association with smoking they may also have coexisting, comorbid problems such as chronic

obstructive pulmonary disease (COPD). In England and Wales, only 27% of male and 30% of female lung cancer patients are alive after 1 year; this drops to 7% and 9%, respectively, at 5 years (CRUK, 2011).

Every patient with a diagnosis of lung cancer should have a management plan developed by a lung cancer multidisciplinary team (NICE, 2011). Treatment options are determined by the type and stage of cancer and medical fitness, but may include surgery, chemotherapy, radiation, biological therapies or a combination of these. There are many side effects associated with these treatments and nutritional compromises are pronounced in lung cancer.

Nutritional screening

Most patients with lung cancer will have multiple disease related symptoms, such as breathing difficulties, cough, pain, anorexia, fatigue and weight loss, that are likely to have an effect on nutritional status and overall quality of life. Knowledge of symptom prevalence and distress can be used to develop specific interventions that can reduce distressing symptoms and improve quality of life.

Unintentional weight loss is common in cancer patients. Weight loss is often the first sign of disease in patients with lung cancer and most patients will experience it as their disease progresses. To combat weight loss and malnutrition, best practice suggests that nutritional screening using a validated tool should form part of the initial assessment at the time of diagnosis. In a small study of lung cancer patients at the start of treatment (Khalid *et al.*, 2007), 66% of patients were already reporting symptoms; loss of appetite was the most common, followed by nausea and early satiety. Unintentional weight loss was identified in 28%, with patients who experienced weight loss of 5% or more having significantly more symptoms than patients with no weight loss. Isenring *et al.* (2010) reported a similar association in a mixed group of cancer patients on treatment: those who experienced a greater number of symptoms affecting nutritional intake or status (otherwise referred to as nutrition impact symptoms) were more likely to be malnourished.

Weight loss in lung cancer patients has been reported as anything from 0% to 68% (Beckles *et al.*, 2003). To adequately support a patient's nutritional status it is important to identify the nutrition impact symptoms and set up individual nutritional management plans. These plans must be monitored and adjusted throughout the patient pathway (National Cancer Action Team, 2009).

Treatment options and nutritional implications

Surgery

The type of operation required for lung cancer will depend on the size and position of the tumour. Procedures include a lobectomy (removal of a lobe of the lung), a pneumonectomy (removal of the whole lung or a wedge) and resection/segmentectomy (removal of a small wedge shaped section of cancerous lung and a margin of

healthy tissue around the cancer). The outcome of surgery is closely related to the extent of the operation and preoperative lung function. The role of nutrition in predicting the outcome of lung cancer surgery has not been studied extensively. However, one study found that impaired nutritional status was an important predictor of death and need for postoperative ventilation. Impaired nutritional status was more common in patients with lower body mass index (BMI) and lower fat free mass (Jagoe *et al.*, 2001).

Any surgical intervention is likely to affect nutritional status. Respiration requires energy and the work of breathing after surgery may increase expenditure in patients who may also be experiencing anorexia, early satiety and fatigue, which in combination contribute to an inadequate energy intake. Patients having surgery require ongoing monitoring and nutritional support (see Chapter 6.3).

Radiotherapy

Radiotherapy for lung cancer targets the mediastinal area, which includes the pharynx and the oesophagus, both of which are lined by highly radiosensitive epithelial cells that will be damaged by the treatment. This can lead to a range of radiation related side effects, including oesophagitis and resulting in dysphagia, epigastric pain, indigestion, heartburn and taste changes (Cranganu & Camporeale, 2009). It is important to relieve pain and discomfort caused by oesophagitis, both to support the patient and to maintain adequate nutrition and hydration. For pain control, topical medications, such as sucralfate and antacids may all need to be considered. Avoiding acidic or spicy ingredients and changing the texture of the diet to soft, semi solid or nutritious liquids, including oral nutritional supplements, may be recommended. A change in food temperature such as keeping foods cool or at body temperature can also help.

Administration of chemotherapy alongside radiotherapy improves local control by sensitising the tumour to radiation while treating the disease systemically. This treatment can accentuate the significant nutritional issues caused by the radiotherapy as well as adding chemotherapy specific symptoms such as taste changes and increased nausea.

Prophylactic cranial radiotherapy may be given to SCLC patients who have limited stage disease that has not progressed on first line treatment (NICE, 2011). It is given to the brain to reduce the risk of the lung cancer spreading to that area. Side effects of this therapy can include tiredness, headaches, nausea and vomiting.

Chemotherapy

When the tumour is not considered to be resectable, and in advanced SCLC, chemotherapy is considered the mainstay of treatment. The response is poor and the survival benefit marginal, although there may be a benefit in symptom management. The chemotherapy regimens are generally platinum based, with the most common

nutrition related side effects being nausea and vomiting, early satiety, taste changes and dry mouth.

Biological therapies

Biological therapies are treatments that change the way cells signal each other, either by controlling the growth or switching growth off. Most of the potential side effects of biological therapies are likely to adversely affect nutritional intake, including:

- Tiredness and/or weakness.
- Diarrhoea.
- Sore mouth.
- Lack of appetite.
- Skin rashes.

Supplementation with fish oils

The addition of fish oil [2.5g/day eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)] to standard first line platinum based chemotherapy has been shown to increase response rates and offers clinical benefit in patients with advanced NSCLC without affecting treatment toxicity (Murphy *et al.*, 2011a). The plasma phospholipid EPA concentration after supplementation was a significant predictor of response to chemotherapy, independent of age, sex, BMI, presence of sarcopenia (loss of muscle mass and strength associated with ageing), performance score and weight loss history. This is an important finding given the poor patient compliance often associated with these products. Nutritional intervention with 2.2g of fish oil/day also resulted in weight and muscle mass maintenance during chemotherapy for NSCLC (Murphy *et al.*, 2011b). However, these findings were from small trials; therefore, further investigation of fish oil supplementation is needed.

Fatigue

Fatigue, pain and dyspnoea (difficult or laboured respiration) have been identified as common symptoms associated with particular distress in lung cancer sufferers. Okuyama *et al.* (2001) found that 59% of patients with advanced lung cancer had experienced clinical fatigue (defined as fatigue that interferes with any daily activities). Clinical fatigue is not generally relieved with rest; it can turn everyday life and basic tasks such as cooking, cleaning and shopping into hard work.

Several factors may contribute to fatigue, including the disease itself. In inoperable NSCLC patients, the presence of a systemic inflammation (identified by elevated C-reactive protein) was associated with increased weight loss, a reduction in performance status, increased fatigue and reduced survival; the greater the inflammatory response, the worse those parameters were affected (Scott *et al.*, 2002). Anaemia and problems maintaining an adequate oral intake may also contribute to fatigue. Patients may be unable to stand for long enough to prepare or cook food. Some lung cancer patients will need ambulatory oxygen, which must be disconnected whilst using a

gas cooker. Supporting an adequate oral intake needs to be carefully considered; food and drinks must be nutritious and require minimal preparation effort from the patient. The patient's ability to manage provisions and cooking is crucial. Social support may be recommended, such as the use of Meals on Wheels, ready or prepared meals, and help with shopping and cooking through social services or Age UK. Menu planning with an understanding of the patient's social support, and including nutritious snacks, drinks and oral nutritional supplements, should help with physical symptoms and quality of life (see Chapter 6.3). When using oral nutritional supplements, the volume must be considered. In a study of patients with COPD (which has symptoms similar to those of lung cancer), voluntary intake was limited by the volume, frequency and energy density of food portions because those factors influenced symptoms such as early satiety and bloating. Weight gain was higher in patients who received 125 mL supplements compared with 200 mL cartons despite their lower total energy contribution (Broekhuizen *et al.*, 2005). The optimum volume of supplements should be considered in the dietary management strategy. Gentle exercise, pulmonary rehabilitation and energy conservation techniques can also help; a specialist or palliative physiotherapist can plan a programme.

Recurrent laryngeal nerve palsy

Recurrent laryngeal nerve palsy has been reported in 2–15% of lung cancer patients and is more common in left sided tumours. It is associated with poor expectoration with coughing and an increased risk of aspiration (Beckles *et al.*, 2003). A modified consistency diet may need to be implemented to help manage it.

Supportive and palliative care

Lung cancer is often diagnosed at an advanced stage and can progress rapidly; median survival from diagnosis is <4 months (NHS Executive, 1998). Palliative or best supportive care may need to be implemented from the outset. Patients with NSCL assigned to early palliative care reported better quality of life and fewer depressive symptoms, and their median survival time post diagnosis increased by 2.7 months (Temel *et al.*, 2010). The early identification and proactive management of symptoms clearly offered a benefit. Identifying nutrition impact symptoms and offering supportive management strategies are an important focus for dietitians to help support quality of life in this setting (see Chapter 7.16).

7.15.6 Gynaecological cancers

Mhairi Donald

Key points

- Gynaecological cancer includes a range of cancers originating from the female reproductive tract; these cancers have differing incidences, treatments and survivorship outcomes.
- Women with gynaecological cancer experience many nutritional problems and require a full nutritional assessment at diagnosis.
- Ongoing monitoring and responsive dietary management by a dietitian working within a multidisciplinary team is necessary throughout the treatment pathway, from diagnosis to survival or palliation.

Gynaecological cancer refers to cancers originating in the female reproductive organs, including the ovaries, cervix, endometrium, vagina and vulva. Different forms of gynaecological cancer have differing incidences, treatments and survival outcomes. Gynaecological cancers and their treatments usually have profound and often permanent effects on women, including:

- Rectal, bladder and sexual dysfunction.
- Infertility/onset of early menopause and associated symptoms.
- Changes in body image.

Ovarian cancer

Menstruating women ovulate monthly and it is thought that ovarian cancer may start when the cells on the surface of the ovary do not repair themselves after ovulation.

Ovarian cancer is the leading cause of death in women with gynaecological cancer, with an incidence of 16.2 per 100 000 population [Cancer Research UK (CRUK), 2009]. The incidence rates are higher in postmenopausal women, with the highest rate in the 60–64 year age group. The 5-year survival rate is 34% (CRUK, 2001).

Many women present with advanced disease because the symptoms are often attributed to other conditions, e.g. irritable bowel syndrome. Women (especially those aged 50 years or over) should undergo diagnostic tests if they report the following symptoms on a persistent or frequent basis (NICE, 2011):

- Persistent abdominal distension (referred to as bloating).
- Feeling full (early satiety) and or loss of appetite.
- Pelvic or abdominal pain.
- Increased urinary urgency and/or frequency.

Endometrial cancer

Endometrial cancer involves the lining of the uterus and is the most common type of cancer of the uterus. The incidence rate is 19.4 per 100 000 population (CRUK, 2009), with a 5-year survival rate of 76% (CRUK, 2001).

Risk factors for endometrial cancer include:

- Overweight or obesity (WCRF/AICR, 2007).
- Heightened exposure to oestrogen associated, with early menarche and/or late menopause.
- Pregnancy lowers the risk of endometrial cancer and more than one pregnancy will lower the risk further.

Cervical cancer

Cancer can occur in the cells or glands lining the cervix. The incidence rate is 8.5 per 100 000 population (CRUK, 2009), with a 5-year survival rate of 68% (CRUK, 2001).

Risk factors for cervical cancer include:

- Infection with human papilloma virus (HPV), particularly types 16 and 18.
- Unprotected sexual intercourse before the age of 17 years with multiple partners.
- Smoking.
- A weakened immune system, e.g. HIV/AIDS.

Vaccines to protect against the strains of HPV most likely to cause cervical cancer are routinely offered to schoolgirls aged 12–13 years in the UK.

Vulval and vaginal cancers

These are rarer cancers with a combined incidence rate of 3.1 per 100 000 population (CRUK, 2013).

Nutrition

Malnutrition in cancer patients is associated with a variety of clinical consequences, including reduced quality of life, decreased response to treatment, increased risk of treatment induced toxicity and a reduction in overall survival. However, rates of malnutrition are lower with gynaecological cancers than with other cancers. Laky *et al.* (2007) identified malnutrition in 20% of gynaecological cancer patients at diagnosis; the prevalence varied between specific cancer sites, with the highest rate (67%) in ovarian cancer and the lowest rate (6%) in endometrial cancer.

Treatment

The management of gynaecological cancers includes surgery, radiotherapy, brachytherapy, chemotherapy, intraperitoneal (intra-abdominal) chemotherapy, hormone therapy or a combination of any of these. The nutritional needs of the patients are likely to vary through the course of treatment. It is important to nutritionally assess and manage the patient at all stages of the rehabilitation care pathway (National Cancer Action Team, 2009).

Surgery

Surgery is the definitive treatment for endometrial, cervical, ovarian and vulval cancers. The extent of the surgery, or choice of alternative treatment, depends on the stage, size and histology of the tumour and fitness of the patient. Gynaecological cancer surgery can be a major procedure that may also involve the gastrointestinal or urinary tracts. Surgery is undertaken as part of the Enhanced Recovery Programme (ERP) (Enhanced Recovery Partnership Programme, 2010), the underlying principle of which is to minimise the stress responses in the body during surgery, enabling quicker recovery and hospital discharge. The ERP involves preoperative assessment and management to ensure comorbidities such as anaemia, hypertension or diabetes are managed optimally. It also involves admission on the day of surgery, with minimal periods of preoperative starvation and carbohydrate loading. Postoperative management includes the early removal of nasogastric (NG) tubes and a rapid return to normal nutrition and hydration.

Women with gynaecological cancer will sometimes require formation of stomas (colostomy, ileostomy and/or urostomy) as a result of surgery for tumour removal, or debulking to deal with progression or complications of treatment such as obstruction. If the underlying problem cannot be cured, a palliative stoma may be required to make the woman more comfortable. Individual dietary advice should be offered to patients with new stomas to support an adequate fluid intake and a return to a normal mixed diet.

Chemotherapy

Chemotherapy may be used alone, particularly in the management of ovarian cancer, or in combination with radiotherapy for cervical and endometrial cancer. The nutritional impact symptoms associated with this therapy are oral mucositis, nausea, vomiting, loss of appetite, taste changes and early satiety. Several studies have examined nutritional status and weight changes as prognostic factors for ovarian cancer patients undergoing chemotherapy. Well nourished patients survived 12.6 months longer than severely malnourished women (Gupta *et al.*, 2008); the risk of death increased by 7% for every 5% loss of body weight (Hess *et al.*, 2007). Improving nutritional status from the start of chemotherapy is also associated with better survival (Gupta *et al.*, 2010). Evidence supports the early implementation of strategies to minimise weight loss in women with ovarian cancer and shows that ongoing individualised nutritional input is vital. Further research is required to determine whether these findings apply to other gynaecological cancers.

Radiotherapy

Radiotherapy is predominantly used to treat cervical and endometrial cancer; it can be given externally or internally (brachytherapy) or as a combination of the two. It may be delivered alone or concurrently with chemotherapy, which can increase early toxicity and add to nutritional problems. The radiation treatment can encompass the entire pelvis, which means there may also be damage

to the rapidly dividing cells lining the small and large bowel. It can cause side effects, including diarrhoea, irritable bladder, nausea and tiredness. Malnutrition occurs in approximately 33% of radiotherapy recipients and up to 83% of patients lose weight during treatment (McGough *et al.*, 2004). There is little convincing evidence to support dietary modifications to manage the gastrointestinal side effects of radiotherapy (particularly diarrhoea) (McGough *et al.*, 2004). More randomised controlled trials to establish the efficacy of low fat diets, the elemental diet and the use of probiotic supplementation are required. A current UK trial (CRUK) is investigating whether diets high or low in fibre have a beneficial effect on diarrhoea during pelvic radiotherapy. It is important to identify patients at risk of weight loss or specific nutrition related symptoms and implement individual nutrition support plans; it is likely this will require support from a specialist oncology dietitian.

Medical problems

Bowel obstruction

Bowel obstruction occurs most commonly as a complication of advanced or recurrent ovarian cancer; the bowel may be completely or partially blocked. Blockages can result from the tumour growing into the abdominal area or mesentery of bowel muscle or nerves and compromising bowel motility. The optimal management of bowel obstruction remains controversial and is dependent on the individual clinical picture. Much will depend on the patient's age, nutritional and tumour status, the presence and/or quantity of ascites, and history of chemotherapy or radiotherapy. The goals of treatment for bowel obstruction are to control or relieve symptoms and to optimise quality of life. Treatment may include:

- *Laparotomy with surgical bypass* (Feuer & Broadley, 2000; Pothuri *et al.*, 2003).
- *Pharmacological management* with drugs such as steroids, prokinetics or the antisecretory agent octreotide with NG drainage (Feuer & Broadley, 1999).
- *A venting percutaneous endoscopic gastrostomy* – offers gastric decompression and drainage, often with the resumption of a modified oral intake (Meyer & Pothuri, 2006).
- *Total parenteral nutrition (TPN)* – the risks, burdens and benefits of TPN must be discussed when considering its use. It seems to be of most benefit to women who have good performance status, i.e. the patient is capable of self care (Madhok *et al.*, 2011).
- *Low fibre diet* – the efficacy is not well studied, but patients anecdotally report benefits. In theory, less fibre reduces the amount of faeces and wind produced, resulting in a reduction in symptoms such as bloating and stomach cramps. Dietary information is available via the Ovacome website (Power, 2009).

Ascites

The peritoneum is a fine membrane lining the abdomen. It is made up of two layers: one encloses the organs such

as the small bowel, and the other lines the muscle wall of the abdomen. Ascites is the build-up of excessive fluid in the abdominal cavity between these layers. It is commonly associated with ovarian cancer as a result of malignant cells shedding into the abdominal cavity and impairing normal drainage. The fluid can also accumulate around the lungs, causing a pleural effusion. The symptoms associated with ascites can significantly reduce quality of life. They are:

- Shortness of breath.
- Anorexia.
- Nausea, indigestion and heartburn.
- Discomfort and immobility.

The aim of nutritional management of ascites is to maximise oral intake and quality of life, whilst minimising any detrimental gastrointestinal effects. This largely involves encouraging frequent small meals and snacks, fortifying foods and using low volume oral nutritional supplements.

Survivorship

Although excess body weight does not appear to affect recurrence in endometrial cancer, 72% of endometrial survivors are overweight or obese (von Gruenigen *et al.*, 2008) and their mortality is affected by other comorbidities, e.g. hypertension, cardiac disease and diabetes. A healthy lifestyle after cancer is associated with improved physical and psychological wellbeing and improved survival. Positive lifestyle changes, including increased exercise and avoiding excess weight, should be encouraged.

Some women will develop late effects of pelvic radiotherapy that affect the bladder and/or bowel. In one study 47% of women reported post treatment symptoms, which they had tried to manage with dietary changes (Abayomi *et al.*, 2009). Women should be dissuaded from unnecessarily restricting nutritional intake as this could result in unbalanced diets in the long term. These late gastrointestinal effects and their causes require more detailed investigation and specialist management; women with these effects should be referred to a specialist centre.

7.15.7 Prostate cancer

Saira Chowdhury

Key points

- Prostate cancer is one of the most common malignancies amongst men, with the majority of new diagnoses undergoing curative treatment.
- Diet may play a role in the aetiology of prostate cancer.
- Hormone therapy can cause symptoms of metabolic syndrome and bone thinning; both warrant changes in diet and lifestyle.
- Dietary modifications may be beneficial in managing symptoms of radiation enteritis.

The prostate gland is part of the male reproductive system and makes some of the alkaline fluid that constitutes 20–30% of semen. It is the size of a walnut, located below the bladder and in front of the rectum, with the urethra running through its centre. Prostate cancer is the most common malignancy amongst men in England, with 34 892 new diagnoses made in 2010. This accounted for 26% of all cancer diagnoses in men [Office for National Statistics (ONS), 2012a]. Survival has increased in the past 30 years with 93% and 81% of men now surviving 1 and 5 years after diagnosis, respectively (ONS, 2012b). Inci-

dence is greater in western countries, with the highest rate observed in the USA (124.8 per 100 000 population) and the lowest in Bangladesh (0.3 per 100 000 population) (Hsing *et al.*, 2000; Quinn & Babb, 2002; Baade *et al.*, 2009). Prostate cancer risk increases in migrants to western countries when compared with those in their native countries. This could be the result of migrants adopting western dietary practices (Giovanucci *et al.*, 2007). Ninety per cent of new diagnoses undergo treatment with curative intent (Greene *et al.*, 2005). Treatment may be a combination of surgery, radiotherapy,

chemotherapy and hormones. Some adjunct treatments include the use of bisphosphonates and steroids.

Nutrition

Diet plays a role in disease aetiology, supporting nutritional difficulties during treatment and managing long term side effects resulting from treatment. The incidence of undernutrition in prostate cancer is relatively low compared with other cancers and occurs more commonly in advanced disease (Segura *et al.*, 2005). Weight gain and features of metabolic syndrome are important side effects of hormone treatment and lend a role for dietetics in survivorship.

Nutrition and aetiology

Age, race, family history and diet may influence prostate cancer development. The effect of various nutrients in prostate cancer incidence has been investigated and currently, results mainly suggest a causal relationship. Whilst there is insufficient evidence to translate these findings into public health recommendations, the studies conducted up to now provide a platform for further research. Two reviews explain the role of dietary constituents in prostate cancer prevention (WCRF/AICR, 2007; Ma & Chapman, 2009); the findings are summarised in Table 7.15.9.

The World Cancer Research Fund (WCRF) expert panel concluded that the antioxidants, lycopene and selenium, have the strongest dietary influences in prostate cancer prevention (WCRF/AICR, 2007). Lycopene is found in tomatoes, watermelon, grapefruit, guava and apricot. Cooked tomato products, e.g. tomato ketchup and tomato sauces, have a greater bioavailability of lycopene com-

pared with raw tomato. In 2004, a meta analysis of observational studies suggested a beneficial role for lycopene. It identified a 6% prostate cancer risk reduction in men consuming raw tomatoes and 1% reduction in men consuming lycopene (Etminan *et al.*, 2004). Since this, a Cochrane meta analysis of three randomised controlled trials of lycopene supplements concluded there was insufficient evidence to support or refute the use of lycopene in prostate cancer prevention and that better quality randomised, controlled studies are needed (Ilic *et al.*, 2011). There were several limitations to the studies included in this review, including poorly powered studies and a high risk of bias. More studies into whether dietary lycopene is better than lycopene supplementation and whether any observed benefits of dietary lycopene are due to lycopene alone or the effect of lycopene combined with another nutrient are needed.

A protective role of selenium was suggested by the results of the Nutritional Prevention of Cancer (NPC) study. Between 50% and 60% fewer prostate cancer cases were observed in selenium deficient men taking selenium supplements, compared with those taking a placebo (Clark *et al.*, 1996; Duffield-Lillico *et al.*, 2003). Two studies report a 50–65% increased prostate cancer incidence in men with low selenium levels (Chan *et al.*, 2005; Brinkman *et al.*, 2006). The effect of vitamin E was observed in the Alpha-T, Beta-Carotene (ATBC) Cancer Prevention Study; a randomised, double blind placebo controlled trial where alpha-tocopherol supplementation in smokers showed a reduced prostate cancer incidence (ATBC Study Group, 2003). The Selenium and Vitamin E Cancer Prevention Trial (SELECT), a double blind, randomised controlled trial, examined the role of dietary supplementation of these two nutrients in prostate cancer prevention. Initial results showed that selenium and vitamin E taken alone or together did not prevent prostate cancer and subjects were advised to stop taking supplements. There was a non-statistically significant increase in prostate cancer incidence with vitamin E supplementation (Lippman *et al.*, 2009). The results of additional follow-up 3 years after the participants had stopped supplementation showed that men who had been taking selenium or vitamin E alone or in combination had increased prostate cancer incidence compared with the placebo group. However, this finding only reached statistical significance in the vitamin E group, with a 17% increased incidence of prostate cancer (Klein *et al.*, 2011). The reasons for the contrasting results for vitamin E in SELECT compared with the ATBC study are not fully understood. The reduced prostate cancer incidence with vitamin E supplementation in the ATBC study could be due to chance as it was a secondary finding in a trial not designed to investigate supplementation on prostate cancer. The dose of vitamin E used in SELECT was much higher than in the ATBC study and could be too high to provide benefit.

A recent Cochrane review has concluded that while an inverse relationship between selenium levels and prostate cancer incidence exists, further research is needed to provide more convincing evidence of a role (Dennert

Table 7.15.9 Influence of dietary components on prostate cancer risk [source: WCRF/AICR Report 2007. Reproduced with permission of the World Cancer Research Fund International (www.dietandcancerreport.org)]

Strength of evidence	Decreases risk	Increases risk
Convincing	Nil	Nil
Probable	Foods containing lycopene Foods containing selenium Selenium supplements	Calcium
Limited (suggestive)	Pulses (legumes) Foods containing vitamin E Alpha-tocopherol	Milk and dairy products

Limited – no conclusion

Alpha-tocopherol, cereals (grains) and their products; dietary fibre; potatoes; non-starchy vegetables; fruit; meats; poultry; eggs; total fat; plant oils; sugar (sucrose); sugary foods and drinks; coffee; tea; alcohol; carbohydrate; protein; vitamin A; retinol; thiamine; riboflavin; niacin; vitamin C; vitamin D; delta-tocopherol; vitamin supplements; multivitamins; iron; phosphorus; zinc; other carotenoids; physical activity; energy expenditure; vegetarian diets; Seventh Day Adventist diets; body fatness; abdominal fatness; birth weight; energy intake

et al., 2011). A recent meta analysis has examined selenium status in relation to prostate cancer incidence (Hurst *et al.*, 2012). It showed decreasing prostate cancer incidence with selenium serum or plasma levels up to 170 ng/mL and selenium toenail concentrations of 0.85–0.94 µg/g. However, as the observed relation was over a relatively narrow range of selenium status, further studies in low selenium populations are recommended. In contrast to the NPC study and the studies in the Hurst *et al.* (2012) meta analysis, the participants in the SELECT trial were not selenium deficient. Whilst SELECT did not demonstrate a preventative role for selenium in a non-selenium deficient population of men, there may be a beneficial role for supplementation in selenium deficient men. At present, selenium supplementation for prostate cancer prevention has not been proven, and therefore its use cannot be recommended based on current evidence.

The WCRF/AICR (2007) reported limited evidence to suggest that pulses (including soya and soya products) reduce prostate cancer risk. Part of the protective role from soya is related to the oestrogen-like effects of its isoflavone component. Two meta analyses published since 2007 concluded there was evidence of a protective role from soya, related to the quantity and type of soya consumed. Non-fermented soya (e.g. soyabeans, tofu and soya milk) appears to offer a protective role, whilst the role of fermented soya, e.g. miso, is less clear. The protective effect of soya is seen in groups with the highest intake when compared with groups with the lowest intake. However, the level of soya intake required to acquire benefit has not been established. It is important to highlight that soya encompasses a number of foods and the magnitude of the effect of soya on prostate cancer incidence may be variable with soya type. This can influence the results of research where a variety of soya products are investigated (Hwang *et al.*, 2009; Yan Spitznagal, 2009).

Other foods demonstrating protective properties are shown in Table 7.15.9; however, evidence for these are weak and variable. There is a positive correlation for calcium, grilled and processed meats, milk and dairy products, and fat intake with increased prostate cancer risk. The strongest and most convincing correlation is with calcium, where intakes above 1.5 g/day were associated with increased risk, but no increase in risk was observed with intakes up to 1.2 g/day (Baron *et al.*, 2005; WCRF/AICR, 2007). Limited evidence suggests an increased prostate cancer risk with grilled and processed meats (particularly at over five servings a week), milk and dairy products (irrespective of fat content) and increased fat intake. This is particularly the case with animal and saturated fats (WCRF/AICR, 2007; Ma & Chapman, 2009). These findings reinforce the importance of following guidelines for healthy eating for the general population as part of prostate cancer prevention.

Treatment

Surgery

A prostatectomy may be undertaken in the curative setting. Nutritional difficulties preoperatively are gener-

ally uncommon. In the postoperative setting, ileus is an important although infrequent complication, occurring in <5% of all patients, but more commonly following an anastomotic leak with an incidence of 55% (Sukkarie *et al.*, 2007). Where a prolonged ileus occurs, the timely instigation of parenteral nutrition should be considered to support postoperative recovery.

Radiotherapy

Radiotherapy is often used in a curative setting. While treatment is directed at the prostate gland, the bowel and rectum sometimes receive radiotherapy. As a consequence of this, diarrhoea due to mucosal damage may occur. This is known as acute radiation enteritis. Temporary changes in bowel motility, lactose intolerance, bile acid malabsorption, bile acid and pancreatic enzyme damage to bowel mucosa, and bacterial overgrowth may also be observed. There is some research showing dietary modifications may improve symptoms of acute radiation enteritis, e.g. a low fat or elemental diet, probiotic supplementation and reducing fibre intake. Whilst the evidence supporting these therapeutic diets is weak due to inadequacies in research methodology with results confounded by poor compliance in treatment groups, a trial may nonetheless be beneficial in symptomatic patients (McGough *et al.*, 2004; Wedlake *et al.*, 2012). A limited number of patients may experience longer term gastrointestinal disturbances due to chronic radiation enteritis, causing impaired quality of life. Andreyev *et al.* (2012) provide guidance on managing the acute and chronic gastrointestinal problems arising from cancer treatment. In planning radiotherapy, and throughout treatment, patients may be required to make dietary changes, e.g. a low fibre diet, avoidance of carbonated drinks and reduced consumption of foods known to cause wind. Bowel gas can influence the position of the prostate gland and therefore affect treatment. More research is needed to assess the effectiveness of this intervention, although some centres may already recommend patients follow advice (McNair *et al.*, 2011).

Hormone treatment

Hormone treatment may use antiandrogen therapy, lutein hormone releasing hormone analogues and oestrogen. Hormones treat prostate cancer by reducing the effects of testosterone in the body to shrink or delay tumour growth and reduce symptoms; hormone treatment may continue for a number of years. Nutritional consequences include weight gain and features of metabolic syndrome, e.g. abdominal obesity, increased total body fat mass, dyslipidaemia, increased diabetes risk and hyperinsulinaemia (Tayek *et al.*, 1990; Smith *et al.*, 2002). The effect of hormone treatment on lipid profile is summarised in Table 7.15.10. Tailored interventions for weight management and advice on principles of healthy eating to manage these side effects can be effective (Jones & Demark-Wahnefried, 2006; Demark-Wahnefried *et al.*, 2012) (see Chapter 7.12 and 7.14.3).

Reduced bone density is another important implication of antiandrogen therapy. Consideration should be given

Table 7.15.10 Effect of hormone therapy on lipid profile (Fillippatos *et al.*, 2008)

Hormone therapy type	Total cholesterol	Low density lipoprotein	High density lipoprotein	Triglyceride
Oestrogen	↓	↓	↑	↑
Anti-androgen	↓	↓	↑	↑
Lutein hormone releasing hormone analogues	↑	Unchanged	↑	Not available

to vitamin D and calcium supplementation. Bisphosphonates may be prescribed to preserve bone density by reducing osteoclast activity and increasing osteoblast activity in bone (see Chapter 7.9.1).

Chemotherapy

Chemotherapy is given where cure is no longer possible, and aims to shrink and slow the growth of the cancer, control symptoms such as pain and improve quality of life. Side effects with potential nutritional implications include stomatitis, taste changes, anorexia, nausea, vomiting, changes in bowel habit and fatigue. These side effects are temporary and resolve shortly after completing treatment. Short term dietary changes and oral supplementation may be necessary to help manage eating more easily. Advanced cancer can influence appetite and cause difficulties with eating. Dietary advice and supplementation should be considered with the aim of preserving quality of life. Steroids may sometimes be given with chemotherapy to make treatment more effective and this can also help improve appetite.

Disease progression and survivorship

Men with prostate cancer can live for many years with the disease. Foods and dietary supplements for this patient group that have been investigated include: processed meats, eggs, plant based diets, lycopene and/or tomato, vitamin E, alpha-tocopherol, beta-carotene, soya/isoflavones, soya (in conjunction with other supplements), low fat diets, pomegranate juice and green tea. A number of review articles all provide similar conclusions in that further research is needed to prove a definitive role for diet in this patient population (Chan *et al.*, 2005; Bekkering *et al.*, 2006; Van Patten *et al.*, 2008; Ma & Chapman, 2009; Davies *et al.*, 2011).

Dietary changes can help manage the long term health implications of hormone treatment and radiotherapy. To reduce the risk of developing comorbidities associated with weight gain and dyslipidaemia, advice on healthy eating and lifestyle measures, including exercise, should be integrated into the patient's care. It is possible that the benefits of this may also extend to a positive impact on disease progression and survival (Davies *et al.*, 2011).

Conclusion

There is great consumer interest in the role of diet in disease prevention and management. When a cancer diag-

nosis is received, diet provides individuals with a readily available method to actively control their own health. Whilst evidence points towards certain correlations with prostate cancer, diet and use of dietary supplements, the lack of high quality studies and publication of consistent results has not provided sufficient evidence to translate these into public health or clinical practice recommendations. Individuals may seek advice on diet and prostate cancer and it is important for dietetic professionals to understand the evidence available. Further research is needed to substantiate current findings. However, the existing knowledge from studies provides a basis for dietitians in giving patients and the general public guidance on diet and prostate cancer.

7.15.8 Haematological cancers and high dose therapy

Julie Beckerson

Key points

- High dose chemotherapy, radiotherapy and stem cell transplant provide potential cure or remission for many haematological cancers.
- Treatment associated side effects such as severe mucositis, nausea and vomiting can lead to rapid deterioration of nutritional status. Nutrition support is therefore recognised as an important adjunct to high dose therapy.
- The benefit of dietary restrictions during neutropenia is not clear, and advice should focus on minimising food poisoning risk whilst optimising choice at a time when nutritional intake may already be compromised.

Haematological cancers involve the blood or lymphatic system and include leukaemia, lymphoma, myeloma, myelodysplastic syndromes and lymphoproliferative disorders. These are rare in children and young adults, but become more common with increasing age and account for approximately 35 000 UK cases per year (www.hmrn.org/Statistics/Incidence.aspx). Non-Hodgkin's lymphoma, leukaemia and myeloma are the fifth, 12th and 17th most common cancer diagnoses, respectively (www.cancerresearchuk.org/cancer-info/cancerstats).

Leukaemia refers to a proliferation and accumulation of abnormal white blood cells in the bone marrow (abnormal blasts). As the disease progresses, abnormal cells spill out of the bone marrow and infiltrate and damage other tissues. Leukaemia is described as either myeloid or lymphoid according to the origin of the abnormal cells. Acute and chronic leukaemia are differentiated by the maturity of the cells affected. Acute leukaemia affects immature white blood cells that continue to divide after normal cells have stopped. In chronic leukaemia, mature cells are affected, increasing their lifespan and number in the marrow and circulation.

Lymphoma results from abnormal replication of cells within lymph nodes or other lymphoid tissues, such as the spleen, bone marrow and thymus. It is broadly classified into Hodgkin's or non-Hodgkin's lymphoma, but within these categories there are numerous disease subtypes according to the cell line that multiplies. High grade lymphomas replicate the quickest, whereas low grade or indolent lymphomas develop slowly and may be asymptomatic for many years.

Myeloma is a malignant proliferation of monoclonal plasma cells that often secrete large amounts of ineffective antibodies known as paraproteins. In addition to bone marrow involvement there may be infiltration of bone, causing osteolytic lesions, kidney damage from elevated plasma paraprotein and/or hypercalcaemia, and isolated lesions known as plasmacytomas.

Diagnosis

The clinical presentation of haematological malignancies frequently reflects the underlying altered haematopoiesis

(formation and development of blood cells). In leukaemia, suppressed or ineffective white blood cells increase susceptibility to infection. Patients may complain of fatigue due to anaemia caused by reduced red blood cells or increased bruising and bleeding resulting from thrombocytopenia (low platelets). Presenting symptoms such as fever, night sweats and weight loss occur in lymphoma and may suggest advanced disease.

Blood tests and bone marrow aspirate are used to determine the type and extent of blood cell abnormalities. Cytogenetic testing of chromosomal changes and immunophenotyping to detect specific molecules on the surface of malignant cells are also used to guide treatment decisions. Other tests include urinary paraprotein, lymph node biopsy and imaging. Subsequent staging and prognosis of haematological cancers will vary significantly according to the disease subtype.

Treatment

Protocols used in haemato-oncology frequently involve the most intensive and high dose regimens. In acute leukaemia, disease onset is rapid and induction chemotherapy must be initiated immediately. However, for some chronic leukaemias, low grade lymphomas and myeloma, treatment may be delayed until symptoms present. The treatment goal is to control disease and maximise quality of life, whilst minimising treatment side effects. Bone marrow, or increasingly stem cell transplants (SCT), can be used to enable higher doses of chemotherapy and radiotherapy with the aim of achieving long term remission or cure. These are usually performed after several courses of induction chemotherapy to control disease or achieve remission.

There are two main types of SCT; autologous (the patient is given back their own cells) and allogeneic (using donor cells). Donor transplants provide the greatest likelihood of long term remission or cure due to the immunological effects of the donor cells against the host's disease. However, autologous SCTs are considered standard care for some conditions, such as myeloma, due to the high morbidity associated with allogeneic transplantation (Bensinger, 2009).

Prior to an infusion of stem cells, a conditioning regimen that may include chemotherapy, radiation and immunosuppressive therapy is given. Cytotoxic agents are given to eradicate tumour cells and destroy host haematopoiesis in preparation for the donor stem cells. Reduced intensity conditioned (RIC) transplants have been developed for older patients less able to withstand high dose myeloablative chemotherapy. Early toxicities are reduced but there is an increased risk of subsequent relapse (Gratwohl, 2005). The choice of SCT depends on the disease, stage, fitness of the recipient and donor availability.

Consequences of high dose therapies and stem cell transplant

Neutropenia and infectious complications

Myeloablative therapy causes neutrophil levels to fall, increasing the risk of bacterial sepsis, pneumonia and fungal infections. This is a major cause of morbidity and mortality; therefore, antimicrobial, antifungal and antiviral medications are routine (Gratwohl *et al.*, 2005). Other preventative measures include contact precautions, hand washing, air filtration and positive pressure isolation rooms.

Infection risk is highest in allogeneic SCT where the period of neutropenia is longer than in autologous SCT. Immunosuppressive therapy and immune reconstitution continue for several months after neutrophil recovery following allogeneic SCT. Viral infections are common during this phase and can be fatal (Cordonnier, 2008).

Mucositis

Mucositis after SCT typically lasts for 1–3 weeks, dependent on the conditioning regimen. It can affect any part of the gastrointestinal tract, resulting in mouth or throat pain, ulceration, abdominal pain, nausea, vomiting and diarrhoea. Up to 80% of SCT recipients will experience severe mucositis, frequently requiring intravenous opioid analgesia (Rubenstein *et al.*, 2004; Keefe *et al.*, 2007). The breakdown of mucosal barriers during mucositis significantly increases infection risk and is associated with worse clinical and economic outcomes (Keefe, 2006; Sonis *et al.*, 2001; Fanning *et al.*, 2006).

Organ toxicity

The high dose chemotherapy and/or radiotherapy used in SCT can cause gastrointestinal, renal, bladder, pulmonary, cardiac, neurological and hepatic complications, resulting in significant morbidity and mortality (Gratwohl, 2008). Around 14% of SCT recipients will develop hepatic veno-occlusive disease (also known as sinusoidal obstructive syndrome), which is characterised by occlusion and injury to hepatic venules and hepatocytes induced by chemotherapy. It often leads to multiorgan failure and is associated with high mortality rates (Coppell *et al.*, 2010).

Graft versus host disease

Immunosuppression is given to allogeneic SCT patients to avoid the potentially fatal complication of graft versus

host disease (GvHD). This occurs as a consequence of interactions between mature donor immune cells (T cells) and antigen presenting cells of the recipient. There are two types. Acute GvHD usually occurs within 100 days of SCT and may affect the skin, gut or liver, manifesting as rash, nausea, vomiting, diarrhoea, ileus and deranged liver function or liver failure. Chronic GvHD is a major long term complication of allogeneic SCT and occurs in 30–70% of transplant recipients. It occurs more than 100 days after transplant and can affect numerous organs and tissues. About 50% of patients will have three or more involved organs (Lee 2010).

Psychological effects

Extended periods in isolation, separation from family and the experience of transplant have major psychological effects (Wagner & Cella, 2004). Reduced attention span and slower cognitive processing can occur as a result of fatigue following high dose therapy, further impacting on mood.

Survivorship

Continued hospital appointments, fatigue and susceptibility to infection significantly impact rehabilitation after high dose therapy. Full return to normal functioning and nutritional status can take >1 year after transplantation (Iestra *et al.*, 2002).

Nutritional assessment

Nutritional screening is recommended to identify subjects for whom nutritional assessment and care planning is necessary (August *et al.*, 2009). Assessment prior to high dose treatment is useful to establish pre-existing malnutrition, discuss potential side effects of treatment, develop rapport and improve compliance with recommended interventions (Iestra *et al.*, 2002). High dose therapies, particularly SCT, have marked effects on metabolic demands and significantly impair nutritional intake. Furthermore, reduced physical activity and loss of mobility due to hospitalisation and prolonged isolation result in reduced muscle mass, particularly in a previously active patient (Coleman *et al.*, 2003).

Optimum nutrition improves tolerance to treatment and outcome in malnourished patients, and well nourished individuals experience shorter treatment delays, less myelosuppression and fewer infections (Aviles *et al.*, 1995). Studies in SCT indicate that poor nutritional status and low body mass index (BMI) are negative prognostic factors in terms of time to engraftment and survival (Hadjibabaie *et al.*, 2008; Schulte *et al.*, 1998). Conversely, high BMI prior to SCT is linked with acute GvHD, infections and poorer 5-year survival rates (Bulley *et al.*, 2008; Fuji *et al.*, 2009).

Anthropometry

Weighing may be inaccurate due to large intravenous infusions given during treatment and changes in organ function. Pathological fractures or vertebral collapse in

Table 7.15.11 Mineral and electrolyte changes with drugs commonly used in stem cell transplantation

Drug	Therapeutic use	Biochemical side effect
Ciclosporin	Immunosuppression	Hyperkalaemia, hypomagnesaemia
Tacrolimus		Hyperkalaemia, hypokalaemia
Amphotericin Ambisome	Antifungal	Hypokalaemia, hypomagnesaemia
Foscarnet	Antiviral	Hypocalcaemia, other electrolyte disturbances

myeloma patients may introduce errors in measuring height. Other anthropometry may provide a better indication of nutritional status, but the use of skinfold callipers is limited during thrombocytopenia due to bleeding risk.

Biochemistry

Regular laboratory monitoring is essential to detect changes in organ function, mineral and electrolyte imbalances, hyperglycaemia or hyperlipidaemia (Lipkin *et al.*, 2005). Biochemistry alone cannot accurately reflect nutritional status. The underlying disease and complications, such as sepsis and GvHD, will confound the interpretation of albumin. In advanced myeloma, this is also lowered at the expense of raised paraprotein.

Mineral and electrolyte losses are common and often exacerbated by antimicrobial and immunosuppressive drugs, examples of which are shown in Table 7.15.11. Multiple blood transfusions may elevate ferritin levels, indicating iron overload. Repeated hospital stays for treatment can result in suboptimal vitamin D status and low calcium levels, which are of particular relevance for those receiving corticosteroid therapy (Lipkin *et al.*, 2005).

Nutritional requirements

Energy expenditure differs between transplant type and the presence of complications, although evidence is limited. Metabolic rate will vary with the phase of illness or stage of treatment, and older studies may not be relevant to current treatment modalities. Current recommendations for energy suggest disease specific elevations in basal metabolic rate of 25–34% in leukaemia and of 0–25% in lymphoma (Weekes, 2011). However, these studies include few haematology subjects and measurements were taken whilst a proportion of subjects were receiving artificial nutrition (Barak *et al.*, 2002).

Nutritional requirements are raised in acute GvHD and there may be significant gastrointestinal losses, resulting in a negative balance for many nutrients, including nitrogen. Chronic GvHD patients have an elevated tumour necrosis factor alpha and elevated resting energy expenditure, which may contribute to chronic weight loss (Zauner *et al.*, 2001).

Evidence is lacking to support specific recommendations for nitrogen intake at different stages of treatment. Negative nitrogen balance is likely during high dose therapy and the catabolic effects of disease, treatment and complications should be considered when estimating protein requirements (Muscaritoli *et al.*, 2002).

Micronutrient requirements may be raised during high dose therapy due to increased oxidation and tissue damage; however, there is no evidence to support routine antioxidant or trace element supplementation (Lipkin *et al.*, 2005). Losses of fluid, electrolytes and other nutrients frequently occur; however, intravenous input from medications, blood products and electrolyte replacement can predispose to fluid overload.

Nutritional intervention in stem cell transplant

The dietitian and appropriate nutritional support are recognised as vital components of the transplant process (August *et al.*, 2009; NICE, 2003). Appropriate nutritional interventions for symptom management during chemotherapy and radiotherapy are discussed in Chapter 7.15.1. The side effects from SCT that impair nutritional intake are frequently severe and may occur concurrently (Figure 7.15.2), and despite aggressive medical management, the SCT patient is often unable to maintain adequate oral nutritional intake.

Artificial nutrition support

The type of transplant, intensity of conditioning and mucositis are the biggest determinants for artificial nutrition support (Iestra *et al.*, 1999). Transplant patients may experience nausea, anorexia and mucositis following chemotherapy, and these side effects are most severe during myeloablative allogeneic SCT. The use of reduced intensity conditioning causes fewer side effects, reducing the need for artificial nutrition (Parker *et al.*, 2002; Topcuoglu *et al.*, 2012; Johansson *et al.*, 2001).

Parenteral nutrition (PN) is recommended for those with severe mucositis, prolonged ileus, intractable vomiting or diarrhoea, those who are malnourished or those for whom it is anticipated that enteral nutrition (EN) will not be tolerated for 7–14 days (August *et al.*, 2009). Further studies in SCT recipients are required to confirm the optimum time without nutrition after which PN demonstrates a survival benefit.

Historically, PN was used extensively during SCT. This was partly due to the high gastrointestinal toxicities of older conditioning regimens and the availability of central access, already established for chemotherapy and stem cell infusion. Recently, better pharmacological management of treatment side effects has allowed safe and effective use of EN during SCT (August *et al.*, 2009; Thompson & Duffy, 2008). Although there is a lack of evaluable data to compare EN with PN (Thompson & Duffy, 2008), EN is recommended for situations where the GI tract remains accessible and functioning (August *et al.*, 2009).

The known infectious risks of PN are likely to be amplified in this immunocompromised group (Black, 2011).

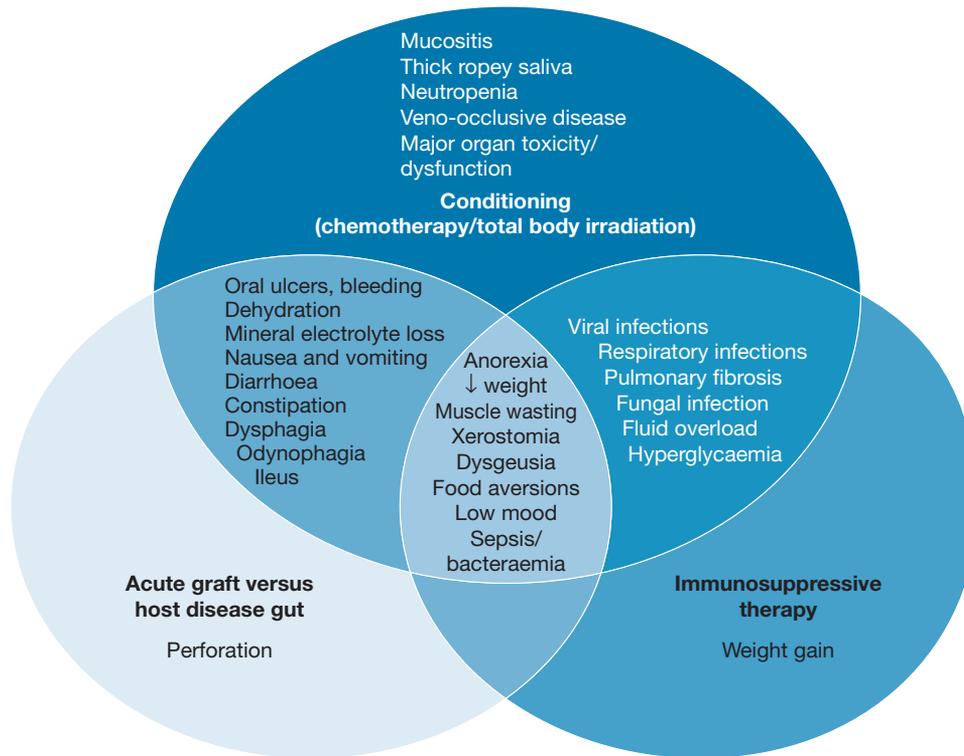

Figure 7.15.2 Side effects of stem cell transplant impacting on nutritional status

During SCT, EN may reduce infectious complications by promoting intestinal recovery since disruption of the mucosal barrier is thought to contribute to the development of 25–75% of bacteraemias during neutropenia (Stiff, 2001). There is also some evidence that the provision of nutrition via the enteral rather than the parenteral route during SCT may reduce acute GvHD incidence (Seguy *et al.*, 2006; Cheney *et al.*, 1991).

Enteral feeding tubes need to be placed prior to the development of mucositis to avoid pain and further mucosal damage. Thrombocytopenia is common and tube placement presents a risk of haemorrhage. Local guidelines will vary, but a platelet count of $>20 \times 10^9/L$ may be adequate (Lipkin *et al.*, 2005). Since feeding tubes are sterile, neutropenia *per se* is not a contraindication to placement of a nasoenteric tube. Waiting until the acute emetic effects of conditioning have settled will reduce the risk of tube dislodgement.

Post pyloric feeding (nasojejunal) feeding may be useful if there is protracted vomiting or gastric stasis and this approach has been adopted by some UK transplant centres (Black, 2011). The prophylactic insertion of gastrostomy or jejunostomy tubes to overcome repeated nasoenteric tube displacements due to vomiting has been trialled. However, stoma site infections resulting in peritonitis and associated treatment delays have limited the use of these tubes (Black, 2011).

Evidence for the optimum enteral feed composition during SCT is lacking; hence, choice should be made according to clinical parameters such as renal function, fluid status and gastrointestinal side effects. Polymeric

feeds may be suitable, but if malabsorption is suspected, then semi elemental or peptide feeds may be better tolerated (Lipkin *et al.*, 2005; Black, 2011).

During gut GvHD, destruction of intestinal crypts, profuse diarrhoea and ulceration can lead to perforation. Acute GvHD can occur in conjunction with mucositis, and in severe cases the most appropriate form of nutrition is PN (Muscaritoli *et al.*, 2002). However, EN was shown to be safe and beneficial in one small controlled cohort study (Imataki *et al.*, 2006) and the use of peptide based and low osmolality feed can be considered for low grade gut GvHD.

The neutropenic diet

The need for and efficacy of a neutropenic diet is controversial (August *et al.*, 2009; Jubelirer, 2011; Mank & Davies, 2008). Damage to the gut mucosal barrier by high dose therapy, bacterial overgrowth and opioid related impairment of peristalsis may increase the risk of translocation and bacteraemia (Black, 2011; Berg, 1999). Recommendations for a low bacterial diet arise from known sources of food borne microorganisms in the food chain (National Digestive Diseases Information Clearing House, 2011) and published case reports of infections, as well as outbreaks of food poisoning in the general population and immunocompromised individuals.

Early studies that placed leukaemia patients on a sterile diet suggested a reduction in infections; however, these results maybe confounded by the use of protective isolation, laminar airflow and antimicrobial gut decontamination. Subsequent small studies have not confirmed the

Table 7.15.12 Dietary restrictions according to neutrophil count (Leukaemia and Lymphoma Research, 2012)

Neutrophil count	Foods to restrict
$<2.0 \times 10^9$	Mould ripened or blue veined cheeses Unpasteurised dairy products Raw or lightly cooked shellfish Raw or undercooked meat, poultry or fish Raw or undercooked eggs Probiotic products Fresh pâté
$< 0.5 \times 10^9$	Raw or unpeeled fruit, dried fruit, vegetables and salad Unpasteurised fruit or vegetable juices or smoothies Water or ice from wells, coolers or bottled water Ice cream from ice cream vans Fresh nuts Uncooked herbs, spices and pepper Unpasteurised honey Unnecessarily large packets of food items

benefit of excluding uncooked fruit and vegetables (Gardner *et al.*, 2008; DeMille *et al.*, 2006) or following a low bacterial diet (van Tiel *et al.*, 2007), and some institutions have removed restrictions without any corresponding increase in infection rates (Tarr & Allen, 2009).

Many UK centres follow recommendations published by Lymphoma and Leukaemia Research (2012) on behalf of the Haematology subgroup of the British Dietetic Association (BDA) Oncology Group. This includes food safety advice on preparation and storage and foods to restrict according to neutrophil count, as shown in Table 7.15.12. Due to contamination of bottled mineral water by coliforms and listeria (Hunter, 1993), freshly run tap water is recommended during neutropenia. Commercial quality water filtration is recommended where institutional tap water is at risk of contamination from *Legionella spp* (Cordonnier 2008).

The American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines for nutrition support during SCT recommend advice regarding safe food handling and avoidance of specific foods that may increase the risk of infection during neutropenia (August *et al.*, 2009). In practice, advice varies significantly between different transplant centres, with inconsistencies around the type of foods restricted, when and for how long to restrict these foods, and guidance for non-neutropenic patients on post transplant immunosuppression (Mank & Davies, 2008).

Glutamine

Radiation or chemotherapy induced tissue damage may be attenuated by adequate tissue glutamine, suggesting a

potential role in the prevention of tissue toxicity during myeloblastic treatments (Wischmeyer, 2003). A meta analysis of three studies suggests oral glutamine may reduce mucositis and GvHD, but robust evidence in this area is lacking (Crowther *et al.*, 2009).

Currently, ASPEN suggests pharmacological doses of parenteral glutamine may benefit patients undergoing SCT (August *et al.*, 2009). A Cochrane review in 2002 indicated beneficial effects of glutamine supplemented PN versus standard PN on length of stay and incidence of positive blood cultures (Murray & Pindoria, 2002). However, subsequent studies and meta analyses suggest the benefits may be limited to the allogeneic SCT population in whom the need for artificial support is likely to be the greatest (Murray & Pindoria, 2008; Crowther *et al.*, 2009; Gama Torres *et al.*, 2008). Further studies of both oral and parenteral glutamine are required to confirm the dose, duration and patient group that will benefit.

Drug–nutrient interactions

The following drugs reduce bioavailability or absorption with oral and enteral nutrition (Wohlt *et al.*, 2009):

- Alendronic acid.
- Ciprofloxacin.
- Lansoprazole.
- Omeprazole.
- Pantoprazole.
- Penicillin V.
- Phenytoin.
- Sucralfate.
- Voriconazole.

Other drugs of note used in this patient group include:

- Ciclosporin – avoid all grapefruit containing foods.
- Posaconazole – requires concurrent oral or enteral nutrition.

Exact recommendations may vary according to formulation and local policy.

7.15.9 Cancer cachexia

Deborah Howland

Key points

- Cachexia is a complex syndrome associated with muscle loss, which is frequently accompanied by increased muscle catabolism, inflammation and anorexia.
- All cachectic patients are malnourished.
- Nutrition support can increase body weight; however, it does not have a demonstrable effect on lean body mass and therefore does not improve functional status or quality of life.
- Nutrition support may reduce carer anxiety and improve a patient's psychological condition.

Cachexia has been described throughout history as a condition associated with illness (Katz & Katz, 1962). The term cachexia is Greek in origin and is a combination of *kakós* (bad) and *bexis* (condition or appearance) (Doehner & Anker, 2002). More than 30% of cancer patients die due to cachexia and >50% die with cachexia (von Haehling & Anker, 2010).

Diagnostic criteria and classification

The causes of cachexia are complex and not fully elucidated. Therefore, there is no agreed definition, criteria or treatment despite several suggestions. A group of experts (Evans *et al.*, 2008) defined cachexia as ‘*a complex multifactorial syndrome associated with underlying illness and characterised by muscle loss with or without loss of fat mass, frequently accompanied by increased muscle catabolism, anorexia and inflammation*’. They suggested the following diagnostic criteria:

- Presence of a chronic disease with weight loss of at least 5% within a 12-month period.
- And three of the following:
 - Decreased muscle strength.
 - Reduced muscle mass.
 - Fatigue.
 - Anorexia.

- Biochemical alterations (anaemia, markers of inflammation, low albumin).

The Cancer Cachexia Study Group (Fearon *et al.*, 2006) proposed a definition of cachexia based on the simultaneous presence of weight loss (>10%), low food intake (<1500 kcal/day) and an increased C-reactive protein (CRP) level (>10 mg/L) indicative of systemic inflammation. The Screening the Nutritional Status In Oncology (SCRINIO) Working Group (Bozzetti & Mariani, 2009) has proposed a classification system and defined four stages of severity (at risk of cachexia to symptomatic cachectic) based on weight loss of >10% or <10% with anorexia, early satiety or fatigue.

Disease process

Cancer cachexia is caused by complex interactions between inflammatory processes, neurohormonal alterations and lipolytic responses (Baracos, 2006; Tisdale, 2008). Inflammation has an important role in cachexia, with increased circulating proinflammatory cytokines, e.g. tumour necrosis factor alpha, and reduced anti-inflammatory cytokines, e.g. interleukin 4, contributing to inappropriate appetite suppression, increased resting energy expenditure and catabolism of skeletal muscle

mass. Chemotherapy increases oxidative stress, thereby exacerbating the inflammatory process.

Muscle proteins are normally in constant flux with a balance between their anabolism and catabolism such that there is no change in muscle mass. However, in cancer cachexia protein synthesis is decreased, protein catabolism is increased and muscle wasting occurs (Baracos, 2001). Muscle wasting is perhaps the most devastating component of cancer cachexia because it results in functional decline, reduced ambulation and reduced quality of life (Dodson *et al.*, 2011).

The incidence of cachexia is highly dependent on the underlying tumour type, with weight loss accompanying the majority of lung, colorectal and pancreatic cancers. It is less common in haematological malignancies, breast cancer and sarcomas (Tisdale, 2009).

Nutritional assessment

Malnutrition is frequently seen in cancer patients and may be the first indication of the presence of the disease. In addition, macro- and micro-nutrient requirements may be increased in cancer (Fearon *et al.*, 2006). Side effects of cancer treatments can cause weight loss and lead to malnutrition; however, the mechanism is distinct from that of cachexia (Coss *et al.*, 2011). Response to chemotherapy can reduce the catabolic stimulus of the tumour and ameliorate cachexia (Giordano & Jatoi, 2005). Not all malnourished patients are cachectic, but all cachectic patients are malnourished (Muscaritoli *et al.*, 2010). Malnutrition is reversible when adequate nutrition is provided; however, cachexia is not treatable by this approach.

The patient generated subjective global assessment (PGSGA) is widely used as an assessment of nutritional risk in cancer patients (Bauer *et al.*, 2002; Thoresen *et al.*, 2002) and includes cachexia related variables. The PGSGA scores several aspects including:

- Weight loss – generated from weight history.
- Amount and type of food intake, including a list of 13 symptoms related to food intake.
- Functional status score.
- Body composition – fat and muscle mass measurement.
- Comorbid conditions.
- Age.
- Cancer stage.
- Presence of fever.
- Corticosteroid use.

The European Palliative Care Research Collaboration (EPCRC) is reviewing cachexia definition and classification, nutritional impact of symptoms and the psychosocial consequences of involuntary loss of appetite or weight in patients with advanced cancer in order to produce a new cachexia assessment instrument (Radbruch *et al.*, 2010). A clear definition of cancer cachexia may inform clinical decision making, so improving treatment plans and assisting further research (Blum *et al.*, 2010). It is essential to adopt a multidisciplinary approach in the management of cachexia (Santarpia *et al.*, 2011).

Nutritional management

Nutrition support (oral nutrition supplements, enteral and parenteral feeding) can increase body weight; however, it does not have a demonstrable effect on lean body mass and therefore does not improve functional status or quality of life (Dodson *et al.*, 2011; Kotler, 2000). However, artificial nutrition support may reduce carer anxiety and improve a patient's psychological condition (Bruera & Sweeney, 2000). Cachexia can be distressing to both the patient and carers. In the absence of starvation and given normal gastrointestinal function and integrity, parenteral nutrition should not be used in patients who are catabolic (Blum *et al.*, 2010). However, patients with active tumours and significant starvation from bowel obstruction or short bowel syndrome benefit from total parenteral nutrition (Hoda *et al.*, 2005). Parenteral nutrition may prevent further deterioration in nutritional status, but will not treat cachexia (Bozzetti *et al.*, 1999) and its use should be considered carefully (see Chapter 6.5).

Nutritional supplements enriched with n-3 polyunsaturated fatty acids and antioxidants are available. Eicosapentaenoic acid (EPA), an n-3 polyunsaturated fatty acid, is found in oily fish. It appears to attenuate weight loss, particularly loss of skeletal muscle mass, by reducing inflammatory processes (Fearon *et al.*, 2003; Cerchiatti *et al.*, 2007; Dewey *et al.*, 2007). However, it does not affect muscle protein synthesis, although combined with protein and energy rich supplements to optimise intake it may regulate inflammatory activity (Siddiqui *et al.*, 2006). The use of fish oil rich in EPA and docosahexaenoic acid (DHA) in pancreatic and lung cancer has been shown to reduce the rate of weight loss (Barber *et al.*, 1999; Bauer *et al.*, 2005; Fearon *et al.*, 2003; Moses *et al.*, 2004). Compliance is often limited by anorexia and an unpleasant aftertaste. Improved palatability may help to improve patient compliance and therefore effectiveness (Arends *et al.*, 2006).

Clinical management

Cancer cachexia treatment may include appetite stimulation, energy intake supplementation, control of catabolism and stimulation of protein anabolism (MacDonald *et al.*, 2003), which are often be used in combination. Many approaches in the treatment of patients with cancer cachexia are required.

Several types of drug have been used in patients with poor appetite, including progestins, glucocorticoids and cannabinoids, (Mantovani & Madeddu, 2009; Muscaritoli *et al.*, 2006), which may successfully stimulate appetite and increase food intake, but any weight gain is usually short lived, consists primarily of fat or water and offers limited benefit for quality of life (Maltoni *et al.*, 2001; Behl & Jatoi, 2007). Table 7.15.13 summarises examples of drugs used in the management of cachexia.

Research is continuing into other agents, including ghrelin (DeBoer, 2008; Kamiji & Inui, 2008). Administration of synthetic ghrelin to cachectic cancer patients

Table 7.15.13 Examples of drugs used in the management of cancer cachexia

Drug	Actions	Disadvantages	Further reading
Megestrol acetate	A synthetic progestogen, which stimulates appetite; mechanisms not fully known but may induce neuropeptide Y and suppress proinflammatory cytokines	Increases resting energy expenditure Increases risk of thromboembolic events Suppresses testosterone production in men No improvements have been shown in physical function, fatigue or lean body mass	Berenstein & Ortiz (2005) Loprinzi <i>et al.</i> (1999) Mantovanu <i>et al.</i> (2009)
Corticosteroids (glucocorticoids)	Improve appetite/ oral intake	Can exacerbate cachexia due to myopathy, insulin resistance and infections	
Cannabinoids	Stimulate appetite	Lower gastrointestinal motility, which undermines the effect on appetite stimulation No quality of life improvement	Jatoi <i>et al.</i> (2002) Sarhill <i>et al.</i> (2003) Strasser <i>et al.</i> (2006)
Thalidomide	Maintains lean body mass through affecting proinflammatory cytokines	No quality of life or survival benefit	Khan <i>et al.</i> (2003) Gordon <i>et al.</i> (2005)

elicited a small non-significant increase in food intake (Strasser *et al.*, 2008). Animal models have shown some success with melanocortin antagonists in disease associated cachexia, but this has not been tested in humans (DeBoer, 2010). Despite ongoing research, drug therapies have not shown significant clinical benefits.

Cachexia management must be considered as part of the overall management plan of patients with cachectic cancer. The aim of nutritional intervention at this stage should be to optimise quality of life rather than nutritional status. Palliation of symptoms is vital and a multidisciplinary approach, involving hospital and community professionals, including dietitians, other therapists and palliative care specialists, is essential. Treatment plans should consider both physiological and psychosocial factors and their impact on the patient and their carers in the widest sense (see Chapter 7.16). Cachexia is particularly distressing and will require sensitive management due to the often conflicting needs and desires of patients and carers.

7.16

Palliative care and terminal illness

Lucy Eldridge and Jane Power

Key points

- Palliative care is the active holistic care of patients with advanced progressive illness, providing management of pain and other symptoms as well as psychological, social and spiritual support.
- The primary nutritional objective is to maintain or improve the quality of life.
- Decisions concerning nutrition should always be patient centred, individualised and open to change in line with the patient's condition.
- Artificial nutritional support is a medical intervention and therefore decision making should consider benefits, burdens, harms and risks.

Palliative care is the active holistic care of patients with advanced progressive illness. There are various definitions of palliative care (Walshe, 2011). The World Health Organization (WHO, 2011) currently describes it as *an 'approach that aims to improve the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems whether physical, psychosocial or spiritual'*.

Palliative care is based on a number of principles (WHO, 2011), which aim to:

- Provide relief from pain and other distressing symptoms.
- Affirm life and regard dying as a normal process.
- Neither hasten nor postpone death.
- Integrate the psychological and spiritual aspects of patient care.
- Offer a support system to help patients to live as actively as possible until death.
- Offer a support system to help the family cope during the patient's illness and in their bereavement.
- Use a team approach to address the needs of patients and their families, including bereavement counselling if indicated.
- Enhance quality of life, and may also positively influence the course of illness.

Palliative care is applicable early in the course of illness; in conjunction with other therapies that are intended to prolong life or symptom control, e.g. chemotherapy or

radiation therapy. Patients may be in the palliative stage of their disease for months or years. It may be difficult to define what stage a patient has reached and, although clear that life expectancy is limited, identifying the length of time remaining may be impossible. Terminal care is a part of palliative care and usually refers to the last few days of life. Patients, carers and some health and social care professionals may associate palliative care specifically with care for dying people, which consequently may have significant implications for acceptability and access (NICE, 2004).

During the past four decades, the emergence of the modern hospice movement has led to the development of a model of care that is now used throughout the health service in the UK and has been adopted worldwide (Help the Hospices, 2011). Palliative and terminal care can be provided at home, in day care centres, nursing homes and hospitals, as well as within a hospice or palliative care unit. It involves a multiprofessional approach that may include healthcare and social professionals, as well as members of charitable, voluntary and independent organisations (NICE, 2004). The aim is to provide care based on individual needs and personal choice. Although palliative care is focused on the patient, providing support to the patient's relatives and carers is recognised as being an integral part of care.

Professionals involved in providing palliative care are either specialist or non-specialist. Specialist providers of palliative care have the expertise to address patient's complex needs. However, it is the responsibility of all health and social care professionals who provide day to day care to assess and meet the needs of each patient and

their families within their limits, and know when to seek advice from or refer to a specialist palliative care service (NICE, 2004). The role of the dietitian within the palliative care setting is to help identify and address nutritional factors that impair a patient's physical and psychological wellbeing, with the primary nutritional objective of maintaining or improving the quality of life for that individual. The dietitian in this setting should:

- Assess the nutritional needs and problems of the patient.
- Establish when nutritional support measures may be appropriate.
- Advise on how the nutritional requirements of the patient may be met.
- Suggest ways in which nutrition related problems caused by the physical or psychological effects of the disease or its treatment may be alleviated.
- Provide advice and guidance for carers.
- Liaise with catering services to provide a flexible approach to food provision.
- Identify need for eating aids to assist independent eating.
- Provide training and support for professional colleagues.

Dietitians working in the field of palliative care require good communication skills in order to create an empathic relationship with patients and carers. Whilst dietitians can play a vital role in the palliative care setting, most palliative care teams or hospices do not currently have an identified specialist dietitian as a core member (Help the Hospices, 2009). However, it is the responsibility of all dietitians involved in the care of those with life limiting illnesses to facilitate the provision of appropriate nutritional care. They should have access to support and advice within the dietetic and multidisciplinary team for more complex cases.

Diagnostic criteria and classification

The target population for palliative care is wide and should not be constrained by diagnosis. Although historically associated with cancer, it is now recognised that palliative care equally applies to those with other non-malignant life limiting conditions, e.g. motor neurone disease, dementia, heart failure, end stage diabetes and renal disease.

In order to provide high quality palliative care regardless of diagnosis, a whole system, involving all providers of palliative care in all locations, coordinated care pathway approach has been strongly recommended (Department of Health, 2008). This requires identification of people approaching the end of life, assessing their needs, initiating discussions surrounding preferences and wishes for end of life care, agreeing a care plan to reflect these and supporting carers both during a person's illness and after their death. Three care models have been recommended by the National Institute for Health and Care Excellence (NICE, 2004) and as part of the national End of Life Programme (Department of Health, 2008); Gold Standards

Framework, Liverpool Care Pathway for the Dying Patient and Preferred Priorities for Care.

Nutritional aspects

In addition to providing nutrients, nutrition has an important psychological, social, spiritual and cultural role in the palliative stages of illness. Eating can help maintain a sense of normality within a patient's life. As food intake is also associated with health and wellbeing, it may evoke feelings of fear and despair in those who are struggling to eat. This can have a major effect on an individual's self esteem and confidence, leading to social isolation and depression. Progressive illness may also affect nutritional status in a number of ways:

- The psychological effect of being diagnosed with an incurable and progressive illness is profound, especially if the diagnosis is unexpected. The consequent anxiety, depression and perhaps sense of hopelessness can markedly impair food intake.
- Worsening symptoms of the disease, particularly those of a fatigue, dysphagic or gastrointestinal nature, may make eating physically difficult and lead to associations with discomfort.
- Medication may cause side effects, e.g. nausea, vomiting or diarrhoea, that reduce food intake. Drowsiness induced by sedatives or pain relievers, such as opioids or narcotics, may make patients disinclined to eat.
- Treatments such as chemotherapy or radiotherapy and associated side effects can markedly affect food intake and increase the likelihood of nutritional deficiencies.
- Nutritional requirements may be increased by the physiological effects of the illness, e.g. pyrexia, secondary infection, increasing tumour mass, or by nutrient losses, e.g. malabsorption.
- As the final phase of the illness develops, physiological functions such as gastric emptying, digestion, absorption and peristalsis may decline. Both appetite and the ability to tolerate food will decrease.

Nutritional assessment

It is important that patients are assessed throughout their illness trajectory to ensure that nutritional support is proactive instead of reactive, thus ensuring that patients do not enter the terminal phases of their illness seriously nutritionally depleted. The assessment of palliative patients will vary according to individual needs, problems and clinical circumstances, but will primarily follow a stepwise process of:

- Defining the clinical condition, prognosis and aim of any medical intervention.
- Assessing eating habits.
- Establishing current nutritional status; it may not always be appropriate to regularly weigh a patient as this can cause anxiety.
- Identifying nutrition related problems or barriers to food and fluid intake, and evaluating their physical and psychological impact.

- Exploring the nutritional concerns of the patient and their family and/or carers.
- Discussing with patients and carers dietary goals that are appropriate and achievable.
- Integrating these goals into the care plan in a way that is compatible with medical and nursing objectives.
- Regularly reviewing progress, evaluating the effectiveness of any measures implemented and modifying them as necessary.

Screening tools and the weighing of patients will vary depending on where the patient is based and local policy and practice; there are no specific palliative care nutrition screening tools. Within a palliative care setting, it is important to assess both quantitative and qualitative issues, including what food means to the individual at any particular stage. Food issues, especially weight loss, can be more distressing to carers than patients (Poole & Froggatt, 2002). The relevance of biochemistry and weighing patients will depend on the prognosis, the medical intent at that stage of palliative care and the patient's preference.

Nutritional management

The principal objectives are to maximise food enjoyment and minimise food related discomfort. It is also important to prevent or treat avoidable and unnecessary malnutrition since this can affect both physical and psychological wellbeing. However, it is equally important that nutritional support measures are not so invasive or unacceptable to the patient that they impair quality of life. The objectives should always be one or more of the following:

- Retain the ability to derive pleasure from food and the social aspects of eating.
- Retain physical strength long enough to fulfil final wishes and ambitions.
- Have sufficient physical strength to obtain benefit from rehabilitation.
- Retain some control over the disease process through attention to nutrition.
- Die with dignity and not as a result of starvation.

Patients should be encouraged to retain an interest in food, and to regard good nutrition as a positive aid to help maintain strength and improve wellbeing. Nutritional counselling on both the use of nutrient dense foods and finding foods the patient enjoys is important, and should consider symptoms, emotional adaptation to illness and social circumstances (Hopkinson *et al.*, 2011). If nutritional needs are not being met, suggestions to improve nutrient intake by increasing frequency of food consumption and choosing foods of greater nutrient density are a useful first step. Fortification strategies to boost energy intake can be effective, but if these prove inadequate or food intake is particularly poor, oral supplements may be helpful. However, it is important to be aware that although nutritional supplements can be useful, they can divert patients from the foods they want to eat. In addition, patients do not always like supple-

ments and may feel guilty if they are unable to take them (Hill & Hart, 2001). Forcing food on those who have no desire to eat and drink can cause distress (McClement *et al.*, 2003; Strasser *et al.*, 2007).

Patients may have reduced their dietary intake for a variety of reasons; however, simple measures can often make an enormous difference to nutrient intake. Ideally, food should be offered that is of high quality and attractively presented. Menus should be tempting and varied, with snacks that can be provided at any time. The giving and receiving of nourishment is a means of showing love and affection, and consequently food refusal can cause offence and create barriers within the family unit. Involving carers in discussions about the nutritional needs and difficulties of the patient and establishing realistic expectations can help defuse problems. Table 7.16.1 gives suggestions that may be particularly helpful for people with palliative care (see Chapter 6.3).

Maintaining good hydration

Good hydration is essential, but it is important that adequate fluid provision is not achieved in such a way that it impairs appetite and compromises nutrient intake from food. If food intake is generally poor, nutrient rich sources of fluids should be encouraged.

Dysphagia

Dysphagia requires expert assessment and management in order to provide food of an appropriate consistency, while also maintaining nutrient intake (see Chapter 7.3). It is important to ensure these are nutrient dense as appropriate. At the end of life, a risk management approach allowing patients to eat and drink even with an unsafe swallow is deemed the most appropriate route, and may offer quality of life [Royal College of Physicians (RCP), 2010].

Therapeutic diets

For patients who have pre-existing conditions that require special diets, e.g. diabetes mellitus and hyperlipidaemia, consideration should be given to the appropriateness of the dietary restriction. For individuals in the advanced stages of disease, the restrictions can be relaxed or stopped; however, this needs to be done with reassurance and encouragement (Diabetes UK Nutrition Working Group, 2011). The priority is symptom management and therefore alteration of drug regimens may be required (Rowles *et al.*, 2010).

Artificial nutritional support

As a result of increasing debility, dysphagia or intestinal failure, a point may be reached when adequate nutrition can only be maintained by enteral or parenteral feeding. However, it is important to remember that for some, artificial nutrition support (ANS) may cause more harm than good and have potentially limited success; therefore,

Table 7.16.1 Dietary guidance for people with palliative care needs

Symptom	Dietary guidance
Poor appetite	<p>Eat small, frequent, attractively presented foods</p> <p>Eat favourite foods or those found to be most enjoyable</p> <p>Consume fluids after, rather than with, meals to maximise food intake</p> <p>Ensure posture helps rather than hinders eating</p> <p>Eat in surroundings that are as pleasant as possible</p> <p>Eat in the company of others unless a preference is expressed to eat alone</p> <p>Consider appetite stimulants, e.g. alcohol, megestrol acetate or low dose steroids</p>
Sore mouth	<p>Replace salty, spicy or acidic foods with blander, less astringent alternatives</p> <p>Eat soft moist foods</p> <p>Cold foods are more soothing</p>
Dry mouth (xerostomia)	<p>Take frequent small sips of water</p> <p>Suck ice cubes, ice lollies or citrus flavoured boiled sweets</p> <p>Chew fruit flavoured sweets</p> <p>Meals should be moist in texture</p> <p>Consider artificial saliva</p>
Taste changes	<p>Problematic foods should be substituted with nutritionally similar alternatives:</p> <ul style="list-style-type: none"> • Poultry or fish instead of red meat • Soft drinks or milk instead of tea or coffee • Boiled sweets or pastilles instead of chocolate <p>Experiment with herbs and spices in cooking</p>
Early satiety	<p>Consume small, frequent amounts of nutrient dense foods</p>
Belching and/or flatulence	<p>Avoid foods and drinks that exacerbate gas production such as:</p> <ul style="list-style-type: none"> • Carbonated beverages, beer, brassicas (broccoli, spinach, cauliflower, Brussels sprouts), peas, beans, sweetcorn, onion and radish <p>Reduce the amount of ingested air by:</p> <ul style="list-style-type: none"> • Eating slowly • Keeping the mouth shut when chewing and swallowing • Avoiding sucking drinks through a straw
Constipation	<p>Ensure adequate medical intervention</p> <p>Increase fluid intake without compromising nutritional intake</p> <p>Clarify the patient does not have an intestinal obstruction or is dehydrated</p> <p>If appropriate, increase fibre rich foods, but care should be taken with patients whose appetite is decreased</p>
Diarrhoea	<p>Establish cause</p> <p>Avoid foods that appear to exacerbate symptoms</p> <p>If appropriate, ensure that anti-diarrhoeal drugs have been prescribed</p> <p>Encourage a wide variety of foods</p>
Hypercalcaemia	<p>Do not reduce or restrict dietary sources of calcium</p> <p>Encourage carbonated drinks containing phosphoric acid</p>

quality of life always needs to be considered (Raijmakers *et al.*, 2011). Cochrane reviews assessing the effects of ANS (Good *et al.*, 2010) and hydration (Good *et al.*, 2011) in palliative patients concluded that there was a lack of randomised controlled studies and therefore no recommendations for practices could be made. Clinicians need to make a decision based on the perceived benefits, harms, risks and burdens of ANS in individual patient circumstances (Table 7.16.2).

Ethical and legal considerations

The RCP (2010) and the General Medical Council (GMC, 2010) provide guidance on end of life care, which includes nutritional advice.

Oral nutrition

Oral nutrition and hydration are considered basic care, both ethically and legally, and should always be provided

unless actively resisted by the patient. It is important that patients are monitored and if a patient refuses food, this issue should be explored with the patient and documented (GMC, 2010). Food should not be forced upon a patient where this causes unavoidable choking or aspiration (Lennard-Jones, 1998).

Artificial nutritional support

All forms of ANS and hydration are deemed medical treatment and as such can be treated as any other form of medical intervention. It is vital that each patient is considered individually, the goals of care are clear and the resulting decision is a joint one involving both the care team and the patient. A patient cannot insist on artificial nutrition if the doctor feels it is not in their best interests (GMC, 2010). However, a patient's wishes are paramount and a competent patient has the absolute right to decide what nutritional support they will or will not accept, even if it may be considered to be of clinical benefit and refusal

Table 7.16.2 Potential benefits, harms, risks and burdens of artificial nutrition support in palliative care (Brotherton & Judd, 2007; Dy, 2006; Raijmakers *et al.*, 2011; Shaw, 2011)

Benefits	Assess for nutrition, fluid and medication May improve quality of life, functional status and a sense of wellbeing May prevent deterioration and reduce fatigue and chronic nausea Support religious beliefs Decrease the pressure to eat
Harms	False hope Exacerbation or cause of symptoms, e.g. gastrointestinal, fluid overload or ascities Altered body image
Risks	Complications of placement, metabolic disturbances, wound infection, abdominal pain, leakage Sepsis
Burdens	Possibly delays discharge or requires hospital admission Period of time required for training and/or to arrange home package of care Carers have greater responsibility Limitations of activities of daily living and of social life Additional monitoring

could lead to starvation or exacerbation of their symptoms. Incompetent patients retain this right through a valid advance refusal (Mental Capacity Act, 2005). In patients for whom death is believed to be inevitable and nutrition intervention is not considered to be of benefit, it can be withheld or withdrawn (GMC, 2010). However, if ANS is withheld or withdrawn, it is important that the anxieties of patients, relatives and carers are addressed. The primary goal of treatment in terminal care is the comfort of the patient; therefore, the decision concerning whether or not to feed must be made on this basis (GMC, 2010; RCP, 2010).

Artificial hydration

In the last few days of life, patients may be too weak to take oral foods and fluids. This may be due in part to declining physical function, but is often attributable to a reduced level of consciousness resulting from the use of sedatives and pain relieving drugs. The use of intravenous hydration at this stage has been a matter of debate and raises a number of ethical issues (Thorns & Garrard, 2003). The extent to which intravenous fluids offer symptomatic relief is unknown as comparative studies are not possible to conduct for ethical reasons. It has been argued that artificial rehydration is necessary to satisfy thirst and other symptoms, such as confusion and headaches (Dalal & Bruera, 2004). Others consider that simpler measures such as attention to oral hygiene are sufficient to prevent discomfort. It is also argued that intravenous hydration at this stage is unnecessarily invasive and can cause a physical barrier between the patient and their family at an important time (Thorns & Garrard, 2003).

Conclusion

The principal conclusion is that a blanket policy of artificial nutrition and hydration or no artificial nutrition and hydration is ethically indefensible. Deciding what is appropriate for each case must be based on an individual basis according to the likely benefits and burdens of such intervention. Good practice decisions concerning artificial nutrition and hydration should involve a multidisciplinary team, the patient and relatives and carers.

7.17

Trauma and critical care

7.17.1 Critical care

Ella Segaran

Key points

- Up to 75% of patients survive an intensive care unit (ICU) admission; however many are left with severe weakness and delayed recovery.
- The critical illness, ICU procedures, equipment and medications all influence nutritional provision and need to be accounted for in nutritional assessments.
- Enteral feeding is the route of choice and feeding should commence within 48 hours of admission to positively influence outcome.
- Controversy exists regarding the optimal timing for supplementing poor enteral feeding with parenteral nutrition.
- One of the biggest dilemmas facing ICU dietitians is the accurate assessment of energy and protein requirements.
- Approximately half of prescribed feed is delivered to patients whilst on an ICU. Strategies need to be employed, e.g. algorithms and prokinetic agents, to reduce interruptions and overcome delayed gastric emptying.

Critical care medicine is primarily concerned with the management of patients with acute life threatening disorders. Compared with other medical specialities it is a relatively new and developing area. The term critical care medicine was first introduced in the late 1950s. During the poliomyelitis epidemic in 1947–1948, manual ventilation evolved and prevented patients dying from respiratory paralysis. By the mid 1950s primitive ventilators were developed, thus allowing the establishment of intensive care units (ICU) and the birth of critical care medicine. Between the 1980s and 1990s huge advancements took place in computer technology and ventilator development. Multidisciplinary critical care teams were formed as well as national and international societies for critical care. Today, ICUs are modern high tech units with a vast array of equipment designed to support each of the body systems. The immediate objective of care is to preserve life and to prevent, minimise or reverse damage to vital organs. The ICU multidisciplinary team usually includes consultant intensivists, medical and nursing staff, pharmacists, dietitians and physiotherapists. To ensure nutritional support is appropriate, the dietitian needs to appreciate all aspects of patient care. The dietitian provides input into:

- The route and timing of nutritional support.
- The most appropriate access route.

- An assessment of the patient's nutritional requirements.
- The use of specialised enteral and parenteral products.
- Adjustments to the nutritional care plan, secondary to the disease state and changes in the patient's condition (Taylor *et al.*, 2005).

Diagnostic criteria and classification

Approximately 160 000 patients a year require admission to English ICUs (NHS, 2011). The Department of Health guidelines (2000) suggest that 1–2% of acute beds in a general hospital should be designated ICU beds, and that this number should be greater where there are specialist units, e.g. cardiac or major vascular surgery, or neurosurgery. Patients are classified according to the severity of the illness and the level of support that is needed rather than their hospital location, e.g. ICU or high dependency unit (HDU) (Table 7.17.1). Typically, there are three groups of patients in the ICU:

- Postoperative, e.g. major elective and emergency surgery.
- Major trauma, e.g. head injuries, road traffic accidents, burns, penetrating injuries.
- Serious sepsis, e.g. respiratory failures, HIV infection.

Table 7.17.1 Classification of patients in the acute hospital setting

Classification	Level of support required
Level 0	Patients whose needs can be met through normal ward care in an acute hospital
Level 1	Patients at risk of their condition deteriorating, or those recently relocated from higher levels of care, whose needs can be met on an acute ward with additional advice and support from the critical care team
Level 2	Patients requiring more detailed observation or intervention, including support for a single failed organ system or postoperative care and those stepping down from higher levels of care
Level 3	Patients requiring advanced respiratory support alone or basic respiratory support together with support of at least two organ systems

Metabolic response to injury, trauma and sepsis

The changes that occur following stress (injury, trauma or sepsis) are different from those to starvation, being designed to mobilise tissues for defence and repair in an attempt to survive. This mechanism takes priority even in the presence of starvation. Cuthbertson's (Cuthbertson *et al.*, 2001) pioneering work introduced the terms *ebb* and *flow* to describe the metabolic response. The response is complex and involves interactions and physiological responses, including counter regulatory hormones and cytokines.

Ebb phase

This occurs immediately after the injury and lasts approximately 24–48 hours. There is a reduction in metabolic activity and oxygen consumption, and a fall in body temperature. Energy reserves, e.g. glucose from liver glycogen and free fatty acids from adipose tissue, are mobilised, but there is impairment in the ability to use them.

Flow phase

Following the ebb phase, there is a second phase called the flow or acute phase. This is characterised by hyper-metabolism, catabolism and increased oxygen consumption. These mechanisms are mediated by cytokines, hormones and changes in nutrient metabolism. The length of the flow phase depends on the severity of the injury and the resolution (treatment) of the traumatic or septic insult. After uncomplicated major surgery, the patient can be expected to enter the anabolic phase within 2–3 weeks, but with major burns or unresolved sepsis the breakdown of lean tissue continues for as long as the pathological stimulus is present.

Counter regulatory hormones

The levels of these hormones, catecholamines, glucagon and cortisol, increase, resulting in increased protein mobilisation and the ensuing catabolism. They are responsible for the hyperglycaemia and insulin resistance commonly seen in critically ill patients. Glucagon stimulates gluconeogenesis, cortisol increases net protein catabolism and the catecholamines lead to glucose intolerance.

Cytokines

Circulating levels of pro- and anti-inflammatory cytokines also increase. Interleukin (IL)-1, IL-6 and tumour necrosis factor alpha (TNF α) are the major proinflammatory mediators. They act in conjunction with the various hormones on hepatic and peripheral tissue to increase lean tissue breakdown and loss.

Gluconeogenesis and protein metabolism

Following injury, glucose is an important fuel for the central nervous system, wounds and the immune system, all of which are metabolically active during stress. Glycogen stores are quickly depleted so the need for available glucose is met from muscle protein breakdown for hepatic gluconeogenesis. Amino acids derived from muscle breakdown are also required for the synthesis of the acute phase proteins, e.g. C-reactive protein (CRP).

During the flow phase, achievement of energy balance (non-protein or total energy) fails to alleviate catabolism in critically ill patients (Frankenfield *et al.*, 1997). In sepsis and trauma, provision of glucose only partially reduces gluconeogenesis, even at maximum rates of glucose provision of 5 mg/kg/min. Therefore, supplying energy to the severely septic or injured patient will never preserve lean tissue and the most that can be hoped for is to attenuate the rate at which it is lost.

Anabolic phase

Eventually catabolism declines and the flow phase passes into the anabolic or recovery phase. Metabolic rate decreases, and fluid status and insulin sensitivity return to preinjury levels, which are usually coupled with an increase in appetite and ambulation. Nutritional therapy should now aim to increase protein synthesis and restore muscle mass.

Disease consequences

Although 75% of patients return home after an ICU stay (NICE, 2009), many are left with multiple health problems and delayed recovery, e.g. severe weakness and fatigue (commonly termed ICU acquired weakness), which typically occurs in a third of patients who have a prolonged stay (Hermans *et al.*, 2008); a third of patients never work again (Hayes *et al.*, 2000; Herridge *et al.*, 2003). Patients in an ICU can lose up to 2% of their muscle mass a day (Griffiths & Jones, 1999). The related respiratory muscle weakness is associated with prolonged ventilation (De Jonghe *et al.*, 2004). Patients can be so

weak on discharge to a ward that they are unable to feed themselves. Impaired coughing and swallowing can place them at risk of aspiration and taste changes can further compromise nutritional status. Poor recovery post ICU is a major public health issue and the subject of guidelines (NICE, 2009). The cause of the ICU acquired muscle weakness is multifactorial (Griffiths & Hall, 2010) and the risk factors include:

- Prolonged controlled mechanical ventilation.
- Inflammation, systemic inflammatory response syndrome.
- Sepsis or septic shock.
- Illness severity.
- Bed rest, immobilisation.
- Neuromuscular blockage, paralysing agents.
- Corticosteroid medication.

Nutritional consequences

At first the ICU environment can be appear very daunting; patients are extremely ill and surrounded with multiple pieces of equipment. Dietitians working in critical care need to take time to familiarise themselves with the equipment, procedures and medications used, to ensure their nutritional assessments and therapy recommendations are safe and appropriate. Table 7.17.2 and Table 7.17.3 give details of equipment and medications commonly used in the ICU and their nutritional implications.

Nutritional assessment

Anthropometry

Many patients are admitted to the ICU as emergencies and therefore cannot give their weight or height. Also, patients are often bedbound and immobile, so obtaining an accurate weight and height is challenging. Some ICU beds have an facility to weigh patients but weights so obtained need to be interpreted with caution. Oedema and fluid retention can cause weight to increase by 10–20% in a single day (Lowell *et al.*, 1990), thus making anthropometric measures commonly used elsewhere inaccurate. Surrogate measures for height can be used, e.g. ulna length or knee height, although it should be noted that these have not been validated for use with critically ill patients and therefore should be used as a guide only.

Biochemistry

Assessment of biochemistry is carried out frequently in the ICU, often twice a day. Many factors during critical illness, e.g. losses from the gut, excess diuresis, volume expansion and internal redistribution, and renal replacement therapy, alter biochemical values such as potassium, magnesium and phosphate. Low levels of these are not always related to nutritional status or refeeding syndrome. Twenty four hours is a long time in the ICU, thus blood results from 3 days previously may be of little help in assessing the current picture (Runcie & Dougall, 1990).

Table 7.17.2 Commonly used equipment in the intensive care unit (ICU) and their nutritional implications

Equipment	Purpose	Nutritional considerations
Mechanical ventilator	Controls the breathing pattern Different settings to suit patient's needs, e.g. mandatory ventilation (machine doing all the breathing) and spontaneous ventilation (the patient initiates the breaths)	The different ventilator settings can either reduce (mandatory ventilation) or increase (spontaneous ventilation) the work of breathing, which influences energy expenditure and energy requirements (Hoher <i>et al.</i> , 2008)
Endotracheal tubes (ETT)	Tubes used to provide mechanical ventilation The ETT is passed through the mouth or nose into the trachea. Used for short term ventilation	The tube makes it difficult to coordinate swallowing Oral intake is usually avoided Can cause temporary dysphagia when removed
Tracheostomy	Tracheostomy is inserted (endoscopically or surgically) into the trachea via the neck Used for mid to long term ventilation	Swallowing difficulties as above In special circumstances oral trials can be facilitated, usually with the help of an experienced speech and language therapist
Airflow cooling blanket	Used to decrease body temperature Aims to achieve body temperature of 35°C Used as a treatment for traumatic brain injury, following cardiac surgery and after cardiac arrest	Significantly lowers energy expenditure and energy requirements. Use a predictive equation that takes temperature into consideration (Faisy <i>et al.</i> , 2003; Frankenfield <i>et al.</i> , 2004)
Continuous renal replacement therapy	Used to treat acute kidney injury in ICU patients Clears unwanted solutes and large volumes of fluid	Loss of electrolytes, e.g. phosphate and magnesium Loss of 5–10g of protein/day dependent on modality type Loss of water soluble vitamins Loss of trace elements, e.g. selenium (Cano <i>et al.</i> , 2009)

Table 7.17.3 Drug–nutrient interactions

Drug	Nutritional consideration
Opioid analgesia/sedation agents, e.g. fentanyl and morphine	Can cause constipation and decrease gut motility, resulting in reduced gastric emptying
Propofol	1.1 kcal/mL – contributes additional energy Only take into consideration if taken over a prolonged period Risk of fat overload
Paralysing agents, e.g. atracurium and pancuronium	Decrease energy expenditure and gut motility
Phenytoin/rifampicin/ciprofloxin	If given via the enteral route, require a break from feed to allow drug absorption
Intravenous fluids, e.g. crystalloids and colloids	Can contribute to sodium overload
Inotropes and vasopressors, e.g. noradrenaline (norepinephrine), adrenaline (epinephrine), dobutamine and vasopressin	High doses cause a reduction of hepatic, renal and splanchnic blood flow Can lead to risk of gut ischaemia
Prokinetics, e.g. metoclopramide and erythromycin	Enhance gut motility and help overcome delayed gastric emptying
Sliding scale insulin therapy	Hypoglycaemia risk with interruptions to feeding
Stress ulcer prophylaxis, e.g. lansoprazole, esomeprazole, omeprazole and ranitidine	Alters pH and can make nasogastric tube placement confirmation by pH paper unreliable

All values need to be interpreted with care, taking the clinical situation into consideration.

Clinical assessment

Clinical condition and treatments will influence the assessment of nutritional status, nutritional requirements, and route and tolerance of the nutritional support provided (Table 7.17.4). The reason for the patient's admission often relates to preadmission nutritional status:

- *Following major elective surgery*, e.g. surgery to the gastrointestinal tract – the patients tend to be moderately depleted of body protein preoperatively and, without nutritional support, lose approximately another 5% (approximately ~43 g/day) body protein in the first 2 weeks postoperatively (Hill, 1992).
- *Trauma or brain injury* – most of these patients are young and in good health prior to injury. Initially they are not protein depleted but do lose a large amount of body protein (approximately 110 g/day) in the first 10 days after trauma, despite provision of nutritional support (Monk *et al.*, 1996).
- *Serious sepsis* – these patients may be older and have pre-existing nutritional depletion and chronic medical

Table 7.17.4 Factors commonly associated with either an increase or decrease in energy expenditure in hospitalised patients

Factors increasing energy expenditure	Factors reducing energy expenditure
Pyrexia	Sedation
Disease state	Anaesthesia
Surgery	Neuromuscular blocking agents, barbiturates, coma
Abnormal losses, e.g. wound exudate, diarrhoea and vomiting	Mandatory ventilation
Infection	Hypothermia, active cooling
Pain	Starvation
Extraneous movements, e.g. following head injury	Reduced mobility
Spontaneous ventilation and weaning from ventilator	

conditions. Large protein losses occur (approximately 150 g/day) despite aggressive nutritional support (Streat *et al.*, 1987).

Dietary assessment

Up to 61% of ICU patients have been shown to be moderately malnourished, with 23% severely malnourished on admission (Barr *et al.*, 2004). Patients with malnutrition develop poor muscle function and their immunological function becomes depressed, placing them at increased mortality risk and worsened hospital discharge functional status (Tremblay & Bandi, 2003). Patients with a body mass index (BMI) of <18.5 kg/m² have an significantly increased 60-day mortality after developing acute respiratory distress syndrome (ARDS) compared with normal and obese patients (Gong *et al.*, 2010).

Nutritional assessment informs the selection of the most appropriate route for nutritional support and the dietitian can further advise on the best route of delivery. Most ICUs will have an enteral feeding starter regimen, where feed is started and a goal target reached. The dietitian is usually responsible for assessing if this meets the patient's requirements or if modifications are necessary.

Nutritional management

Route of nutrient delivery

International guidelines consider enteral feeding to be the best way to feed critically ill patients (Kreyman *et al.*, 2006; McClave *et al.*, 2009). However, the evidence is conflicting regarding the optimum route (enteral or parenteral) of delivery. Three meta analyses of trials comparing enteral nutrition (EN) with parenteral nutrition (PN) in critically ill patients have been published (Gramlich *et al.*, 2004; Heyland *et al.*, 2003; Simpson & Doig, 2005). Heyland *et al.* (2003) reported no difference in mortality between EN and PN, but EN was associated with a significant reduction in infections. Gramlich *et al.*

(2004) also found no difference in mortality and a significant reduction in infections with EN. Simpson & Doig (2005) found a significant reduction in mortality with PN, but this appears to exist when the provision of EN was delayed, i.e. started after 48 hours. They also found a significant increase in infections in the PN group. Simpson & Doig concluded that EN remains the feeding route of choice until more evidence is available. Critically ill patients relying solely on EN do not often achieve energy intake targets (Reid, 2006), leading to significant underfeeding. Underfeeding is associated with increased infections (Rubinson *et al.*, 2004) and other complications such as prolonged ventilation, prolonged length of stay and pressure ulcers (Dvir *et al.*, 2006; Villet *et al.*, 2005).

In European ICUs the consensus is for the combined use of EN with PN to optimise nutritional support early in a patient's admission (Kreymann *et al.*, 2006). However, there are important differences between the American and European societies' recommendations for the use of PN in critically ill patients. The joint American Society for Parenteral and Enteral Nutrition (ASPEN) and Society of Critical Care Medicine (SCCM) (McClave *et al.*, 2009) guidelines recommend PN is given to non-malnourished ICU patients during the first 7 days, to reduce the risk of infectious morbidity and mortality. In contrast, the European Society for Parenteral and Enteral Nutrition (ESPEN) guidelines (Kreymann *et al.*, 2006) focus on preventing an early energy deficit by preferentially using EN and supplementing with PN if needs are not met by the fourth day.

The two different approaches have been compared in the recent EPaNIC trial (Casaer *et al.*, 2011), which aimed to study the impact of early initiation of PN (European guidelines) with late initiation (American guidelines) to supplement inadequate EN. The findings suggest that early supplementation of PN is associated with worse outcomes than those where PN initiation is delayed for 7 days. The late initiation group had a significantly shorter ICU stay and fewer infectious complications, and shorter duration of mechanical ventilation and renal replacement therapy; no differences in mortality were observed. The results need to be interpreted with caution as there were study design limitations. The eight centres were all from one European country and the majority of patients were admitted following cardiac surgery, which make the generalisability of the results questionable. Also, the energy targets appear higher than used elsewhere and these were not individualised. Tight glycaemic control was employed in both groups, which is no longer standard practice. Finally, it was unclear how many patients were still on the ICU at day 8 to receive late PN, or how many actually needed either early or late PN.

Timing of initiation of nutritional support

Early nutritional support is commonly defined as commencing 24–48 hours after admission and assumes that the patient has been adequately resuscitated and is haemodynamically stable. It is associated with signifi-

cantly shorter hospital stays and a trend towards reduced mortality (Martin *et al.*, 2004). It is now standard care to implement EN within 24–48 hours following ICU admission (Singer *et al.*, 2009).

Estimated energy requirements

One of the biggest dilemmas facing ICU dietitians is the accurate assessment of metabolic rate for critically ill patients. The most accurate method for this is indirect calorimetry, although very few dietitians have access to this equipment in the clinical setting. Therefore, standardised equations are used to estimate the metabolic rate. Many equations are available, but data are sparse on how they compare against measured energy expenditure (MEE) in a range of critically ill patients, e.g. sepsis, trauma and obesity. The energy expenditure (EE) of critically ill patients is variable, influenced by the impact of the illness and its treatment. Several factors other than the severity of illness modify EE (Table 7.17.4) (see Chapter 6.1).

There are published predictive equations for use in critically ill patients, including Swinamer (Swinamer, *et al.*, 1990), Ireton-Jones (Ireton-Jones *et al.*, 1992), Penn State (Frankenfield *et al.*, 2004), Brandi (Brandi *et al.*, 1999) and Faisy (Faisy *et al.*, 2003). With the exception of the Ireton-Jones equation, the others incorporate physiological factors such as temperature and ventilation settings, making them more applicable to this group of patients. Frankenfield *et al.* (2009) carried out the largest and most complete validation study of metabolic rate equations for critical care use. Nine different equations were compared with MEE via indirect calorimetry in 202 critically ill patients. The Penn State equation was the most consistent, being able to predict EE within a 10% range on 67% of occasions. When using a predictive equation it is preferable to use one that is designed for critical care use, taking clinical parameters into consideration (Table 7.17.5).

Estimated protein requirements

Optimal protein requirements are a challenge to determine during critical illness. The nitrogen balance obtained from 24-hour urine collections does not reflect whole body protein balance. Protein is synthesised and lost via the liver, gut and immune system, and estimations of these losses are needed. As discussed above, in healthy individuals muscle mass is controlled by a balance between muscle protein synthesis (MPS) and muscle protein catabolism (MPB), so that it remains constant. However, in critical illness this balance is altered (Rennie, 1985); there is a decrease in MPS and increase in MPB (Puthuchery *et al.*, 2010). The ability of protein or amino acids to stimulate MPS is positively correlated with physical exercise, which is not possible in bed bound critically ill patients (Barazzoni *et al.*, 2004; Biolo & De Cicco, 2004; Biolo *et al.*, 1997). Patients are unlikely to achieve a positive nitrogen balance whilst critically ill (Wolfe & Miller, 1999). Protein dynamics are

Table 7.17.5 Predictive equations for use in critical care

Equation	Reference:	Advantages	Disadvantages
20–25 kcal/kg (84–105 kJ/kg) 25–30 kcal/kg (105–126 kJ/kg)	ACCP (Cerra <i>et al.</i> , 1997), ESPEN (Singer <i>et al.</i> , 2009)	Quick and easy Designed to avoid harmful overfeeding	Consensus decision Not age, gender, condition specific Ambiguity over which weight to use Individual interpretation as to when patient is in the recovery phase Very low accuracy compared with MEE (Reid, 2007)
Schofield and stress factors (SFs)	Schofield (1985)	Gender, age, disease and activity specific	Based on data from healthy individuals Use of SFs introduces substantial error SFs based on outdated references – ICU practices have improved considerably since, thus impacting on energy expenditure Does not reflect clinical parameters Associated with under- and over-feeding when compared with MEE (Reid, 2007)
Penn State University	Frankenfield (2011), Frankenfield <i>et al.</i> (2009)	Gender, age, height specific Includes clinical parameters specific to ICU, i.e. temperature and ventilation settings 67% accuracy within 10% of MEE in 202 patients (Frankenfield <i>et al.</i> , 2009) Useful for obese patients	Day to day variability due to clinical parameters Time required Needs familiarity with ventilation settings Does not capture activity – need to add a factor for physical activity
Ireton-Jones	Ireton-Jones <i>et al.</i> (1992)	Best known ICU specific equation Gender and age specific Includes factors for trauma and burns	Developed on burns and trauma patients Overestimates in non-obese and underestimates in obese patients 46% accuracy compared with MEE (Frankenfield, <i>et al.</i> , 2009)
Faisy	Faisy <i>et al.</i> (2003)	Age, height specific Includes clinical parameters specific to ICU, i.e. temperature and ventilation settings	Developed on medical critical care patients only Mean age 61 years Not gender specific 53% accuracy compared with MEE (Frankenfield, <i>et al.</i> , 2009)

MEE, measured energy expenditure; ICU, intensive care unit; ACCP, American College of Chest Physicians; ESPEN, European Society for Parenteral and Enteral Nutrition.

influenced by both severity of injury and underlying nutritional status.

Several studies have investigated the influence of differing levels of protein intakes on protein metabolism (Larsson *et al.*, 1990; Shaw *et al.*, 1987; Ishibashi *et al.*, 1998). Larsson *et al.* (1990) found that nitrogen balance was improved in patients who received 1.3 g/kg of protein for the first week following injury. Ishibashi *et al.* conducted a similar study in general ICU patients (including trauma, head injury and sepsis patients) using enteral feeds and found that protein losses were minimised at intakes of 1.2 g/kg, with intakes in excess of 1.5 g/kg conferring no further benefit.

In septic patients, Streat *et al.* (1987) demonstrated a 12.5% loss of total body protein (TBP) during the first 10 days of the illness, despite apparently adequate nutritional support. Trauma patients appear to show even greater protein losses, with TBP losses of 16% seen over a 21-day study period (Monk *et al.*, 1996). In these studies, approximately 70% of protein losses came from skeletal muscle, which has serious implications for patient recovery and rehabilitation.

The recommendations for protein requirements are summarised in Table 7.17.6.

Obese patients

Obesity impacts on acute illnesses, with increased numbers of obese patients requiring intensive care. Internationally approximately 20% of mechanically ventilated ICU patients are obese (BMI 30–40 kg/m²) and 4–7% morbidly obese (BMI >40 kg/m²) (Akinnusi *et al.*, 2008; Anzueto *et al.*, 2011; Oliveros & Villamor, 2008). As BMI increases, patients are more likely to experience complications than non-obese patients, e.g. increased ventilator days, higher incidence of ARDS, increased infections, acute kidney injury and longer ICU and hospital stays (Akinnusi *et al.*, 2008; Dossett *et al.*, 2008; Hogue *et al.*, 2009; Morris *et al.*, 2007; Oliveros & Villamor, 2008). On discharge obese patients are more likely to require rehabilitation facilities or enter a nursing home (Morris *et al.*, 2007). However, obesity is not associated with increased ICU mortality (Akinnusi *et al.*, 2008; Anzueto *et al.*, 2011; Frat *et al.*, 2008; Gong *et al.*, 2010; Hogue *et al.*, 2009;

Table 7.17.6 Protein requirements in critical care patients

Patient group	Protein recommendation (g/kg/day)	Reference	Comments
Trauma and burns	1.3	Larsson <i>et al.</i> (1990)	Used parenteral nutrition
General intensive care unit (ICU)	1.2	Ishibashi <i>et al.</i> (1998)	Used enteral nutrition
Severe sepsis	1.5	Shaw <i>et al.</i> (1987)	Used parenteral nutrition
ICU on continuous renal replacement therapy (CRRT)	1.5 up to 2.5	Cano <i>et al.</i> (2009), Bellomo <i>et al.</i> (2002), Scheinkestel <i>et al.</i> (2003)	Increased requirements to compensate for losses via the filtering process

Morris *et al.*, 2007; Oliveros & Villamor, 2008; Sakr *et al.*, 2008).

The increasing numbers of obese patients in ICUs has not led to an increase in studies regarding their nutritional needs; therefore, the best way to nourish these patients is under debate. However, it is agreed that the preservation of muscle mass is vitally importance. Due to the multiple comorbidities associated with obesity, the avoidance of overfeeding has been proposed (McClave *et al.*, 2009).

Estimated energy requirements

Controversy remains surrounding the most appropriate weight to use in predictive equations for obese patients. Determining body composition in obese patients is difficult, as actual weight does not reflect the amount of metabolically inactive body fat. Resting metabolic rate is mainly dependent upon fat free mass (Miller & Blyth, 1953; Webb, 1981). However, while weight is gained from both fat and lean body mass (Horgan & Stubbs, 2003), in severe obesity there is a greater proportion of fat tissue deposited (Forbes, 1982; 1987). These differences in body composition make it challenging to determine which weight to use in predictive equations. As a result of the larger fat free mass, using ideal body mass (IBW) in obese patients is likely to underestimate energy needs, and the use of actual body weight (ABW) will overestimate this as a consequence of the metabolically inactive fat mass. Adjusted body weight (AdjBW) has been proposed (Amato *et al.*, 1995) on the assumption that the obese have a lean body mass that equates to 25% more than that of the non-obese. This approach has not been validated and is not recommended as the original predictive equations were developed using ABW and the use of an AdjBW for predicting EE in obese patients will result in an underestimation (Frankenfield *et al.*, 2003).

Anderegg *et al.* (2009) compared 13 different prediction methods against MEE in obese hospitalised adults and found that the Harris–Benedict equation (HBE) (Harris & Benedict, 1919) with AdjBW plus a stress factors and 21 kcal/kg of ABW most frequently predicted the EE within $\pm 10\%$ of the MEE, albeit only in 50% of participants. This was a single centred small trial of only 36 patients and not all patients were mechanically ventilated. Measured energy expenditure was assessed once per individual and it is unclear on what day from admission the

readings were undertaken. The authors concluded that the agreement between all predictive equations and MEE was poor and no equation could be recommended over the others.

In a study by Frankenfield *et al.* (2009) half of the 100 participants were obese (BMI 30–112 kg/m²); the Penn State equation had an accuracy rate of 70% in the young obese but only 53% in the elderly obese. The MEE readings were only undertaken once per patient and the mean day of measurement was day 6 of the ICU stay (range day 2–27). In a follow-up study, a revised Penn State equation devised for use in those aged over 60 years with a BMI of >30 kg/m² achieved an accuracy rate of 74% when compared with MEE (Frankenfield, 2011).

The ASPEN/SCCM guidelines (McClave *et al.*, 2009), recommend that energy requirements for those with a BMI of >30 kg/m² are calculated as 11–14 kcal/kg of ABW or 22–25 kcal/kg of IBW. This recommendation is based on pooled findings of six studies undertaken in obese patients (Dickerson, 2004). Patients experienced shorter ICU lengths of stays, and fewer antibiotic days when fed 11–14 kcal/kg of ABW compared with those who received 19–25 kcal/kg of ABW. This recommendation needs to be interpreted with caution as the studies used very different protocols; only one was conducted in ICU patients. All of the studies were inadequately powered to evaluate major end points such as morbidity and mortality; nitrogen balance was the primary outcome assessed. Only two studies were randomised and used PN, and one that collected data retrospectively investigated the use of EN. None of the studies looked at body composition, protein turnover or muscle function. Due to these severe limitations, it can be concluded that there is inadequate evidence to make any recommendation.

To conclude, predictive equations in obese critically ill patients are inaccurate and can result in significant under- and over-feeding. Indirect calorimetry (IC) remains the best way of ascertaining EE, but without this the Penn State predictive equations, which include a specific equation for obese elderly patients, may be the best option.

Estimated protein requirements

No trials have evaluated a range of protein intakes, so the optimal protein requirements for obese patients remain unknown. The ASPEN/SCCM guidance (McClave *et al.*, 2009) of 2g/kg of IBW for those with a BMI of

30–40 kg/m² and 2.5 g/kg of IBW for those with a BMI of >40 kg/m² is based on the six trials of nutritional support in hospitalised patients (Dickerson, 2004). The severe limitations of these studies have been discussed above. In addition, it should be noted that five of the trials used PN and only the retrospective EN study was in critically ill patients. Only the PN trials achieved a positive nitrogen balance, but these patients were not critically ill. The Parenteral and Enteral Nutrition Group of the British Dietetic Association (Todorovic & Micklewright, 2007) recommends that for patients with a BMI of >30 kg/m², approximately 75% of the value should be estimated from weight and for those with a BMI of 50 kg/m² this should be approximately 65%. It is unclear how this recommendation was derived as no studies are referenced. Further studies investigating the optimum protein intake for obese patients need to be undertaken. Until such time, expert guidelines should be consulted and clinical judgement used.

Overfeeding

Overfeeding macronutrients to critically ill patients can negatively affect organ function, particularly that of the lungs, liver and kidneys. Any excessive intake, but particularly excessive carbohydrate, can result in hypercapnia (carbon dioxide retention), which increases the work of the lungs and potentially prolongs the need for mechanical ventilation (Liposky & Nelson, 1994). Additionally, overfeeding carbohydrate can lead to hyperglycaemia, hypertriglyceridaemia and an accumulation of fat in the liver. Overfeeding protein can lead to azotaemia, uraemia, hypertonic dehydration and metabolic acidosis if the kidneys are unable to sufficiently adjust urea excretion or acid–base balance. Excessive fat infusions can result in hypertriglyceridaemia and fat overload (Klein *et al.*, 1998).

Non-feed energy sources need to be considered when they make a significant energy contribution. The anaesthetic propofol is administered in a lipid base (Intralipid) and contributes 1.1 kcal/mL of additional energy. In addition, this high fat infusion can cause hypertriglyceridaemia and fat overload syndrome when used in excessive doses. Intravenous 5% dextrose is also frequently used in the ICU and contributes 200 kcal/L.

In underweight patients, rapid attempts to restore body mass and nutritional status may have adverse metabolic consequences (Klein *et al.*, 1998). The underweight, overweight and elderly are particularly vulnerable to overfeeding, because of the difficulties in assessing their true requirements.

Feeding protocols

The use of ICU feeding protocols to promote early and safe enteral feeding is encouraged. Units that follow simple algorithms are able to feed patients earlier and achieve calorie goals sooner (Doig *et al.*, 2008; Heyland *et al.*, 2004). Their use has been shown to increase the number of patients receiving EN, and reduce the number

receiving PN or not being fed at all (Heyland *et al.*, 2004). Feeding protocols positively influenced outcomes, including a reduction in hospital stay and in hospital mortality rate (Martin *et al.*, 2004). The combination of a feeding protocol and dietetic input on ward rounds was an effective method of increasing enteral feed delivery in intensive care (Adam & Batson, 1997). The key to successful protocol/algorithm implementation is simplicity, as cumbersome protocols are more likely to be ignored or incorrectly applied (Doig *et al.*, 2008). Although feeding protocols may vary between institutions, they have the following features in common:

- Aim to promote early, safe EN.
- Advocate use of prokinetics to improve tolerance.
- Recommend alternative routes of feeding if any intolerance persists, e.g. post pyloric feeding or PN.

Interruptions to feed

The unpredictable nature of critical illness and the medical management of these patients frequently lead to disruption in the delivery of nutritional support, especially EN. In practice, it is rare for all the prescribed daily feed to be delivered. On average, between 43% and 58% of prescribed feed is delivered (Heyland *et al.*, 2004; Reid, 2006). A large multicentre study found that ICU patients were uniformly underfed, with an average of 59% of energy and 56% of protein prescriptions being received (Alberda *et al.*, 2009). Two thirds of feed cessations are attributable to avoidable causes (McClave *et al.*, 1999). Reasons for the discontinuation of feeds on the ICU are listed in Table 7.17.7.

Gastric residual volumes

Feeding intolerance is frequently responsible for poor enteral feed delivery. Large gastric residual volumes (GRVs) are used as a marker of gastric emptying and assumed to reflect enteral feed intolerance. Other symptoms of delayed gastric emptying are nausea, vomiting, abdominal distension and discomfort. The incidence of patients experiencing large GRVs varies between 22% and 56% (Adam & Batson, 1997; Heyland *et al.*, 1995; Reintam *et al.*, 2009). There is no agreement in the literature for the definition of a large GRV or their management, such as whether feed should be withheld after a single high GRV or how long feeds should be withheld for before checking GRVs. The reported values for the designated cut-off for withholding feed vary from 150 mL up to 500 mL. The main concern with GRVs of >200 mL is the associated risk of pulmonary aspiration of gastric contents, resulting in the development of pneumonia. However, it has been suggested that GRVs may have very little clinical meaning and do not consistently correlate with aspiration risk (McClave *et al.*, 2005). However, the perceived risk often causes unnecessary delays and frequent interruptions of EN.

McClave *et al.* (2005) reported that increasing the designated GRV cut-off for cessation of enteral feeding from 200 mL to 400 mL did not increase the risk of aspiration.

Table 7.17.7 Reasons for discontinuation of enteral feed on the intensive care unit

Category	Example	Frequency of occurrence (%)	Considered potentially avoidable (%)
High gastric residual volumes (GRVs)	Volumes >200 mL – even though commonly isolated events	45	70
Tube displacement	Patient or staff removal	41	66
Procedures	Bronchoscopy, tracheostomy, transoesophageal echo, endoscopy, surgical intervention	39	80
Diagnostic tests	Chest X ray, CT or MRI scan, ultrasound	27	52
Nursing care	Patient baths, changing bedding, tracheostomy care	30	99
Other	Haemodynamic instability, nausea, vomiting and ileus	32	52

CT, computed tomography; MRI, magnetic resonance imaging.

Conversely, dropping the designated GRV cut-off from 400 mL to 200 mL failed to reduce the risk and protect patients from aspiration. Recommendations were that feeds should not be stopped for GRVs below 400–500 mL in the absence of other signs of intolerance. The recent REGANE study (Montejo *et al.*, 2010) compared GRV cut-offs of 200 mL and 500 mL. High GRVs were experienced in 42% of control (200-mL GRV) and 26% of intervention (500-mL GRV) patients. The mean enteral feed delivery was significantly higher in the intervention group, although the incidence of pneumonia, duration of mechanical ventilation and ICU length of stay were similar in both groups. It appears that increasing the volume of the GRV cut-off to 500 mL is not associated with worse complications or outcomes and can be recommended as a normal limit for GRV.

As 80% of high GRVs are isolated events (McClave *et al.*, 1999), clinicians should be encouraged to look for a trend of gradually increasing GRVs, with abrupt cessation of feeds being reserved for those patients with overt regurgitation and aspiration. Causes of large GRVs are:

- Mechanical ventilation.
- Sedation.
- Use of paralysing agents.
- Use of vasopressors.
- Sepsis.
- Traumatic brain injury.

Prokinetic agent treatment

Delayed gastric emptying may be overcome by the regular administration of prokinetic agents, which increase gastrointestinal motility. It is hypothesised that their use leads to improved tolerance to feeds and nutritional indices, and reduced infectious morbidity. However, studies of their use have often been small and have methodological weaknesses, such as varying doses of drugs and a range of GRV cut-off values (Booth *et al.*, 2002). Metoclopramide and erythromycin are used most frequently. Their intravenous use has been found to promote gastric emptying, but erythromycin appears to be the more effective (MacLaren *et al.*, 2008; Nguyen *et al.*,

2007b). However, the effect on gut motility is short lived, with the effect wearing off after 24–72 hours (Chapman *et al.*, 2000; Nguyen *et al.*, 2007b). When the two drugs are combined, the effect is superior to erythromycin alone (Nguyen *et al.*, 2007a).

It should be noted that there are safety concerns regarding the use of erythromycin, an antibiotic, as its routine use may result in antibiotic resistance. However, for a prokinetic effect erythromycin is administered at a subantibiotic dose and there is no evidence that short term use results in adverse effects.

Reducing the risk of aspiration

Preventative measures include (McClave *et al.*, 2009; Metheny *et al.*, 2004):

- Elevate the head of the bed to $\geq 45^\circ$ and if this is not possible, position the patient in reverse Trendelenburg.
- Consider the use of prokinetic agents, e.g. metoclopramide and erythromycin.
- Change formula delivery method from bolus or intermittent to continuous.
- Consider the placement of a post pyloric tube; regularly assess feeding tube placement to ensure that it has remained in the correct position.
- Consider the use of chlorhexidine mouthwash.
- Reduce the level of sedation when possible.
- Minimise the transport out of the ICU for diagnostic tests and procedures.

Post pyloric enteral nutrition

Post pyloric enteral feeding is often considered an effective way of overcoming large GRVs and therefore reducing the risk of aspiration; however, studies to support this assumption are limited. Nasoduodenal or nasojejunal tubes are difficult to place and to keep in the correct position; endoscopic placement can be time consuming and labour intensive. Self propelling tubes are available, but in one study only 26–38% of tubes placed in to the stomach moved spontaneously into the duodenum and the majority retroperistalsed back into the stomach (Rees

et al., 1988). The use of a fluoroscopic technique to place tubes has been shown to be successful in critically ill patients (Welpé *et al.*, 2010). Others have also achieved successful tube placement with an electromagnetic tracking system (Taylor *et al.*, 2010).

There is conflicting advice regarding the use of jejunal feeding. The ASPEN/SCCM guidelines (McClave *et al.*, 2009) support their use, whilst the European guidelines (Kreymann *et al.*, 2006) concluded that the results of 11 randomised controlled trials do not justify general recommendations. The studies described in both guidelines comparing gastric with jejunal feeding are small and report on differing outcomes. The adequacy of nutritional support provided was only discussed in six of the trials; these demonstrated superior nutrient delivery with jejunal feeding. There was no difference observed between jejunal and gastric routes with regards to the time to achieve nutritional goals. The ICU length of stay was significantly reduced in two of the six studies, but there was no difference in mortality or pneumonia incidence between the two groups. Despite this, both guidelines recommend the use of post pyloric feeding in those who are intolerant to gastric feeding, providing access can be easily gained.

Glycaemic control

An acute state of insulin resistance and hyperglycaemia is characteristically seen following the metabolic effects of sepsis and injury, although the exact mechanisms precipitating this response remain unclear (Carlson, 2001). It is considered to occur secondary to raised endogenous production or exogenous provision of insulin antagonists, e.g. noradrenaline (norepinephrine), adrenaline (epinephrine), cortisol and glucagon (Bessey *et al.*, 1984). Proinflammatory cytokines are also thought to play a key role in the development of insulin resistance (Carlson, 2004). Insulin resistance can be correlated directly with the severity of illness and determines the speed of recovery (Carlson, 2001). Hyperglycaemia is not exclusive to patients with pre-existing diabetes, but appears to be related to the extent of critical illness. In most cases, it will resolve as the clinical condition improves. Excessive carbohydrate intake (particularly from PN) will result in hyperglycaemia, but this is rarely the primary cause.

Following the study by van den Berghe *et al.* (2001), close attention has been paid to glycaemic control in the critically ill. A significant reduction in the morbidity and mortality of surgical ICU patients was achieved with the aggressive use of insulin to maintain normoglycaemia. Favourable outcomes were attributed to the tight control of blood glucose levels between 4.4 and 6.1 mmol/L compared with a control group where the target blood glucose was 10.0–11.1 mmol/L. It was concluded that this tight glycaemic control and early aggressive feeding resulted in a reduction in mortality by 33% in surgical ICU patients.

Since the publication of this trial, six independent prospective randomised controlled trials involving nearly 10 000 patients have been unable to reproduce the same mortality benefits, leading to international controversy

surrounding the benefits of tight glycaemic control. The Normoglycaemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation trial (NICE SUGAR) (Finfer *et al.*, 2009), compared intensive glucose control (4.5–6 mmol/L) with a conventional glucose control target of 10 mmol/L; the end point was death from any cause within 90 days of randomisation. Mortality was 27.5% in the intensive glucose group and 24.9% in the conventional group, which was a statistically significant difference. The study concluded that intensively treated patients experienced more periods of hypoglycaemia and these contributed to the increased mortality.

The original Van den Berge *et al.* study has limitations; it was conducted in a single centre, in cardiac surgery patients and was not blinded. Participants were given large doses of intravenous glucose on day 1 and nutrition was commenced within 24 hours of admission to the ICU, predominantly as PN. All of these factors result in a lack of applicability to other critical care populations. The NICE SUGAR trial on the other hand was a multicentre trial involving 42 hospitals, had a robust study design and was conducted in a mixed ICU population. In light of the conflicting findings, there is still a lack of international recommendations of the optimal glucose range for critically ill patients. Until further guidance is provided, many have opted for a moderate range of blood glucose management of 6–10 mmol/L (Bellomo & Egi, 2005).

Immune modulating nutritional support

Enteral formulations

Immune modulating enteral feeds are characterised by increased quantities of specific nutrients that may have the potential to improve immune function and modulate the inflammatory response. Such nutrients include arginine, n-3 polyunsaturated fatty acids, glutamine, ribonucleic acid (RNA) and antioxidants, including vitamin C and selenium. Although the use of immune modulating enteral feeds is recommended in international guidelines (ASPEN, Canadian), their routine use in UK clinical practice is still controversial. Factors influencing uptake include the lack of a definitive optimum time for starting these products, and evidence for the most advantageous combination of nutrients and which patients are likely to gain benefit.

Meta analyses (Heyland *et al.*, 2001; Montejo *et al.*, 2003; Waitzberg *et al.*, 2006) and systematic reviews (Marik & Zaloga, 2008; 2010) suggest that immune modulating enteral feeds are of benefit in reducing duration of mechanical ventilation, infections, wound complications and length of stay compared with standard enteral feeds. There is no overall impact on mortality. It appears that the benefits are seen in those undergoing major surgery rather than trauma and septic ICU patients.

Specific nutrients

Fish oils

Three studies have investigated enteral feed enhanced with eicosapentaenoic acid (EPA), δ -linolenic acid (GLA)

and antioxidants in septic ICU patients with ARDS (Gadek *et al.*, 1999; Pontes-Arruda *et al.*, 2006; Singer *et al.*, 2006) The findings were combined in a meta analysis that showed a reduction in mechanical ventilation and intensive care days, as well as a decreased risk of developing new organ failures and mortality in those who received the EPA/GLA enteral feed (Pontes-Arruda *et al.*, 2008). The original studies have a number of limitations; no power calculations were undertaken to determine appropriate study size, there was a lack of blinding and the studies were conducted over a short time period (4–7 days). In addition, the sickest patients were excluded, bronchoscopy was used to diagnose ARDS, differing levels of EPA and GLA were used, and a high fat, low carbohydrate control feed was used, which is not representative of a standard ICU enteral feed. The source of fat was rich in n-6 fatty acids, i.e. linoleic acid, which could potentially produce an upregulation of the inflammatory response. All of these limitations inhibit the applicability of the studies.

In 2011, Pontes-Arruda *et al.* used a high carbohydrate, high protein feed as the control, aiming to better represent a standard ICU enteral feed and overcome the criticisms of the earlier studies. However, the study's aim was different from the original studies as it investigated if EPA/GLA supplemented enteral feed could prevent early sepsis progressing to severe sepsis. The results suggested that the intervention group (EPA/GLA) developed significantly less sepsis, and cardiac and respiratory failures, and experienced 6.5 fewer ICU days and 8.9 fewer hospital days. The results seem remarkable, but there are also limitations to this study. It was single centred and despite being conducted in ICU patients, the majority of these were not intubated and had no organ failure. They received in excess of 95% of prescribed volume of feed and had a mean age of 70 years, which are not representative of most ICU patients. Another trial, the EDEN-Omega study, investigated whether administering n-3 fatty acids and antioxidants as a bolus was more beneficial than within an enteral feed in patients with acute lung injury/ARDS (Clinicaltrials.gov 2011). However, this study was stopped early for futility in the treatment effect.

Arginine

Arginine is one of the most controversial immunomodulatory nutrients. Studies show improvements in clinical outcomes and reduced mortality with arginine supplementation of enteral feeds (Atkinson *et al.*, 1998; Caparros *et al.*, 2001; Galban *et al.*, 2000), although some investigators have suggested that it can be detrimental. An increase in the inflammatory response and greater mortality have been observed in severely septic patients (Bertolini *et al.*, 2003; Heyland & Samis, 2003). The proposed mechanism is that in severe sepsis, arginine may be converted to nitric oxide, which contributes to haemodynamic instability. For this reason, recent international guidelines suggest caution or avoidance of arginine in severe sepsis (Critical Care Nutrition, 2009; McClave *et al.*, 2009).

Glutamine and selenium

Parenteral route

The systematic review conducted as part of the Canadian guidelines suggests that parenteral administration of glutamine to critically ill patients reduces mortality and new infections, whilst selenium supplementation can reduce mortality but has little effect on infections (Critical Care Nutrition, 2009). However, the trials included in the systematic review were small and many were of poor quality.

The results of the recent SIGNET trial (Andrews *et al.*, 2011), a large multicentre randomised double blind trial, examined the influence of glutamine, selenium or both added to PN on new infections and mortality in critically ill patients. The trial intervention was for a maximum of 7 days. The findings suggested that addition of glutamine (0.2–0.3 g/kg) and/or selenium (500 µg) to PN did not decrease new infections or mortality. In the subgroup analysis of those who received the intervention for 5 or more days (46% of the original population), selenium supplementation significantly reduced new infections. There was no effect of glutamine on new infections. The median duration of PN in the trial was 5 days and it is possible that timing of administration (especially for glutamine) was not optimal and it needed to be continued for longer. The PN was commenced at the ICU team's discretion and it could be argued that the treatment might have offered more benefit if it had been commenced earlier. The dose was also low and probably subtherapeutic compared with the recommendation of 0.5 g/kg/day in the ESPEN/SCCM guidelines (McClave *et al.*, 2009).

Enteral route

Enteral nutrition supplemented with glutamine is recommended by the ESPEN and ASPEN/SCCM guidelines in trauma and burns patients only. Its use in general ICU patients or surgical patients is not recommended as no benefits have been found over standard EN (Schulman *et al.*, 2005). Enteral glutamine may be associated with a decrease in mortality in burns patients, and reduced infections and length of stay in both burns and trauma patients. However, these findings are based on a meta analysis of six studies that were all carried out in single centres, and the likelihood of the results being replicated in other settings is low. It is not possible to confirm the optimal dose of enteral glutamine (Critical Care Nutrition, 2009).

Vitamin and mineral requirements

In critically ill adults who do not otherwise have extraordinary needs for particular micronutrients, the majority of standard enteral and parenteral formulae contain suitable quantities of vitamins and minerals. The micronutrient needs of most patients can be met if target energy intakes are achieved. The reference nutrient intake (RNI) should be the minimum aim, bearing in mind that excessive amounts of trace elements may compromise the response to infection. Thiamine and vitamin C deficits

seen in patients who abuse alcohol can pose risks on admission to the ICU. Thiamine supplementation should be provided during the first 3 days (Singer *et al.*, 2009). Patients with major burns and those on continuous renal replacement therapy will have additional vitamin and mineral needs (Berger *et al.*, 2004).

Fluid management

Fluid management in ICU patients is complex as it encompasses many factors. The medical team sets daily fluid balance targets. The simplistic tool of 30–35 mL/kg is not appropriate for use in this setting. Injured and postoperative patients find it more difficult to excrete sodium and water as there is an increase in capillary permeability to water and to the smaller plasma proteins, e.g. albumin, and a resulting loss of intravascular fluid into the extravascular space. Intravenous fluids given for resuscitation also pass into the interstitial space and are retained for the duration of the acute phase of the illness, causing interstitial oedema. Even in the absence of exogenous fluid administration, these compartmental shifts in fluid distribution occur. Fluid retention following surgery can amount up to 7L (BAPEN, 2011). In severe sepsis and organ dysfunction, around 5–15L are retained, although fluid retention of up to 35L has been recorded (Foley *et al.*, 1999).

Fluid requirements are based on the following parameters:

- Clinical history.
- Changes in weight.
- Fluid balance charts.
- Urine output.
- Blood pressure.
- Capillary refill.
- Autonomic responses.
- Skin turgor and dry mouth.
- Serum and urine biochemistry.

Types of intravenous fluids

There are two different categories of intravenous fluids routinely used in the ICU:

- *Crystalloids* – small molecular weight salts or sugars dissolved in water.
- *Colloids* – larger molecular weight molecules, insoluble in water.

Crystalloids

The most commonly used crystalloids are normal saline (0.9% NaCl), dextrose (5–50% glucose), dextrose saline (4% glucose:0.18% NaCl) and Hartmann's solution (Ringer's lactate). All are approximately isotonic, but once infused distribute differently between the different fluid compartments that they are used to maintain.

Colloids

The most frequently used colloids contain gelatine (large molecular weight, approximately 35 000) dissolved in an isotonic crystalloid, e.g. Gelofusine. The large molecules do not dissolve completely and therefore can remain in

the blood for longer, expanding the plasma volume. They are commonly used to resuscitate intravascular volume.

Electrolytes

For optimal physiological function, humans must maintain fluid and electrolytes within narrow limits. Homeostasis mechanisms function to maintain these balances; however, critically ill patients frequently have fluid and electrolyte abnormalities that overcome homeostatic mechanisms and may contribute to morbidity and mortality (Lobo, 2004). Sodium and chloride are the most common extracellular cation and anion, respectively, and potassium and inorganic phosphate the intracellular equivalents. No international guidance is available for electrolyte requirements or supplementation during artificial nutrition. The ESPEN guidelines for PN (Singer *et al.*, 2009) state that as requirements are highly variable, they should instead be determined by plasma electrolyte monitoring.

Sodium

The normal requirement for sodium is approximately 70–120 mmol/day. The BAPEN (2011) recommendation is 50–100 mmol/day in 1.5–2.5 L of water. However, additional amounts should only be given to correct deficit or continuing losses.

Hypernatraemia

Hypernatraemia is common in the critically ill patient and is usually caused by a combination of excessive sodium administration, inadequate fluid intake or excessive fluid losses. It is not uncommon for postoperative patients to have 700 mmol of sodium overloaded (BAPEN, 2011). Retention may occur in acute renal failure or as a stress induced syndrome of inappropriate antidiuretic hormone (SIADH). A 24-hour urine collection for measurement of urinary urea, electrolytes and osmolality can identify the cause of hypernatraemia.

The use of low sodium feeds to treat hypernatraemia is not recommended. Instead it is important to determine the cause of the high sodium level and to treat this. In many cases the use of additional enteral water can be effective at achieving a gradual improvement in biochemistry. However, treatment decisions should be made in consultation with the medical team, with overall fluid balance targets in mind.

Hyponatraemia

Hyponatraemia is commonly due to fluid overload, with or without inadequate sodium intake, or associated with hepatic failure (Arieff & Ayus, 1991). Fluid restriction to raise serum sodium levels is the first line treatment, but sodium supplementation may be necessary (Ayus & Arieff, 1999). Desired changes in serum sodium should not exceed 6–8 mmol/24 hours, as more rapid repletion and dehydration is associated with neurological damage.

Potassium

Dietary requirements are in the region of 80–120 mmol/day and the BAPEN (2011) recommendation is 40–80 mmol/day in 1.5–2.5 L of water.

Hyperkalaemia

Hyperkalaemia may be iatrogenic, or associated with excessive use of potassium sparing diuretics, potassium supplements (often administered intravenously), catabolic states such as rhabdomyolysis (where muscle tissue destruction releases intracellular potassium), or the metabolic acidosis of progressive renal failure.

Hypokalaemia

Hypokalaemia is associated with the use of steroids, diuretics, continuous renal replacement therapy or SIADH resulting in increased urinary losses of potassium. Hypokalaemia secondary to cellular uptake of glucose is more pronounced with insulin therapy. The body has no known potassium retaining hormone, so increased urinary or gastrointestinal losses may also induce hypokalaemia. A low potassium feed may be indicated if a patient has deteriorating renal function but is not to receive continuous renal replacement therapy. However, it is not indicated for patients on continuous renal replacement therapy; in addition to being low in potassium, the feed is also low in protein. Additional protein supply is required to counteract the protein losses from the haemofiltration process.

7.17.2 Traumatic brain injury

Kirsty-Anna Mclaughlin and Gemma Moore

Key points

- Early nutritional support is associated with better outcomes and full nutritional requirements should be safely met as soon as possible post injury.
- Hypermetabolism and catabolism cause higher energy and protein requirements in the acute phase of traumatic brain injury over and above those seen in many other hypermetabolic conditions.
- Regular monitoring of anthropometry, biochemistry, feed tolerance and nutritional intake will help to ensure appropriate nutritional management.
- The multidisciplinary team is key throughout the acute and rehabilitation phases in ensuring optimal outcomes.

There are three stages of traumatic brain injury (TBI):

- *Acute* – intensive care aiming for medical stabilisation and prevention of secondary brain damage.
- *Post acute* – ward based care to provide transition from intensive care to rehabilitation.
- *Rehabilitation* – multidisciplinary therapy to maximise physical and cognitive functioning and to minimise chronic disability.

The duration of these stages will differ considerably between patients. Krakau *et al.* (2010) found that on average 73% of TBI patients remain in an intensive care unit (ICU) for 2–33 days, a mixed ward for 5–115 days and a rehabilitation unit for 7–299 days.

Traumatic brain injury is thought to be the leading cause of disability and mortality in young people and 30% of head injured patients are children under the age of 15 years (Maas *et al.*, 2008; NICE, 2007). Each year 600 000 people attend emergency departments with a head injury in England and Wales, with the majority of cases considered to be mild (NICE, 2007). Moderate and severe cases account for 15% of head injuries, with 113 000 people admitted to hospital annually in England (NICE, 2007; Krakau, 2010). The primary causes of head injury include falls (22–43%), assaults (30–50%) and road traffic accidents (approximately 25%). The incidence of head injury is greater in males (approximately 72% of cases). Alcohol consumption is thought to be involved in up to 65% of adult head injuries (NICE, 2007).

Table 7.17.8 Commonly used terms in traumatic brain injury

Commonly used terms	Definition
Traumatic brain injury (TBI)	Specifically defined by the presence of symptoms ranging from behavioural and neuropsychological alterations in mild cases to altered consciousness, coma, seizure, focal sensory or motor neurological deficit or confusion in more severe cases (Bruns & Hauser, 2003)
Head injury	Less specifically defined by the presence of external injuries to the face, scalp and calvarium. TBI may not be present (Bruns & Hauser, 2003)
Coma	Unarousable with lack of spontaneous eye opening, and an inability to wake the patient even with vigorous sensory stimulation (Giacino <i>et al.</i> , 2002)
Vegetative state	'A complete absence of behavioural evidence for self or environmental awareness. However, the presence of sleep wake cycles indicates that the capacity for spontaneous or stimulus induced arousal remains' (Giacino <i>et al.</i> , 2002)
Minimally conscious state	Similar to vegetative state but with some consciousness preserved (Giacino <i>et al.</i> , 2002)
Brain stem death	Irreversible coma: 'unresponsiveness and lack of reactivity, the absence of movement and breathing, the absence of brain stem reflexes, and coma whose cause has been identified' (Wijdicks, 2001)

Definition

There are many terms commonly used to classify TBI and head injury (HI) (Table 7.17.8). Head injury is classified as either closed or penetrative, and the damage from TBI either primary brain damage or secondary brain damage.

- *Closed head injury* – 'A blow to the head or a severe shaking. The skull may be fractured but there is no penetration of the skull or brain tissue' (NICE, 2007).
- *Penetrating head injury* – 'Head injury where an object penetrates the scalp and skull and enters the brain or its lining' (NICE, 2007).
- *Primary brain damage* – occurs immediately as a result of trauma. Factors that may cause brain damage include shearing of white matter tracts, focal contusions, haematomas and diffuse swelling (Maas *et al.*, 2008).
- *Secondary brain damage* – occurs hours or days after the initial trauma and is caused by inflammatory and stress responses (Maas *et al.*, 2008). It is possible to prevent secondary brain damage by controlling clinical parameters.

Diagnostic criteria and classification

Assessment and classification of TBI is primarily guided by the Glasgow Coma Score (GCS) (Teasdale & Jennett, 1974). The minimum possible GCS is 3 and the maximum is 15; severity of TBI is classified as severe (GCS 3–8), moderate (GCS 9–12) or mild (GCS 13–15).

Morbidity and mortality

Mortality rates from TBI have not been thoroughly researched in the UK. A systematic review by Tagliaferri *et al.* (2005) proposed an average mortality rate of 15 per 100 000 per year from TBI across Europe. Thornhill *et al.* (2000) reported that 38% of patients with severe head injury were deceased or vegetative at 1 year post injury. Morbidity varies considerably between patients, although long term effects are extensive and persistent (Tagliaferri *et al.*, 2005). Thornhill *et al.* (2000) found that 29% of patients with severe head injury had a severe disability and 19% had a moderate disability at 1 year post injury. One study found that 34% of patients reported difficulties subsequent to their injury and 11% were medically unfit for employment (McCartan *et al.*, 2008). Consequences may include memory problems, physical disability and neuropsychological difficulties.

Clinical investigation and management

Initial priorities include resuscitation and pain management, as pain can lead to a rise in intracranial pressure. Early imaging is also a priority, as this will ensure detection of complications, leading to better outcomes. Computed tomography imaging of the head forms the primary investigation to detect brain injuries. Neurosurgery may also be required depending on the nature of the injury. The medications frequently used in TBI and relevant nutritional considerations are collated in Table 7.17.9.

Multidisciplinary approach

It is essential that patients with TBI are treated by a multidisciplinary team (MDT). Table 7.17.10 describes the dietetic role within the MDT. Some rehabilitation units may include art and music therapists. The specialist MDT facilitates improvements in patient outcomes (Turner-Stokes *et al.*, 2011).

Nutritional consequences

Metabolic response to traumatic brain injury

Traumatic brain injury may cause an abnormal regulation of nervous, endocrine and inflammatory systems in order to enable a continuous supply of substrates for cell growth and repair (Agha *et al.*, 2004a; Ghirnikar *et al.*, 1997). These changes may be caused by a metabolic response to stress and by direct injury to the brain, the major organ responsible for regulation and homeostasis. Possible alterations in regulatory systems include:

Table 7.17.9 Medications used in traumatic brain injury that affect nutritional status

Use	Examples	Effect on nutritional status/treatment
Sedative – to manage raised ICP	Propofol	Causes reduced activity levels and suppression of cerebral metabolism, leading to reduced energy expenditure Propofol is formulated in 10% lipid emulsion, which provides 4.6 kJ/mL (1.1 kcal/mL). NB: Consider when calculating energy intake High dose and use for >48 hours may cause metabolic acidosis, hyperlipidaemia and hyperkalaemia
	Midazolam	Reduced activity levels leading to reduced energy expenditure
Barbiturate – to manage raised ICP	Pentobarbital Thiopental sodium	May reduce metabolic rate to 80% of BMR (Gross <i>et al.</i> , 2010)
Analgesia – to manage pain and potentiate effects of sedatives	Morphine	Long term analgesia may lead to constipation. Review fluid and fibre intake and consider laxatives
	Fentanyl	
	Alfentanil	
	Remifentanil	
Intracranial hypertension treatment – reduces cerebral oedema and ICP	Mannitol	Osmotic effect can cause polyuria, leading to fluid and electrolyte loss. Monitor fluid balance to assess hydration and electrolyte levels. Liaise with the medical team to assess fluid requirement in line with medical treatment and correct electrolyte imbalance if necessary
	Hypertonic saline Solution	May increase serum osmolality and lead to acid–base abnormalities (Gross <i>et al.</i> , 2010). Hyponatraemia may occur
Anticonvulsants	Sodium valproate	Consider vitamin D supplementation as long term use of antiepileptic drugs is associated with reduced bone mineral density
	Carbamazepine	Consider vitamin D supplementation in patients who are immobilised for long periods or who have inadequate sun exposure or dietary intake of calcium. May precipitate when administered with enteral nutrition and withholding EN pre and post administration will reduce this (Gross <i>et al.</i> , 2010)
	Phenobarbital	Consider vitamin D supplementation
	Topiramate Phenytoin	Ensure adequate hydration to reduce the risk of nephrolithiasis Consider vitamin D supplementation. Absorption is reduced when administered with enteral nutrition and therefore withholding enteral nutrition for 2 hours post and pre phenytoin administration is advised (Gross <i>et al.</i> , 2010)
Musculoskeletal and skeletal muscle relaxants	Baclofen	Gastrointestinal disturbances
Thyroid hormones	Levothyroxine	Give at least 2 hours apart from iron supplementation as levothyroxine sodium reduces absorption of oral iron
Prokinetics	Erythromycin	May be more effective than metoclopramide at improving feed tolerance (AANN, 2009)
	Metoclopramide	May help to improve feed tolerance but evidence is not convincing (AANN, 2009)

ICP, intracranial pressure, BMR, basal metabolic rate.

- Increased production of proinflammatory cytokines tumour necrosis factor alpha (TNF α), interleukin 1 (IL-1) and IL-6 (Charrueau *et al.*, 2009).
- Increased circulation of the counter regulatory hormones cortisol, glucagon and catecholamines (Vizzinni & Aranda-Michel, 2011).
- Production of acute phase proteins from the liver (Charrueau *et al.*, 2009).
- Increased cardiac output and hypertension, leading to elevated CO₂ production and O₂ consumption (Vizzinni & Aranda-Michel, 2011).

The subsequent effects on metabolic processes are shown in Figure 7.17.1.

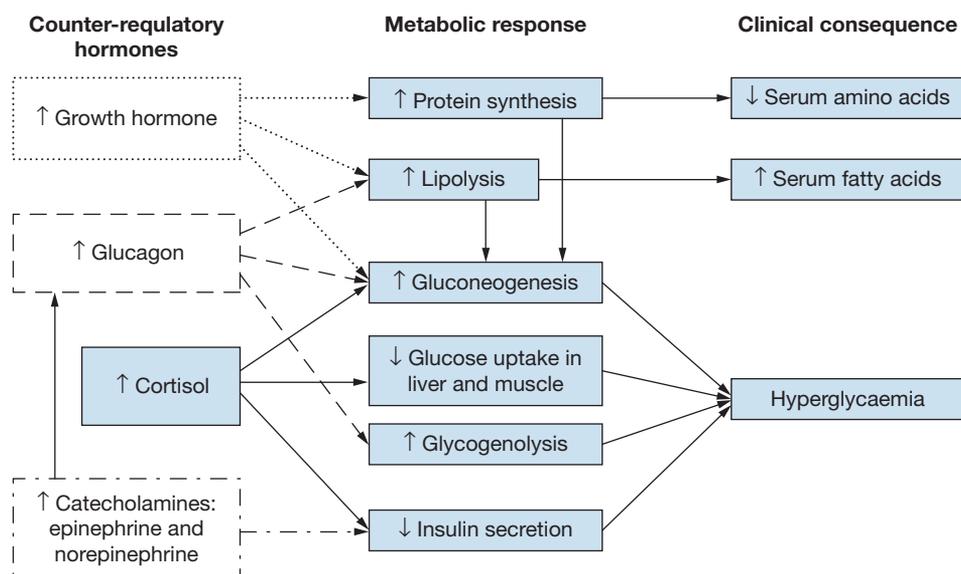

Energy expenditure

Frequency of severe hypermetabolism in TBI ranges from 31% to 57% within 72 hours post injury (Ott *et al.*, 1994; Raurich & Ibanez, 1994). Foley *et al.* (2008) reported that hypermetabolism continues for 30 days post injury; however, there is a lack of evidence examining measured energy expenditure (MEE) for longer than this period. Hypermetabolism is defined as the ratio of MEE to predicted energy expenditure (PEE), and can be expressed as a percentage of the PEE (Krakau *et al.*, 2007):

- Hypometabolism <0.9 (90%).
- Hypermetabolism 1.1 (110%).
- Severe hypermetabolism 1.3 (130%).

Table 7.17.10 Link between the dietitian and other members of the multidisciplinary team (MDT)

MDT member	Liaise with dietitian regarding
Speech and language therapist	Method of communication Texture modification in dysphagia Joint sessions with patient to aid communication and understanding
Physiotherapist	Weaning and decannulation of tracheostomy tube and progression to oral feeding. Activity/mobility to assess energy requirements Positioning regarding potential impact on feeding and safety of delivery Possible member of the team who can weigh when hoisting patient
Occupational therapist	Functional ability to self feed Identification of issues such as hemineglect Practicalities of shopping, preparing and making meals Encouraging appropriate food shopping and cooking specific to the patient's nutritional needs
Nursing staff	Nutritional screening and regular monitoring Issues with feeding regimen practicalities Issues with gastrointestinal intolerances Dietary intake issues/progress Family concerns and comments Special diet awareness training
Psychologist	Regarding mood and behaviour and effect on nutritional intake
Doctor	Diagnosis, treatment and prognosis Discharge planning Safe enteral feeding tube removal date
Pharmacist	Medication and relevant drug–nutrient interactions Medications given via enteral feeding tubes Medications with gastrointestinal side effects Medications that affect appetite and weight
Coordinator/keyworker	Discharge planning – can provide information on transfer/discharge destination May need to transfer to another acute, community or home enteral feeding dietitian Carer training regarding special diets and/or enteral tube feeding Recommendations for monitoring of nutritional status and feeding Liaison with GP of dietary needs and any supplement prescriptions

**Figure 7.17.1** Metabolic response to traumatic brain injury

The degree of hypermetabolism is believed to be proportional to the severity of head injury (Fruin *et al.*, 1986). A systematic review (Foley *et al.*, 2008) found that mean percentage of PEE ranged from 116% to 200% up to 7 days post injury in patients without sedation, paralysis or barbiturate induced coma (Raurich & Ibanez, 1994; Haider *et al.*, 1975), whereas patients with barbiturate induced coma, sedation or induced paralysis had a mean percentage of PEE of 80–123%. Coma reduces metabolism, whereas paralysis reduces motor activity, leading to a reduced energy requirement (Clifton *et al.*, 1984; Dempsey *et al.*, 1985; Bruder *et al.*, 1998). Other factors that may affect energy expenditure include:

- Morphine – may reduce energy expenditure by 8% (Raurich & Ibanez, 1994).
- Controlled mechanical ventilation – may reduce energy expenditure by 4–25% due to a reduction in motor activity (Lewis *et al.*, 1988; Bursztein *et al.*, 1978).
- Weaning from mechanical ventilation – may cause an increase in energy expenditure for a limited period (Bruder *et al.*, 1991).

In addition, some symptoms may affect energy expenditure, including pyrexia, which can increase energy expenditure by 13%/°C (Bruder *et al.*, 1998), muscle contractions and autonomic storming, a dramatic increase in activity of the sympathetic nervous system. Autonomic storming describes the consequences TBI can have on the sympathetic and parasympathetic (autonomic) nervous system. It results in a hyper stress response that can affect a number of processes, including regulation of digestion, perspiration, breathing, temperature and heart rate. Dietary induced thermogenesis and the use of steroids are unlikely to directly affect energy expenditure (Foley *et al.*, 2008).

Catabolism

Catabolism is observed in the majority of patients with TBI during the first 2 weeks post injury and nitrogen excretion is elevated (Krakau *et al.*, 2007; Young *et al.*, 1988; Clifton *et al.*, 1984). The severity of catabolism is reported as varying from a negative nitrogen balance of –3 to –16g/day (Krakau *et al.*, 2007), although nitrogen losses have been reported to be as high as 30g/day. This level of protein breakdown can cause a 10% loss of lean body mass within 7 days post injury, increasing to a 10–29% loss of total body mass within 2 months (Rajpal & Johnston, 2009; Krakau *et al.*, 2007).

Hyperglycaemia

Hyperglycaemia is frequently observed in the head injured patient as cells become insulin resistant to ensure glucose provision for brain functioning and to mobilise substrates for defence and repair. Hyperglycaemia occurs as a result of circulating counter regulatory hormones, which are released in response to trauma and cause an increase in gluconeogenesis despite persistent hyperglycaemia (Figure 7.17.1). Blood glucose levels above 11 mmol/L in the first 24 hours post TBI have been associated with poorer outcomes, including increased mortality, lower

GCS at day 5 post injury and increased length of hospital stay (Jeremitsky *et al.*, 2005; Vizzinni & Aranda-Michel, 2011). Intensive insulin therapy is an integral part of acute traumatic brain injury management. The dietitian plays a key role in monitoring and assessing the potential impact of feeding on glycaemic control and aims to avoid overfeeding that may exacerbate hyperglycaemia.

Gastroparesis and gut dysfunction

Gastroparesis is frequently reported in patients with head injury; with one study reporting delayed gastric emptying in 80% of patients (Kao *et al.*, 1998). The cause of gut dysfunction remains unclear, but theories include a possible suppression of vagal nerve activity caused by an increased intracranial pressure, which leads to delayed gastric emptying; and alteration in brain gut peptides, including vasoactive intestinal peptide and cholecystikinin, which is associated with enterogastric reflex (Tan *et al.*, 2011). In addition, hyperglycaemia, disordered intestinal flora, inflammation, electrolyte disturbances and medication are associated with gut dysfunction (Tan *et al.*, 2011) (see Chapter 7.4.4).

Nutritional assessment

Nutritional assessment of the head injured patient can be complex, as nutritional status is affected by many factors (Table 7.17.11). Thorough and frequent monitoring is essential due to the potential for rapid changes in clinical condition. Monitoring is also important to assess feed tolerance, which can be an ongoing issue for this patient group.

Nutritional management

Nutritional requirements

Estimating nutritional requirements in this patient group is extremely difficult due to rapid changes in clinical condition and a wide range of complex symptoms that can dramatically affect energy requirements (see Chapter 6.1 and Chapter 7.17.1).

Energy

Indirect calorimetry is considered the gold standard method of measuring energy requirement. However, this may not be realistic in practice due to cost and time implications. In practice, all factors contributing to fluctuations in energy requirement should be considered to estimate energy requirements for individual patients. Schofield or Harris–Benedict equations are frequently used to predict energy requirements, with an addition of 0–30% in the acute phase (Bruder *et al.*, 1991; Weekes & Elia, 1996). More recently, the Scientific Advisory Committee on Nutrition recommended the use of the Henry equations (2005). The key to establishing whether estimated requirements are accurate is to monitor weight changes or changes in body composition, amending the feeding regimen as appropriate. Overfeeding is associated

Table 7.17.11 Assessment and monitoring of nutritional status in the brain injured patient

Parameter	Relevance to dietetic practice	
Biochemistry	Urea and electrolytes	Assess hydration status and potential effects of refeeding May indicate the need for a low sodium feed or fluid restriction
	White blood cells and C-reactive protein	Raised levels can indicate infection \pm inflammation A stress factor should be added to BMR; energy and protein requirements will be increased
	Glucose	Hyperglycaemia may occur as a result of metabolic stress or overfeeding, and may be a side effect of chronic steroid use Hypoglycaemia may occur with suboptimal feeding/nutritional intake alongside intensive insulin therapy
Anthropometry	Anthropometry is useful to measure outcomes in nutritional goals Obtain a baseline measurement on admission, monitor regularly and on transfer/discharge	
	Weight	Influences nutritional requirements If applicable, calculate weight loss percentage and highlight any significant risks Rapid weight gain/loss over 1–2 days can indicate oedema or fluid losses
	Body mass index	To assess and monitor nutritional status To formulate nutritional goals, e.g. weight gain, stability or reduction
	Triceps skin fold	Use with caution in hemineglect patients as muscle loss may not be directly attributable to nutrition
	Waist circumference	Used in rehabilitation to assess central adiposity and monitor changes
Gastrointestinal tolerance	Constipation	Sedation, paralysis and analgesia may result in reduction in bowel activity. A proactive approach to aperients therapy is required Review the fibre and fluid content of the feeding regimen
	Diarrhoea	Inappropriate continuation/overuse of laxatives and/or other medications, e.g. antibiotic therapy, may result in frequent and/or loose stools. A side effect of traumatic brain injury on the parasympathetic nervous system Consider increasing fibre in the feeding regimen
	Vomiting/reflux	Increased risk of dehydration Reducing the rate of feeding or bolus sizes and choosing a lower fibre feed may improve symptoms
	Bloating	Review medications and the use of antiemetics Review the fibre content, total volume of feed and fluid Consider bolus feeding versus continuous feeding
	Suspected infection Gastric aspirates	Stool samples should be analysed alongside a medicine review Large residual volumes can be observed in the acute stage due to reduced gastric emptying. Prokinetics and/or proton pump inhibitors may be beneficial
Fluid balance	Hyperhydration Dehydration	Consider fluid used with drug administration when calculating fluid balance Consider diuretics and other drugs that may cause polyuria Tracheostomy patients may have a higher fluid requirement due to tracheostomy secretions. Consider volume, frequency and viscosity of secretions in order to replace fluid losses
	Regulatory hormone disturbances	Monitor for perspiration (duration and frequency) in order to replace fluid losses Diabetes insipidus, cerebral salt wasting (CSW) and syndrome of inappropriate antidiuretic hormone secretion (SIADH) Liaise with medical colleagues with regards to therapeutic fluid management plans. (see Table 7.17.12)
Medication	Drug–nutrient interactions, nausea, vomiting, diarrhoea, weight gain and loss can be common side effects (see Table 7.17.9)	
Body temperature	Can fluctuate due to potential hypothalamus dysfunction Pyrexia may indicate the presence of infection or sepsis, which can affect energy expenditure and fluid requirements	
Dietary intake	Increased requirements	Oral intake is likely to be insufficient without significant nutrition support. Thorough assessment of oral intake is paramount
	Respiratory infections	Recurrent infections may indicate aspiration of oral intake
	Sunlight exposure	In rehabilitation units, the patient may be at risk of reduced sunlight exposure Advise a diet high in vitamin D \pm supplementation
Nutritional status prior to injury	Individuals, who overuse alcohol, are elderly or have coexisting medical conditions may be at increased risk of malnutrition Previous weight can help in formulating a patient specific weight goal in rehabilitation	
Skin integrity	Long periods of immobility can increase the risk of pressure sores Regular positional changes, hygiene care and nutrition can help to minimise this risk	

with poorer outcomes, including prolonged ventilator dependency as a result of excessive carbon dioxide production; hyperglycaemia; metabolic acidosis; and impaired liver function (Griffiths, 2007).

Protein

Protein requirements for patients with TBI are controversial. Twyman *et al.* (1985) found that providing 2.2 g of protein/kg/day resulted in a positive nitrogen balance (9.9 g of nitrogen retained over 10 days), even though nitrogen losses were high compared with the control group who received 1.5 g of protein/kg/day and had a negative nitrogen balance (−31.2 g of nitrogen retained over the same period). However, this level of protein provision is not realistic in practice and lean tissue loss may be unavoidable in patients with TBI regardless of nutritional intervention (Hoffer, 2003). In addition, sufficient energy is required to maximise nitrogen retention and utilisation. Provision of high protein levels to meet requirements without adequate energy leads to an increased nitrogen loss (Hoffer, 2003). Caution is necessary to avoid excessive energy intake when aiming to meet elevated protein requirements as this may lead to the potentially detrimental effects of overfeeding. Minimising obligatory losses in lean body mass is a primary aim. The Brain Trauma Foundation (2007) recommends that protein should provide 15–20% of calories and evidence suggests that there may be little benefit in providing protein in excess of 1.5 g/kg/day for trauma patients (Hoffer, 2003).

Micronutrients

Dietary reference values (Department of Health, 1991) should be met; however, there are some amendments for specific nutrients in TBI in the critically ill (Vizzinni & Aranda-Michel, 2011) (see Chapter 17.7.1). Patients with TBI have increased urinary zinc excretion as well as a reduced serum zinc concentration (McClain *et al.*, 1986). Young *et al.* (1996) reported an improved GCS and visceral protein level in a zinc supplemented group of TBI patients. A recent study found that supplementation of zinc sulphate for 2 weeks led to a reduction in C-reactive protein (a marker of inflammation); however, there was no significant effect on GCS score (Meshkini *et al.*, 2009).

Fluid and electrolytes

Fluid and electrolyte levels may be depleted in acute TBI patients. In addition, nutritional intervention may be delayed post injury and therefore electrolytes should be monitored closely and promptly corrected if there is risk of refeeding syndrome. Drugs such as mannitol can cause fluid loss through polyuria and subsequent hypomagnesaemia, hypokalaemia and hypophosphataemia (Polderman *et al.*, 2001). Polderman *et al.* (2001) found that induced hypothermia via use of water circulating blankets was associated with severe electrolyte depletion as a result of increased urinary excretion during the cooling phase. In addition, damage to the brain can cause changes in regulatory systems, resulting in neurohypophysial dysfunction in some patients. The resulting conditions are:

Table 7.17.12 Diagnostic criteria of cerebral salt wasting syndrome (CSWS) and syndrome of inappropriate antidiuretic hormone secretion (SIADH) (Cerdeira-Esteve *et al.*, 2008; Zafonte & Mann, 1997)

Parameter	CSWS	SIADH
Plasma volume	↓	↑ or normal
Salt balance	Negative	Variable
Water balance	Negative	↑ or normal
Signs and symptoms of dehydration	Present	Absent
Serum osmolality	↓	↓
Urine sodium	↑↑	↑
Urine volume	↑↑	↓ or normal
Serum potassium	↑ or normal	↓ or normal
Blood urea nitrogen	↑	Normal
Uric acid	Normal	↓
Weight	↑	↓
Treatment	Normal saline, hypertonic saline, fludrocortisone	Fluid restriction, hypertonic saline, democycline, furosemide

- *Diabetes insipidus (DI)* – can be caused by an insufficient secretion of vasopressin. Symptoms are polyuria and polydipsia; polyuria can lead to hypernatraemia (Tisdall *et al.*, 2006). A low sodium feed may be required.
- *Syndrome of inappropriate antidiuretic hormone secretion (SIADH)* – can be caused by an excessive secretion of the antidiuretic hormone vasopressin. Symptoms are reduced urine output, hyponatraemia presenting within 2–18 days post injury (Behan *et al.*, 2007) and, possibly, fluid overload. Fluid restriction and additional sodium may be necessary (Table 7.17.12).

Cerebral salt wasting syndrome (CSWS) is a rare endocrine condition secondary to TBI. Symptoms are polyuria, polydipsia and a strong desire for salt. This is in response to hyponatraemia due to renal loss of sodium (Cerdeira-Esteve *et al.*, 2008). The aetiology is not certain; however, reports suggest that neural activity on renal tubular function may be responsible (Zafonte & Mann, 1997). Treatment tends to be increased fluids and salt replacement using intravenous infusion or sodium chloride tablets (Table 7.17.12).

Nutritional support

There is a paucity of research examining the effects of nutritional support in TBI patients and the limited research that is available has not provided conclusive evidence.

Enteral feeding

Enteral feeding is the preferred route in head injured patients as it maintains the integrity of the intestinal

mucosa and is also cheaper (see Chapter 6.4). Feeding into the stomach is the first line approach; this is generally via a nasogastric tube. Orogastric tubes are often placed when there is a (suspected) base of skull fracture.

Post pyloric feeding

Jejunal feeding may provide better outcomes in patients who cannot tolerate gastric feeding (Kreymann *et al.*, 2006). The Sussex Critical Care Network (2009) recommends nasojejunal feeding if feed is not absorbed by day 4 of nasogastric feeding and after the use of prokinetic therapy. However, local policies regarding post pyloric feeding and prokinetic therapy may vary. Jejunal feeding has been associated with lower rates of pneumonia (Kreymann *et al.*, 2006; Acosta-Escribano *et al.*, 2010). A nutrition support team with input from a doctor, nutrition nurse, biochemist, pharmacist and dietitian is essential to ensure that an appropriate decision is made to feed post pylorically as this may further delay feeding if unsuccessful.

Parenteral feeding

Parenteral feeding is indicated if the gastrointestinal tract is not functioning and the patient cannot be fed sufficiently by enteral feeding (Kreymann *et al.*, 2006) (see Chapter 6.5).

A Cochrane review (Perel *et al.*, 2006) found that parenteral nutrition (PN) was associated with better outcomes; however, this may have been as a result of earlier initiation of feeding rather than PN itself. This review also reported a trend towards increased incidence of infection in parenteral feeding when compared with enteral feeding, and also an association with hyperglycaemia (Kreymann *et al.*, 2006). Conversely, PN was associated with lower rates of pneumonia.

Initiation of feeding

A number of guidelines recommend initiation of feeding within 24–48 hours of TBI as the evidence suggests that early nutritional intervention is associated with better outcomes (Kreymann *et al.*, 2006; Doig *et al.*, 2009). However, feeding is often not initiated for >48 hours in 60% of patients on the ICU despite the well documented benefit of early intervention (Doig *et al.*, 2008). A Cochrane review (Perel *et al.*, 2006) found that earlier initiation of nutritional support resulted in improved survival and reduced disability. Furthermore, a meta analysis examining initiation of enteral nutrition (EN) within 24 hours found that earlier feeding resulted in a significant reduction in mortality and pneumonia (Doig *et al.*, 2009). The American Brain Trauma Foundation (2007) suggests that brain injured patients should meet full nutritional requirements by day 7 post injury.

Rehabilitation

In rehabilitation, the overarching aim is to help patients regain their functional independence, which may take from many months to several years. Specialist head injury

rehabilitation units offer high intensity rehabilitation that provides earlier physical and cognitive functional gains (Turner-Stokes *et al.*, 2011). This is often accompanied by slow stream rehabilitation in the community that is thought to maintain the progress made in post acute rehabilitation. Multidisciplinary treatment focuses on physical, cognitive and behavioural rehabilitation, and psychosocial, vocational and recreational therapy and counselling.

Nutritional considerations

As in the acute phase of TBI, the brain injury will dominate the body's central and autonomic nervous system. The clinical parameters to consider for patients at nutritional risk are listed in Table 7.17.7. Where a nutrient requirement has not been identified as been altered, the dietary reference values are accepted (Department of Health, 1991).

There can be a marked increase in weight in TBI rehabilitation, possibly due to changes in energy requirements and altered eating behaviours. McEvoy *et al.* (2009) described 25% of rehabilitation patients as being hypermetabolic and 25% being hypometabolic. The mechanisms for hypermetabolism and weight loss are as discussed in the acute phase. Weight gain secondary to a reduction in metabolic rate is likely to be multifactorial including:

- Loss of lean body mass in the acute stage leads to decreased basal metabolic rate (McEvoy *et al.*, 2009).
- Less physically activity than normal population (Patratoon-Ho *et al.*, 2005).
- Hypothalamopituitary dysfunction (Medic-Stojanoska *et al.*, 2007; Popovic, 2005) is found in 27.5–50.9% of TBI rehabilitation patients (Schneider *et al.*, 2007; Tanriverdi *et al.*, 2006; Agha *et al.*, 2004b).
- Loss of neuronal integrity (Shiga *et al.*, 2006).

Overweight and obesity have been observed by a number of researchers and experts (Greenwood, 2002; Voevodin & Haala, 2007). However, a pilot study by French & Merriman (1999) showed that obesity rates were similar to those for the normal population. In the TBI rehabilitation population, appropriate energy restriction is essential to minimise unnecessary weight gain. However, there is limited strong evidence for energy requirements in TBI rehabilitation (McEvoy *et al.*, 2009), which suggests that regular holistic assessment by a dietitian to formulate the appropriate care plan is essential.

Dysphagia and enteral nutrition

Gastrostomy tube feeding is recommended as the optimal form of feeding in rehabilitation if tolerated (Cook *et al.*, 2008–2009). In addition to the recommendations in Chapter 7.6.6 regarding enteral tube feeding, Table 7.17.7 shows the nutrition related issues within TBI rehabilitation to consider when assessing nutritional status. Designing a feeding regimen around therapy input, meeting nutritional requirements and managing any gastrointestinal intolerance issues can be complex. A good knowledge

of commercially available feeds and the patient's therapy timetable combined with effective communication skills to involve the patient in decision making where possible are paramount in creating an optimum feeding regimen.

Dysphagia and oral nutrition

Approximately 40% of patients on admission are dysphagic, decreasing to 0.4% after 1 year in rehabilitation (Brown *et al.*, 2007). The complexity of regaining a safe swallow in head injury patients is affected by their cognitive, behavioural and communication related impairments (Cherney & Halper, 1996). A multidisciplinary approach facilitates the rehabilitation of dysphagia. The transition from enteral to oral diet has three defined stages:

- Enteral feeding only with regular swallow assessment by a specialist speech and language therapist (SLT).
- Enteral tube feeding and oral texture modified diet (TMD) as recommended by the SLT.
- TMD with nutritional supplementation or food fortification.

Regular formal assessment of oral intake to assess adequacy of energy and protein intakes is necessary (Rajpal & Johnston, 2009) (see Chapter 7.3). The enteral tube feed should then be reduced accordingly to ensure that enteral feeding plus oral intake meets the total estimated nutritional requirements. Oral intake tends to increase as swallow function improves and strengthens. More information on the enteral to oral transition period is given in Chapter 7.6.6. Dietetic intervention should maximise oral intake safely and minimise unnecessary weight gain.

Patients can accidentally remove or dislodge feeding tubes if agitated or confused. Also the feeding tube may be removed prematurely if dysphagia is seen to have improved, causing problems with receiving vital medication, adequate nutrition and hydration. It may be necessary to intervene if requirements cannot be met orally and with supplementation.

Eating behaviour

The senses of taste and smell can be distorted in occipital or frontal injuries (Greenwood, 2002). Advice on choosing foods to compensate for anosmia (loss of smell) and ageusia (loss of taste) should be provided (see Chapter 7.15.1). Visual problems can also result in changes in eating behaviour. Ensuring meals, snacks and drinks are presented in an appropriate manner, and prompting when necessary, can improve nutritional intake.

Disinhibition is another common consequence of frontal lobe damage in TBI (Oder *et al.*, 1992). This has a marked effect on a patient's behaviour and this can be very different from their preinjury persona. The following are common signs of disinhibition (Walker & Wickes 2005):

- Short attention span.
- Fatigue.
- Frustration and irritability.
- Inflexibility and argumentativeness.

- Reduced initiative.
- Impulsiveness.
- Socially and sexually inappropriate behaviour.
- Difficulty forming relationships.

Disinhibition can have nutritional consequences such as weight gain or loss and difficulties with compliance to dietetic advice. Kluver–Bucy syndrome is a rare neurobehaviour syndrome associated with TBI and exists when there is damage to both anterior temporal lobes of the brain (National Institutes of Health, 2008). A nutritional consequence is hyperphagia, which can potentially increase body weight. For both disinhibition and Kluver–Bucy syndrome, dietetic input should focus on managing portion size, choosing a balanced diet, and patient and carer education on the health benefits of a balanced diet.

Conclusion

Traumatic brain injury can have lasting and profound effects on the patient's physical and cognitive functioning. Providing adequate and safe nutritional support early post injury has been shown to promote better outcomes in recovery. Close monitoring of anthropometry, biochemistry, clinical and dietary aspects throughout the acute and rehabilitation stage will help to ensure the patient receives timely and apt adjustments in nutritional care.

7.17.3 Spinal cord injury

Anthony Twist and Samford Wong

Key points

- Energy expenditure in the acute post injury period is reduced; care is needed to avoid overfeeding.
- Protein requirements may be high.
- A reduction in energy expenditure during rehabilitation increases the risk of excessive weight gain.
- Neurogenic bowel dysfunction may require dietary fibre intake adjustment.
- There is a high risk of pressure ulcers; therefore, nutritionally balanced diets are essential.

There are approximately 40 000 people living in the UK with spinal cord injuries (SCIs) (Spinal Injuries Association, 2009), with an incidence of approximately 8–12 cases per million population. In 2001 (the most recent year for which figures are available), 744 people experi-

enced spinal pathology sufficiently serious to require admission to a spinal unit in the UK or Ireland. The most common causes of SCI were falls and road traffic accidents (Table 7.17.13). Other injuries such as head and chest injury often coexist and may complicate management and

Table 7.17.13 Causes of spinal pathology in the UK and Ireland in people admitted to spinal cord injury centres in 2001 [from Inman, the British Association of Spinal Cord Injury Specialists (BASCIIS)]

Cause of injury	Number	%
Trauma		
Road traffic accidents	230	39.0

<i>Total non-trauma</i>	<i>155</i>	<i>100</i>

rehabilitation. The UK has eleven SCI centres, which have a total of 458 beds for the rehabilitation of people with a SCI. The first UK SCI centre was opened in Stoke Mandeville in 1944.

The metabolic response to injury is well documented (see Chapter 7.17.1) and the prevalence of malnutrition and its effects on the person with SCI have been recognised since the time of Hippocrates (Guttmann, 1973). Prior to World War II, few people with SCI survived more than 2 years. Today long term survival is normal and the mean age for sustaining a SCI appears to be increasing. For example, the Northern General Hospital, Sheffield's SCI centre showed a rise in mean age for new admissions from 32 years in 2007/8 to 48 years in 2009/10 (personal communication).

As with anyone suffering acute injury necessitating subsequent rehabilitation, dietetic care should be an integral

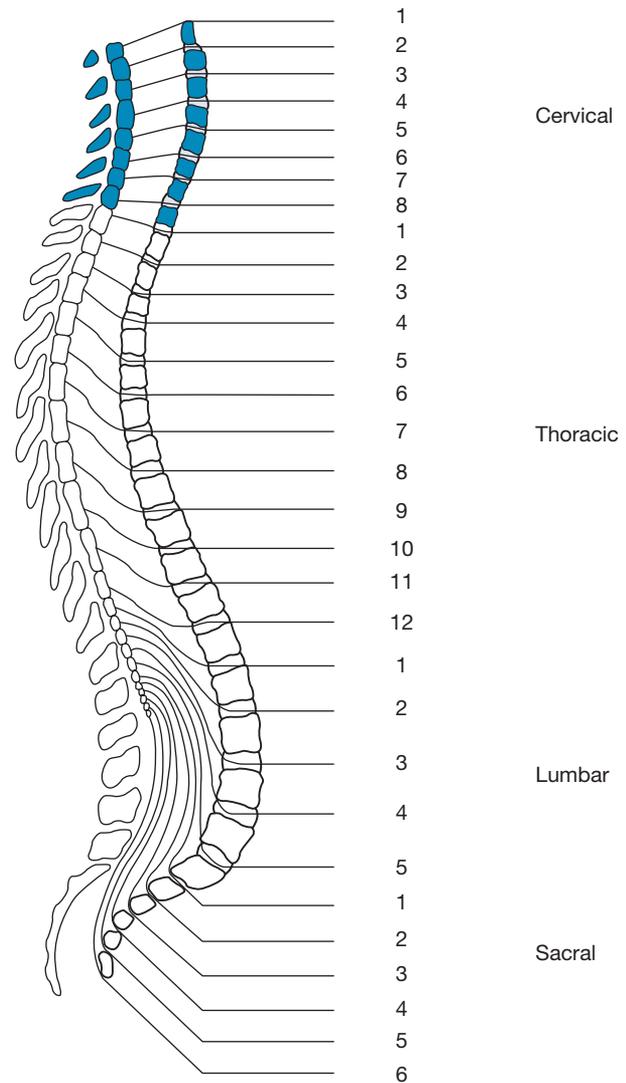

Figure 7.17.2 The spinal cord

part of management. Dietetic provision in UK spinal injury centres is very variable, ranging from 7.5 to 31 hours/week (Wong *et al.*, 2012a). The level of experience of the dietitians is also variable, with some units employing specialist dietitians (NHS band 8a) and others using relatively less experienced staff (NHS band 5).

Definitions

The effects of a SCI depends on which segments of the spinal cord are damaged (Figure 7.17.2). The American Spinal Injury Association Impairment Scale (ASIA, 2002) focuses on 10 key muscles and 10 key sensory points to be tested during neurological assessment. Figure 7.17.3 shows the likely consequences of SCI on both motor and sensory dermatomes (areas of skin supplied with afferent nerve fibres by a single posterior spinal root) as defined by the International Spinal Cord Society (ISCOS, 2006). These consequences may include:

REV 04/11

Figure 7.17.3 International standards for neurological classification of spinal cord injury (source: International Standards for Neurological Classification of Spinal Cord Injury 2013. Reproduced with permission of the American Spinal Injury Association)

- **Complete and incomplete lesions:**
 - In a complete lesion, all neurological function is lost below the level of the lesion.
 - In an incomplete lesion, there is partial preservation of neurological function and any combination of motor (muscle), sensory (feeling) or autonomic function may be spared (nerves of the autonomic system control those body functions, which are not under conscious control).
 - Brown-Séquard syndrome or central cord syndrome describes different patterns of incomplete lesion, usually occurring as a result of neck injuries. These and other syndromes are described in the ABC of Spinal Cord Injury (see Further reading).
- **Paraplegia** – function of the lower limbs is lost as a result of damage to the thoracic, lumbar or, to a lesser extent, sacral cord segments.
- **Tetraplegia (quadriplegia)** – this results from damage to cervical cord segments causing loss of function in all four limbs.
- In both paraplegia and tetraplegia there is impairment of autonomic function, including bladder and bowel control.
- **Muscle wasting** – post injury this results in a reduction of lean body mass and, in the longer term, immobility encourages an increase in total body fat (Shizgal *et al.*, 1986; Rasmann Nuhlicek *et al.*, 1988; Spungen *et al.*, 2003).
- **Autonomic dysreflexia (AD)** – people with SCI above the T6 level (thoracic vertebra) can experience AD. It is a group of abnormal signs and symptoms triggered by a noxious stimulus below the level of the lesion that causes an increase in autonomic activity (Consortium for Spinal Cord Medicine, 2008). It is characterised by a sudden, severe headache secondary to an uncontrolled elevation of blood pressure, flushing and profuse sweating. If untreated, the hypertension may progress to fatal complications, such as cerebral haemorrhage or acute myocardial infarction. The most common nutrition related stimuli are an over

Muscle Function Grading

- 0 = total paralysis
- 1 = palpable or visible contraction
- 2 = active movement, full range of motion (ROM) with gravity eliminated
- 3 = active movement, full ROM against gravity
- 4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position.
- 5 = (normal) active movement, full ROM against gravity and full resistance in a muscle specific position expected from an otherwise unimpaired person.
- 5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present.

NT = not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of >50% of the range of motion).

ASIA Impairment (AIS) Scale

- A = Complete.** No sensory or motor function is preserved in the sacral segments S4-S5.
- B = Sensory Incomplete.** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5 (light touch, pin prick at S4-S5; or deep anal pressure (DAP)), AND no motor function is preserved more than three levels below the motor level on either side of the body.
- C = Motor Incomplete.** Motor function is preserved below the neurological level**, and more than half of key muscle functions below the single neurological level of injury (NLI) have a muscle grade less than 3 (Grades 0-2).
- D = Motor Incomplete.** Motor function is preserved below the neurological level**, and at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3 .
- E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

**For an individual to receive a grade of C or D, i.e. motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The Standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

NOTE: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the **motor level** on each side is used; whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the **single neurological level** is used.

Steps in Classification

The following order is recommended in determining the classification of individuals with SCI.

- Determine sensory levels for right and left sides.
- Determine motor levels for right and left sides.
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.
- Determine the single neurological level.
This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
- Determine whether the injury is Complete or Incomplete. (i.e. absence or presence of sacral sparing)
If voluntary anal contraction = No AND all S4-5 sensory scores = 0 AND deep anal pressure = No, then injury is COMPLETE. Otherwise, injury is incomplete.

- Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete?

NO

Is injury motor **Incomplete?**

YES

Are at least half of the key muscles below the single neurological level graded 3 or better?

NO

AIS=C

YES

AIS=D

If sensation and motor function is normal in all segments, AIS=E

Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

Figure 7.17.3 (Continued)

distended bladder, bowel impaction, urinary infection and pressure ulcers.

Management

Initial post injury period (within the first week of injury)

Complex physiological changes occur following SCI and these vary with:

- Level of the lesion.
- ASIA scale or Frankel classification (extent of damage to the spinal cord).
- Presence of concomitant injury or illness.
- Time elapsed since injury.

These physiological changes result in a dynamic metabolic state that may adversely affect the nutritional status at any time (Worthington *et al.*, 1993). If left untreated, this catabolic state can lead to loss of lean muscle mass and poorer clinical outcomes, including impaired wound healing, and increased risk of infection, premature mortality and healthcare costs. The association between acute SCI and deterioration in nutritional status can persist for several months post injury (Marian, 2004).

The presence of delayed gastric emptying and paralytic ileus during this initial post injury period often preclude or complicate enteral feeding (see Chapter 7.17.1). Unfortunately, other priorities in clinical care may result in neglect of nutritional needs. Additionally, weighing the SCI individual is often difficult, as is interpretation of anthropometry. However, most people with SCI transferred from a general hospital to a spinal injury centre should have had at least a nutritional risk assessment by a validated nutrition screening tool, such as the Spinal Nutrition Screening Tool (SNST) (Wong *et al.*, 2012b) (see Appendix A11), in order to identify the need for further nutritional interventions; this assessment should have been repeated periodically unless transfer occurred very quickly.

Nutritional requirements

Energy requirements

The energy needs of SCI individuals are far from clear (Cox *et al.*, 1985; Kearns *et al.*, 1992; Peruzzi *et al.*, 1994; Rodriguez *et al.*, 1997; Barco *et al.*, 2002). However, in contrast to people with trauma or head injury, it appears that energy expenditure is reduced after SCI (Shedlock & Laventures, 1990; Buchholz & Pencharz, 2004). Patients with SCI have reduced metabolic activity

due to denervated muscle and actual energy needs are at least 10% below predicted needs [American Dietetic Association (ADA), 2009]. Indirect calorimetry (IC) is more accurate than estimation of energy needs, but in the absence of IC, interpreting predicted energy requirements with caution is recommended. This should avoid overfeeding, which can have adverse effects on glucose tolerance and lead to respiratory dysfunction due to excessive carbon dioxide production (EAST, 2003). Dietitians must exercise judgement and be alert to emerging research on energy requirements in SCI.

Iron

Anaemia is common in acute SCI even without visible blood losses (Huang *et al.*, 1990). Providing an adequate nutritional intake of iron is essential. Adequate vitamin C intakes help improve iron absorption from non-haem sources.

Vitamins

Laven *et al.* (1989) demonstrated deficiencies in a variety of vitamins, including vitamin C, folate and thiamine, which drop to their lowest level 2 weeks following injury and remain low for some weeks. They suggested full vitamin screens to ensure these deficiencies are recognised and rectified. Rice *et al.* (1995) recommended that a daily multivitamin should be given to all acute SCI individuals.

Subsequent post injury period (within the first 12 weeks following injury)

An SCI individual should be transferred as soon as possible to an SCI centre, where the importance of nutritional assessment, early identification of those at nutritional risk and appropriate nutritional support is being increasingly recognised (RCP, 2008; MASCIP, 2010). Dietitians who manage people with SCI need to understand the extent of their injuries (Figure 7.17.2) and acknowledge the profound psychological effects of these injuries. Whenever clinically possible, SCI individuals should be fed in a semi recumbent position; this may not be possible if they have not undergone spinal fixation. Consideration then needs to be given to options for safely feeding SCI individuals in a fully recumbent position.

Nutritional status is adversely affected by SCI, particularly during the first 2–4 weeks (Cheshire & Coats, 1969; Laven *et al.*, 1989), and nutritional depletion resulting from the initial metabolic response to trauma may be severe. Negative nitrogen balance after SCI is inevitable, correlating with the level and extent of injury, and may persist for as long as 7 weeks (Hadley, 2002). Protein needs are unclear but 2g of protein /kg/day is suggested (Kearns *et al.*, 1992; Peruzzi *et al.*, 1994; Marian 2004; ADA, 2009).

Gastrointestinal problems arise in both the acute and long term setting, with paralytic ileus and gastric ulcers commonly occurring during the first 4 weeks post injury, and lower tract dysfunction thereafter (Frost, 1998).

Table 7.17.14 Factors that may reduce dietary intake in spinal cord injury (SCI)

Category	Factors
Neurological	Extent of SCI Pain associated with SCI Surgical intervention of spinal cord
Psychological	Depression due to SCI Social isolation Confusion
Infections	Urinary tract Bladder Chest Catheter related Infected pressure ulcers
Drugs	Polypharmacy Nausea and vomiting Diarrhoea
Physical difficulties	Bed rest post SCI Refusal or reluctance to eat and drink Mechanical dysphagia due to ventilator
Respiratory	Chest infections Ventilating support Tracheostomy tube
Gastrointestinal	Neurological or mechanical dysphagia Paralytic ileus Nausea and vomiting Gastrointestinal bleeding; Diarrhoea or constipation Early satiety Abdominal injuries
Social	Recreational drug use Alcohol abuse Stress Lack of social support

Nutritional assessment

The prevalence of malnutrition is common amongst SCI individuals. A recent study of people admitted to UK SCI centres found that approximately 40% were at risk of undernutrition and 45% were overweight (Wong *et al.*, 2011a). Factors that are likely to reduce dietary intake are summarised in Table 7.17.14. Factors likely to increase nutritional requirements include:

- Associated injuries, e.g. long bone fractures and head injuries.
- Pressure ulcers.
- Fever, infection and sepsis.

Use of the disease specific nutrition screening tool

National and international reports (NICE, 2006; RCP, 2008; Council of Europe, 2003) have highlighted the importance of nutritional screening as an important step to address malnutrition. The SNS tool (see Appendix A11) has been developed for use in people with SCI and externally validated in this population (Wong *et al.*, 2012b). It is based on eight parameters:

- Body mass index (BMI).
- Age.

- Level of SCI.
- Presence of comorbidities.
- Skin conditions.
- Diet.
- Appetite.
- Ability to eat.

Assessing weight loss since injury

The degree of weight loss since SCI is an important indicator of nutritional depletion; most individuals will be able to recall their preinjury weight. Obtaining current weight can be difficult even if bed weighing scales are available. It is recommended that weight be taken on admission, and this repeated periodically for those identified to be at nutritional risk (NICE, 2006). In some cases, estimation of weight loss has to be done visually; however, it should be borne in mind that muscle wasting may have resulted from denervation following the SCI and bed rest rather than nutritional depletion.

Other assessments

Estimates of muscle mass from measurements such as mid arm muscle circumference are likely to be distorted by the effects of the SCI and any consequent paraplegia. Estimates of adiposity from BMI will be dependent on the ability to obtain a meaningful estimate of current body weight. While direct measurement of height is likely to be impossible, a reliable estimate of height can be estimated from ulna length measurements (see Appendix A7); knee height or ulna length should be acceptable. A 24-hour urine collection to measure urea nitrogen can be useful in determining protein status (Agarwal *et al.*, 1987). Bio-electrical impedance measurement is potentially useful, although hydration states can fluctuate in the acute period.

Current dietary intake

Although it is often possible to obtain estimates of previous and current dietary intake from the SCI individual, records of food and fluid intake and changes in appetite noted by care staff should also be taken into account. People with SCI appear to have a reduced dietary intake in SCI centres, but due to the enforced immobility, they may be meeting their energy requirement (personal communication).

Continuing rehabilitation phase (after 12 weeks post injury)

The aim of rehabilitation is to enable the individual to develop the maximum potential possible for their disability (Chapter 7.6.6). For the person who has lost weight during the immediate post injury period, weight regain and restoration of muscle mass are a priority so that the person is able to derive maximum benefit from physiotherapy and occupational therapy sessions. Where normal food intake is insufficient, additional nutritious snacks and prescribed oral nutritional supplements may be required. Reduction in energy needs is proportional to the amount of denervated muscle a SCI individual has.

Table 7.17.15 Guide to weighing individuals with spinal cord injuries

Degree of mobility	Suitable weighing method
Fully mobile SCI individuals	
Good balance	Standing scales
Poor balance	Sit down scales
Wheelchair dependent	
Able to transfer and can hold legs free from the floor	Sit down scales
Unable/inconvenient to transfer from wheelchair	Wheelchair weighing scales
Able to transfer but cannot hold legs free from the chair	Weighbridge Wheelchair weighing scales Weighbridge
On bed or trolley and can be lifted by hoist	Hoist scale with sling or stretcher attachment
Bed bound and bed not easily moved	Weighbridge
Bed bound, bed cannot be moved	Bed with weighing device Portable bed weighing scales

Manufacturers of this equipment are given at the end of this chapter.

The ADA (2009) suggested using 22 kcal/kg of body weight for those with quadriplegia and 28 kcal/kg for those with paraplegia to estimate (with caution) energy needs. If individuals are unable to meet their nutritional needs by oral intake alone, overnight enteral feeding may be a useful method of nutritional support, as this strategy does not interfere with daytime therapy sessions (see Chapter 6.4).

At this rehabilitation stage it is usually easier to measure and monitor SCI individuals than in earlier stages; Table 7.17.15 lists methods of weighing. However, due to the associated muscle wasting, the ideal BMI range is suggested to be 18.5–22 kg/m² (Laughton *et al.*, 2009).

Obesity

As rehabilitation progresses, becoming overweight is an increasing risk as appetite and food intake return to, or even exceed, preinjury levels. Body composition changes occur after SCI in response to reduced physical activity, immobilisation and muscle atrophy, resulting in basal metabolic rate (BMR) reduction by 7–48% (Mollinger *et al.*, 1985), depending on the level of injury. Predicting energy expenditure with the use of standard equations can therefore lead to overestimation of energy requirements (Cox *et al.*, 1985; Monroe *et al.*, 1998). In a cross sectional study of 133 men with SCI, Spungen *et al.* (2003) found that body composition changes were exaggerated with advancing age and resulted in adiposity levels and loss of muscle mass significantly greater than those of an ethnicity matched able bodied cohort.

The management of obesity in individuals with SCI is very important due its high prevalence (Groah *et al.*, 2009). There is limited data on the rate of weight gain after SCI in the UK, but in comparison with the UK

national survey data (Henderson *et al.*, 2003), SCI individuals (Groah *et al.*, 2009) seem more likely to become overweight and obese than the able bodied population (74% and 40%, respectively).

The detrimental health consequences of obesity are well documented (see Chapter 7.13.1). The risk of mortality associated with cardiovascular disease (CVD) is twice as high in SCI individuals compared with able bodied individuals (Myers *et al.*, 2007). In long term SCI individuals, CVD morbidity and mortality now exceeds that caused by renal and pulmonary conditions, with CVD becoming the primary cause of death (Myers *et al.*, 2007). In addition, overweight SCI individuals are higher risk of developing pressure ulcers (Elsner & Gefen, 2008), and have increased difficulties in managing daily life compared with overweight individuals without SCI (Abresch *et al.*, 2007).

Evidence suggests a simple dietetic intervention (Chen *et al.*, 2006; Wong *et al.*, 2011b) can help individuals with SCI to lose weight without compromising lean body mass. Although the intervention incurs additional cost, it has the potential to significantly decrease long term health-care expenditure if health outcome and quality of life are improved. Dietetic intervention, including comprehensive nutrition education and counselling on a cardioprotective diet, should be offered to at risk individuals. This is particularly important for those who may previously have had little interest or knowledge of nutritional issues.

Other nutrition related problems

Neurogenic bowel dysfunction

Neurogenic bowel dysfunction (NBD) is one of many impairments that result from SCI and is often quoted as being one of the most distressing problems (Lynch *et al.*, 2000). According to Stiens *et al.*, (1997) two patterns of NBD occur post SCI:

- *Upper motor neurone (UMN) or reflexic bowel syndrome* – generally occurs in cervical and thoracic injury. It results in constipation with faecal retention behind a spastic anal sphincter.
- *Lower motor neurone (LMN) or areflexic bowel syndrome* – generally occurs in lumbar or sacral injury where the conus (the conical end of the spinal cord) or nerve roots are damaged. It produces constipation with a high risk of frequent incontinence through a lax external sphincter mechanism.

Each type of NBD requires different bowel management and adjustments to dietary intake (particularly dietary fibre) may be required to produce an ideal stool consistency. Chemical stimulants are commonly used in UMN where a softer stool is required. A high fibre intake with adequate fluids may be helpful. Manual evacuation is commonly used if a harder or drier stool is required and a reduced fibre intake may be more appropriate.

The SCI centres have produced guidelines on bowel management (SCIC-UK&I, 2009), which emphasise that, whilst it is important to maintain a balanced diet, either an increase or decrease in dietary fibre intake (particularly insoluble fibre intake) may be helpful and that each

person with SCI should be individually assessed. Further research is needed to determine the exact optimal dietary fibre intake for individuals with SCI.

If enteral feeding is required, it has been found anecdotally to be best tolerated if started with a non-fibre feed and then introducing fibre containing feed gradually to toleration, perhaps ending with a feed that is a mixture of fibre and non-fibre. Additional fluids may be necessary due to the slower colonic transit time that results in increased resorption of fluid. In practice, at least 2L or more of fluid is usually recommended.

Pressure ulcers

Individuals with SCI are at high risk of pressure ulcers due to the loss of sensation of pressure, skin ischaemia, incontinence, poor nutritional intake and inability or reluctance to change position. Both underweight and overweight increase the likelihood of pressure sore development. Pressure ulcers can significantly increase nutritional requirements due to protein rich exudate and also expose tissue to infection. Antibiotic treatment of pressure sores may also reduce food intake as a result of associated side effects (see Chapter 7.17.6).

Metabolic syndrome

The SCI population is at higher risk of diabetes mellitus, metabolic syndrome and coronary heart disease due to decreased mobility, increased obesity and, in particular, central obesity. Early lifestyle modification and dietetic intervention targeted for at risk individuals to prevent the development of nutrition related complications should be part of the rehabilitation programme.

Renal calculi

The SCI population has a greater risk of renal calculi, primarily as a result of recurrent bladder infections, increased retention of calcium by the bladder and kidneys, and immobility. To help prevent bladder infections, SCI individuals are normally recommended to drink at least 2L/day of water based fluids; restriction of calcium is not indicated (Rice *et al.*, 1995).

Some people take cranberry juice in the belief that it might help in preventing bladder infections; however, there little research on this topic. A Cochrane review (Jepson *et al.*, 2004) in otherwise healthy adults indicated that, while there is some evidence of beneficial effects from regular cranberry consumption in women, the optimum dosage or method of administration, e.g. juice or tablets, remains unknown and that further better designed trials are needed. Since cranberry juice may enhance the anticoagulant effect of warfarin, those on warfarin should avoid it. In addition, it may provide a significant amount of energy and contribute to weight gain.

Osteoporosis

Individuals are at increased risk of osteoporosis due to lack of weight bearing exercise; therefore, osteoporotic fractures occur mostly in the lower limbs and pelvis. Risk is greatest within the first post injury year (Harrison,

2006). A well balanced diet incorporating sufficient calcium is recommended (see Chapter 7.9.1).

Nutritional support may be required at any stage following a SCI to offset catabolic losses and commence the process of nutritional repletion (see Chapters 6.3).

7.17.4 Burn injury

Mark Windle

Key points

- Severe burn injury elicits one of the most pronounced inflammatory responses likely to be encountered in a clinical setting.
- Goals are to minimise loss of lean body mass and to optimise immune function, skin graft take and wound healing.
- Early nutritional support may reduce wound infection rates, catabolism and incidence of stress ulceration.
- Glutamine supplementation is now recommended for critically ill burns patients.

Burn injury accounts for approximately 16 000 admissions to hospital per year in the UK (National Burn Care Committee, 2001). Care may be provided in a range of clinical settings, including general surgery wards, plastic surgery wards and intensive care units, depending on the severity of illness and availability of services. Those with severe burn injuries may be managed in a specialist burns centre. Burns patients typically spend longer, often up to 3 weeks or more, in a critical care environment than the general intensive care population (Windle, 2006).

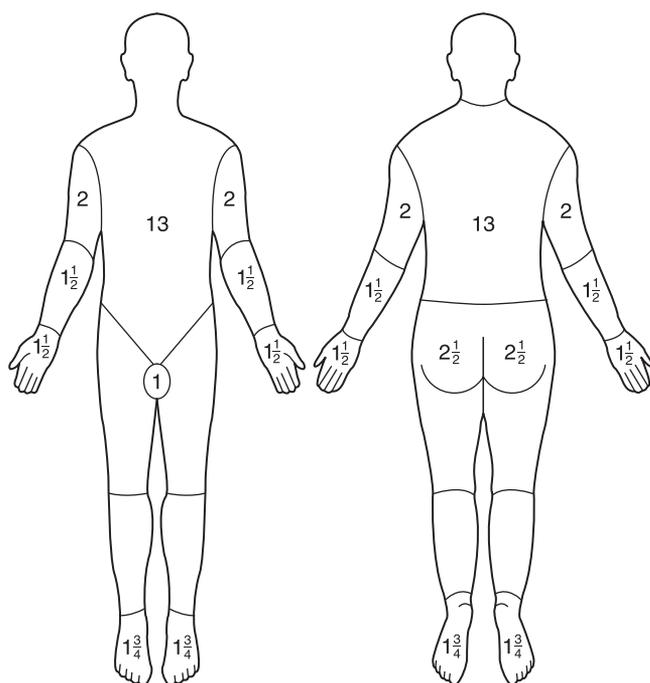

Young children present with a range of burn injuries, although scalds are the most frequently encountered (Hettiaratchy & Dziewulski, 2004). Whilst this chapter focuses on the management of adults with severe burns, metabolic and physiological consequences and interven-

tional approaches in paediatric burns are similar in many respects. Dietetic management of children with severe burns is discussed comprehensively elsewhere (McCarthy & Gurry, 2007).

Adult admissions may be more mixed. Types of burn injury are diverse and include flame, fat and water scalds; chemical, friction and contact burns; and electrical injury.

Diagnostic criteria and classification

A major burn injury in adults is defined as one affecting around 20% total body surface area (TBSA) or greater (Saffle & Graves, 2007). Regular assessment of size, distribution and depth of burn is essential for surgical planning; TBSA is assessed with the aid of pictorial charts

Age	Age (years)					
	0	1	5	10	15	Adult
Head and neck	21	19	15	13	11	9
Thigh	5 $\frac{1}{2}$	6 $\frac{1}{2}$	8	9	9	9 $\frac{1}{2}$
Calf	5	5	5 $\frac{1}{2}$	6	6 $\frac{1}{2}$	7

Figure 7.17.4 Percentage of different parts of the body at different ages (source: Kemble & Lamb, 1984. Reproduced with permission of Elsevier)

(Figure 7.17.4). Wound depth is described as partial thickness (affecting superficial dermal or deeper dermal areas) or full thickness, which may extend to muscle and bone.

Metabolism and physiology

Major burn injury is characterised by an extreme systemic inflammatory response syndrome (SIRS). Tissue damage releases proinflammatory cytokines that initiate several metabolic, haemodynamic and systemic effects, including activation of the clotting cascade. Systemic inflammatory response syndrome is characterised by increases in temperature, heart rate and respiratory rate (Bone *et al.*, 1992). Increased vascular permeability, transcapillary escape and exudate loss leads to rapid hypovolaemia, hypoperfusion and organ failure if uncorrected. Adrenaline (epinephrine) increases amino acid utilisation from skeletal muscle for gluconeogenesis, cellular immunity, tissue repair and positive acute phase protein synthesis. Secondary inflammatory hits may also occur from local infection, sepsis and repeated surgical insults.

Public health aspects of burns

Any individual in society may sustain a burn injury. However, the profile of major burns admissions often includes patients with complex social needs, physical disability, mental health issues (self immolation), the very young, elderly, those with chronic disease and those who abuse alcohol. Some of these patients may also be nutritionally at risk. Fifteen per cent of patients in a UK burn centre were found to have a body mass index (BMI) on admission of $<20 \text{ kg/m}^2$ (Windle, 2004).

Consequences of injury

Risk of death increases with injury severity, age and chronic disease. Burns survivors are often left with long term physical disfigurement, disability and psychological disorders. Large burns are now more survivable with refinements in a range of surgical, medical, nursing and nutritional interventions. This increases the need for intense multidisciplinary rehabilitation input and long term follow-up.

Hydration and nutritional consequences

Fluid losses via exudate can be massive; immediate and aggressive intravenous fluid resuscitation is required to minimise potentially fatal hypovolaemia. Exudate is albumin and micronutrient rich, and contributes to rapid zinc and copper loss (Berger *et al.*, 1992). Even with aggressive nutritional support, weight loss can be considerable. Around a third of adults admitted to a UK burn unit were unable to maintain weight within an acceptable limit, losing up to 22% of their admission or reported preinjury weight (Windle, 2004). Catch-up growth may be delayed in children with significant burn injuries (Rutan & Herndon, 1990). Metabolic rate may be raised above baseline for up to a year post burn injury (Hart *et al.*, 2000). Factors contributing to malnutrition are listed in Table 7.17.16.

Nutritional assessment and monitoring

Due to the often prolonged nature of critical illness and the often constantly changing clinical picture, dietetic assessment, monitoring and intervention can be time consuming in major burns (Windle, 2008). No evidence is available in burns regarding the benefits of monitoring frequency for the prevention of related complications. However, guidelines set by the NICE (2006) and the Parenteral and Enteral Nutrition Group (2007) of the British Dietetic Association for frequency of nutritional, biochemical and clinical monitoring may be suitable for most burn patients.

Weight

Some units have a weighbridge or weighing beds for assessing patients on admission for fluid resuscitation, drug dosage calculation and nutritional assessment

Table 7.17.16 Potential factors contributing to malnutrition and loss of lean body mass after burn injury

Metabolic	Catecholamine and inflammatory cytokine mediated effects: hypermetabolism, muscle proteolysis (mobilisation of amino acid from skeletal muscle for gluconeogenesis, cellular immunity, tissue repair and acute phase protein synthesis) Reduced growth hormone Secondary inflammatory hits from local infection and sepsis
Physiological/functional	Loss of micronutrients via burn wound exudate Increased urinary loss of copper and zinc Gastroparesis in critical illness phase reducing feed delivery Burn injury affecting oral cavity/oesophagus Severe inhalation injury – shortness of breath limiting intake Loss of lean body mass as a result of muscle necrosis from electrical injury
Interventions	Fasting for sedation related procedures for wound debridement and skin grafting Fasting for dressing change sessions which may require sedation (frequently on alternative days) Analgesia (constipation) Antibiotics (diarrhoea, nausea)
Psychological	Psychological effects on appetite (hospital environment, low mood, anxiety, post traumatic stress disorder, pain)

purposes. However, patients are usually transferred from an accident and emergency department in a referring hospital and considerable time may have lapsed between injury and admission to the burn care setting. Initial weight may therefore reflect under or over fluid resuscitation, wound exudate loss and (later) oedema. Nevertheless, an admission weight is useful as a starting point for calculation of nutritional needs if no history can be obtained. In the post extubation rehabilitation phase, regular weighing remains an important part of ongoing monitoring and screening until and beyond discharge from hospital.

Nitrogen economy and catabolism

Urinary nitrogen output is the result of internal nitrogen processing and so may assist in determining changes in protein economy and metabolism. Urinary urea nitrogen (UUN) is used to assess nitrogen balance (see Chapter 6.1) and severity of catabolism. In turn, these may help direct nutritional therapy. Eighty per cent of surveyed Australian and US burn centres regularly utilise nitrogen balance studies (Masters & Wood, 2008). Limitations exist in that protein intake must be accurately assessed and an accurate urine collection is required for use in the assessment of urinary urea excretion to facilitate calculation of nitrogen output. In the sedated critically ill burns patient, some potential barriers may be overcome. Nitrogen

intake can be calculated from observation charts documenting the administration of nutritional support, and urinary catheterisation facilitates an accurate urine collection. However, nitrogen loss from burn wound exudate may be significant and difficult to quantify. The usefulness of accounting for loss from exudate, i.e. loss other than from metabolism, in nitrogen balance calculations is unclear. In addition, ureagenesis is itself influenced in part by nitrogen intake. The catabolic index (CI) takes this into account when categorising the severity of metabolic stress (Bristan, 1979):

$$\text{CI} = [\text{UUN, i.e. urea (mmol/L)} \times 0.028] - (0.5 \times \text{nitrogen input} + 3 \text{ g})$$

where <0 = no stress, 0–5 = moderate stress and >5 = severe stress.

Overestimation of CI may occur at high levels of nitrogen intake or where protein utilisation is lower than the assumed rate of 50% of intake. A further limit is the factors used to convert UUN to total urea nitrogen. Current factors used may not account for increased non-urea components in metabolically stressed patients, and higher conversion factors may be required for burns (Konstantinides *et al.*, 1992).

Biochemistry

Serum albumin concentration is a poor marker of nutritional status. Levels may reflect the extent of the inflammatory response and physiological insult in burns. Hypoalbuminaemia is the consequence of transcapillary escape, wound exudate loss and reduced albumin synthesis in preference for positive acute phase protein production. Serum concentration trends should be interpreted alongside inflammatory markers such as C-reactive protein. Anaemia may be related to acute blood loss from injury and surgery, and to cytokine effects on bone marrow suppression (Posluszny & Gamelli, 2011). However, in view of the potential for preburn suboptimal nutritional status in some patients, a nutritional cause should be excluded if possible. Again, interpretation of test results for specific nutrient or biomarker assays (such as ferritin for suspected iron deficiency, or zinc, copper and selenium status) is unfortunately difficult in a setting of inflammation. These limitations place emphasis on full consideration of clinical and diet history, lifestyle factors, nutritional intake since admission, and inflammatory markers.

Clinical management

Clinical goals concern survival from acute injury, recovery to the preinjured state and return to society with unaltered potential as far as possible. The 7 'Rs' to clinical management are as follows (National Burn Care Committee, 2001):

- *Rescue, resuscitation and retrieval* – the injured individual is removed from the location of injury, formal

intravenous fluid resuscitation is initiated where necessary to minimise hypovolaemia, and the patient is transferred to the specialist area of care.

- **Resurfacing of skin** – debridement and dressing application, temporary or permanent skin coverage or grafting as soon as possible after injury, in order to reduce the inflammatory stimulus. Repeated theatre visits may be required for weeks or months. Full thickness areas will require skin grafting. Some partial thickness injuries may heal with conservative management or without surgery beyond initial removal of burned tissue. However, depth is often mixed and the surgical approach is often influenced by wound distribution and clinical stability. Other skin treatments may include application of cultured skin cells and synthetic skin replacement.
- **Rehabilitation** – this includes nutritional support, physical therapy, scar modulation, psychological management and discharge planning back into society. A multidisciplinary approach is required, including the involvement of dietitians, physiotherapists, occupational therapists and clinical psychologists.
- **Reconstruction and review** – surgical reconstruction may be required for years post injury for contracture release and cosmetic purposes. Outpatient monitoring is likely to be required for a number of years following major burn injury.

Nutritional management

Routes of feeding and timing of nutritional support

Parenteral nutrition may be associated with increased morbidity and mortality in critically ill patients, including those with burns (Gramlich *et al.*, 2004). This may be related to metabolic characteristics specific to burns; bacterial translocation and exacerbation of hepatobiliary complications have been observed in major burn injury (Herndon, 2007). Enteral feeding remains the route of choice, and all steps to utilise the gastrointestinal tract should be pursued. Gastroparesis may be managed by prokinetic therapy, or post pyloric tube placement where this fails (see Chapter 7.4.4).

Early initiation of nutritional support in burns patients appears safe, and may confer advantages in terms of avoiding stress ulceration, reducing incidence of wound infections, and when in combination with early surgical excision of wounds, reduction in skeletal muscle catabolism (Hart *et al.*, 2003, Mosier *et al.*, 2011). However, it is unclear how early this should commence and what the extent of clinical benefit is (Wasiak *et al.*, 2007). There has been concern regarding the risk of ischaemic injury in initiating enteral nutrition (EN) support in underperfused patients (Andel *et al.*, 2002). In practice however, by the time the patient is admitted, fluid resuscitation is usually well underway. Most units commence EN support within 24–48 hours of injury and benefit continues to be demonstrated in terms of reduced wound infection rates and intensive care unit length of stay (Mosier *et al.*, 2011).

Nutritional requirements

Energy

Energy requirements are largely influenced by the extent of inflammation. After an initial hypometabolic phase (ebb), an extended period of hypermetabolism (flow) occurs (see Chapter 7.17.1). The extent of the rise may vary depending on additional events such as dressing changes, septic episodes, surgical interventions, infectious complications and time post injury, and is not always related to injury severity. At one time energy prescriptions of up to 33.4 MJ (8000 kcal)/day were advocated for burns patients (Wilmore *et al.*, 1971). Since then, more conservative prediction formulae have been developed. These are particularly important in light of more recent knowledge gained of energy expenditure, complications of overzealous energy provision such as prolonged ventilator dependency, and higher septic mortality rates in hyperglycaemic critically ill patients. Interventions such as early surgery and initiation of nutritional support have contributed to a reduction in the hypermetabolic response (Hart *et al.*, 2003). Nevertheless, no consensus on the predictive equation to use for energy requirements exists.

A range of formulae have been proposed to estimate requirements. Some well known and traditionally used burns formulae were proposed before a range of treatment approaches were developed that blunt the hypermetabolic response, and so are likely to overestimate energy requirements. The Schofield formula (Schofield, 1985) with stress factors related to burn size was previously recommended, but this approach is not specifically validated in burns. Examples of prediction formulae used for burns patients today are shown in Table 7.17.17. Some authors have commented that many equations do not accurately predict measured energy expenditure for the reasons described above, and recommend equations that consider a range of parameters to reflect changing physiology, or the use of indirect calorimetry where facilities are available (Taylor, 2007; Herndon, 2007; Prelack *et al.*, 2007). Whilst the use of indirect calorimetry in US burn units has increased four fold over the last 20 years (Graves *et al.*, 2009), use is less common in the UK and ultimately the technique has its own limitations (Simonson & DeFronzo, 1990).

Protein

Intake of at least 1.5 g/kg protein/day has been suggested to ensure adequate provision in adults, following the observations that amino acid oxidation rates can be increased by 50% in burns patients compared with healthy individuals (Herndon, 2007). Intakes of 0.24 g nitrogen/kg (or 1.5 g/kg) of protein/day is likely to improve nitrogen balance in adults with burns covering >20% of TBSA, and further benefit may be achieved at higher intakes, although optimum levels are unknown due to study limitations (Taylor, 2007). The actual protein level used in surveyed US and Australian burn centres was 2 g/kg of body weight/day (Masters & Wood, 2008). The anabolic steroid oxandrolone is increasingly being used in severe burns. Benefits include improvements in preservation of

Table 7.17.17 Equations for estimating energy requirements in burns patients (kcal/day)

Author	Formula	Comments
Ireton-Jones & Jones (2002)	Spontaneous, breathing 629–11(A) + 25(W) + 609(O) Ventilator dependency 1784–11(A) + 5(W) + 244(G) + 239(T) + 840(B)	Does not account for changes in physiology over time affected by, for example, interventions, pharmacology, reducing burn wound size, presence or absence of sepsis May overestimate in the obese and underestimate in the non-obese
Allard <i>et al.</i> (1990) Toronto formula	REE = –4343 + (10.5 × % TBSA burn) + (0.23 × kcal intake) + (0.84 × HB) + (114 × t) – (4.5 × post burn days)	Complex, requires calculation of HB formula, which itself is an estimate of basal energy expenditure and requires multiplication by a 'static' factor, but for spontaneous breathing patients at least takes account of healing over time
Kreymann <i>et al.</i> (2006)	Maximum 20–25 kcal/kg of body weight in acute phase of critical illness 25–30 kcal/kg of body weight in flow phase	ESPEN generic guidelines for critically ill patients Does not track physiological changes Acute and recovery phases not clearly defined
Frankenfield <i>et al.</i> (2009), Frankenfield; (2011) Modified Penn State formula	Ventilator dependency RMR = Male: 10(W) + 6.25(ht) – 5(A) + 5 or Female: 10(W) + 6.25(ht) – 5(A) – 161 then BMI <30 kg/m ² × 0.96 + T _{max} (167) + Ve(31) – 6212 or BMI ≥30 kg/m ² × 0.71 + T _{max} (85) + Ve(64) – 3085	Considers physiological parameters associated with changes in metabolic rate Not validated specifically in burns patients but predictive ability higher than current validated equations for ventilated patients

A, age (years); B, burn (absent 0; present 1); G, gender (female 0; male 1); O, obesity (absent 0; present 1); W, weight (kg); REE, resting energy expenditure; HB, Harris–Benedict equation; TBSA, total body surface area; t, temperature (°C); ESPEN, European Society for Parenteral and Enteral Nutrition; RMR, resting metabolic rate; T_{max}, maximum body temperature in past 24 hours (°C); Ve, expired minute volume (L/m) at time of reading from ventilator.

lean body mass and muscle function, and shorter hospital length of stay (Demling & DeSanti, 1998; Wolf *et al.*, 2006). Maintenance of nutritional intake whilst on treatment may be essential as restoration of body weight and muscle function has been demonstrated at protein intakes of 2 g/kg/day compared with lower levels (Demling & DeSanti, 1998).

Micronutrient supplementation

Almost all vitamins, minerals and trace elements play a direct or indirect role in wound healing. Important nutrients are listed in Table 7.17.18 (see Chapter 7.17.6). Research interest in trace element supplementation in burns is not surprising when it is considered that 10% of total body zinc and 40% of total body copper may be lost in exudate (Berger *et al.*, 1992), and the role that they play as cofactors for enzyme systems involved in immunity and wound healing. European practice guidelines for adults (Kreymann *et al.*, 2006) support the use of copper, selenium and zinc supplementation at a dose higher than standard, following a randomised controlled trial that demonstrated that administration of 40.4 µmol of copper, 2.9 µmol selenium and 406 µmol of zinc for 30 days after burn injury reduced chest infection rates and length of hospital stay. Other guidelines suggest reserving specific micronutrient supplementation for correcting deficiency states, and note that regular nutritional therapy often provides well in excess of baseline amounts (Prelack *et al.*, 2007). Nevertheless, most US centres routinely

administer additional micronutrient supplements (Graves *et al.*, 2009). This practice is also increasing in the UK with some burn units agreeing a policy of routinely giving intravenous trace elements to all burns patients from admission up to at least day 7. It may be prudent to avoid routine iron supplementation for correction of anaemia in the critically ill as free iron can encourage bacteria growth and may be associated with an increased risk of sepsis and mortality (Lapointe, 2004). In burns patients, high dose ascorbic acid has been used for its antioxidant properties as an additive to intravenous resuscitation fluid. Reduced free radical production leads to less vascular permeability and oedema, although outcomes are inconsistent between studies (Kahn *et al.*, 2011). Enteral supplementation with up to 800–1000 mg/day of vitamin C is likely to be safe (Department of Health, 1991) and vitamin C toxicity issues are generally minor. Perhaps for these reasons, a number of centres include specific supplementation as part of their protocol (Masters & Wood, 2008; Graves *et al.*, 2009). Evidence in burns patients to support routine supplementation is however limited at present.

Immune modulating nutrition

Glutamine

Glutamine, a conditionally essential amino acid in metabolic stress, has a number of roles, including providing an oxidative fuel for lymphocytes and gastrointestinal

Table 7.17.18 Role of micronutrients in burn wound healing

Micronutrient	Role	Notes
Vitamin A	Needed for epithelialisation and stimulation of fibroblasts Antioxidant effect of beta-carotene prevents damage by free radicals in SIRS	
B vitamin	Role in oxidative pathways Cofactor for collagen deposition	
Vitamin C	Cofactor in hydroxylation of proline and lysine Collagen synthesis Antioxidant properties protect metalloenzymes from oxidation	As a free radical scavenger, may reduce vascular permeability and therefore reduce fluid resuscitation requirements
Iron	Promotes collagen synthesis Optimises tissue perfusion	Avoid iron supplements in acute illness – possible increased risk of infection and mortality
Zinc	Role in RNA/DNA replication, lymphocyte function and collagenase enzyme systems	Up to 10% total body zinc lost via wound exudate
Copper	Cofactor in the lysyl oxidase enzyme system, essential for collagen synthesis and maturation	Up to 40% of total body copper lost via wound exudate
Selenium	Component of glutathione peroxidase (antioxidant)	Lost through skin following burn injury

mucosa. Severe glutamine depletion through reduced endogenous production and increased central consumption persists for at least 11 days after burn injury (Gore & Jahoor, 2000). A review of randomised controlled trials and practice guidelines in burns highlighted improvements in biomarkers of intestinal permeability, improved wound healing rates, length of stay, reduction in *Pseudomonas aeruginosa* infection and cost savings following glutamine supplementation (Windle, 2006). Most studies have investigated enteral supplementation, reflecting the primary nutritional approach in burns, although intravenous glutamine has been associated with a decrease in Gram negative bacteraemia and quicker resolution of inflammatory markers (Wischmeyer *et al.*, 2001). Use of glutamine in burn units is increasing and critical care practice guidelines now endorse enteral glutamine for mechanically ventilated burns patients (Heyland *et al.*, 2003; Kreymann *et al.*, 2006; McClave *et al.*, 2009). The optimum dose and duration of supplementation in burns patients is still unknown, although a dose of 0.3–0.57 g/kg of body weight/day for up to 3

weeks post burn injury may be appropriate (Windle, 2006; Kurmis *et al.*, 2010).

Arginine

Arginine has a role in T lymphocyte synthesis and promotes wound healing. However, arginine rich feeds have been associated with increased mortality in patients with sepsis (Heyland *et al.*, 2003). This may be related to an exacerbation of nitric oxide production, which can cause profound hypotension, hypoperfusion and ultimately multiorgan failure. However, others have noted that this mortality effect has not been observed in burns patients (Kurmis *et al.*, 2010).

Omega 3 fatty acids

n-3 Fatty acids compete with n-6 fatty acids for incorporation into cell membranes. A high ratio of n-3 to n-6 fatty acids gives rise to fewer proinflammatory mediators. It is plausible that burns patients may be among the group most likely to benefit from n-3 fatty acid supplementation, although research in this group is surprisingly sparse. Existing studies in burns patients suffer from design limitations, such as small sample size or use of n-3 fatty acids in combination with other nutrients (Kurmis *et al.*, 2010).

Some commercially available enteral feeds provide immune modulating nutrients in combination. A major disadvantage is that the relative effects of constituents are unknown. A review of burns studies has noted mixed results and suggests that the priority should be for defining optimal doses and safety before developing such products (Kurmis *et al.*, 2010).

Follow up post discharge

Dietetic follow-up may be required beyond inpatient discharge to monitor weight maintenance and to support any functional difficulties with eating as a result of injury. Physiotherapy and occupational therapists are inevitably engaged in long term follow-up and may assist in flagging up developing nutritional problems. As regional burn centres tend to serve wide populations geographically, sometimes transfer of or shared dietetic care with a local department is required for logistical reasons. When wounds fully heal, transfer from a high protein high energy diet to a longer term healthy eating approach may require further ongoing support.

Drug–nutrient interactions

The following drugs affect nutritional status:

- Oxandrolone (testosterone analogue steroid) – hyperglycaemia, nausea, vomiting and diarrhoea.
- Morphine salts (opioid analgesic) – paralytic ileus, abdominal pain, anorexia and taste disturbance.
- Meropenem (antibiotic) – nausea, vomiting, diarrhoea and abdominal pain.
- Piperacillin with tazobactam (Tazocin; antibiotic) – nausea, vomiting and diarrhoea; less commonly – stomatitis and dyspepsia; rarely – abdominal pain; and very rarely – hypoglycaemia and hypokalaemia.

7.17.5 Surgery

Rachael Barlow

Key points

- Surgical trauma causes physiological stress, which is related to the severity of the procedure and results in an increase in energy expenditure and protein mobilisation.
- Preoperative weight loss is a recognised cause of postoperative morbidity and mortality.
- Malnutrition is associated with a significantly higher risk of postoperative complications.
- Nutritional screening, assessment and early enteral nutrition are key components of the Enhanced Recovery After Surgery (ERAS) programme; a patient centred pathway that optimises surgical outcome by improving clinical outcomes and patient experience.

Approximately 3 million surgical operations are performed in the UK each year, with an average hospital mortality of 0.8–1%. This equates to over 20 000 deaths following surgery a year (NECPOD, 2011). The range of surgical procedures now practised, along with the diversity of patients undergoing surgery, make it difficult to generalise the metabolic and nutritional responses following surgery. Procedures vary from elective (planned) to emergency surgery, and from laparoscopic (keyhole) to prolonged procedures taking many hours. The type and duration of surgery influence the speed of postoperative recovery. The health status of the patient and the reason for surgery also require much consideration. An emergency appendicectomy in an otherwise fit, healthy adult carries little implication for nutritional intervention, whereas a malnourished, cachectic patient requires nutritional support pre and post surgery if compromised nutritional status is not to adversely affect clinical progress. The majority of this chapter focuses on major surgery patients.

The clinical management of surgical patients has progressed radically over the last 100 years with the availability of prophylactic antibiotics, intravenous fluids and colloids, increased understanding of anaesthetic agents and analgesics, specialist critical care units and an increased understanding of organ function perioperatively. Nutrition is now an integrated component of surgical care.

Effects of surgery

Any surgical trauma causes physiological stress, which is related to the severity of the procedure. An initial surge in sympathetic activity generates a transient rise in catecholamine secretion post trauma. The resultant increase in energy expenditure and protein mobilisation is moderated through cytokine release, especially tumour necrosis factor (TNF) and proinflammatory interleukins (particularly IL-1 and IL-6) (Inui, 1999). A delay in postoperative feeding, coupled with preoperative starvation, often results in significant negative nitrogen balance. Protein depletion postoperatively results in loss of lean body mass

and reduced muscle strength, and thus increased risk of cardiorespiratory impairment; in addition, impaired immunity increases the likelihood of infectious complications (Inui, 1999). Impaired immunity and associated sepsis may also be linked to the altered intestinal permeability seen in the postoperative period (Beattie *et al.*, 2000). A compromised supply of oxygen to the gut during surgery (splanchnic hypoperfusion) has been shown to downregulate local and systemic immune function, increase intestinal permeability and exaggerate the acute phase response. Thus, wherever the site of surgery, the gut has a central modulatory role in the inflammatory and immune responses to major surgery (Holland *et al.*, 2005).

Traditionally, malnourished surgical patients were classified into four groups; depleted, hypercatabolic, hypercatabolic and depleted, or chronic malabsorption (Elwyn, 1980). This is of limited use today, as routine use of a nutritional support and associated pain management strategy has been shown to attenuate the catabolic response to surgical injury (Kehlet, 1999).

Pre-existing malnutrition

Several prospective studies have concluded that patients undergoing surgery are at increased risk and this can have a negative impact on clinical outcome. Malnutrition is of widespread concern in hospitalised patients (see Chapter 6.1). Evidence suggests that the preoperative nutritional status of many surgical patients is poorly documented (Kudsk *et al.*, 2003), despite preoperative weight loss being a recognised cause of postoperative morbidity and mortality. However, poor documentation should be addressed via the Enhanced Recovery After Surgery (ERAS) programme (see later).

Although it is difficult to establish a causal relationship, malnutrition is associated with a significantly higher risk of postoperative complications (Allison, 2000; Salvino *et al.*, 2004) and impaired quality of life (Ferguson & Capra, 1998). Therefore, it is thought that the correction or prevention of malnutrition with the use of nutritional support may impact on health related quality of life (McKenna & Thorig, 1995).

Stages of nutritional support delivery

The delivery of nutritional support in the surgical patient can be divided into preoperative and postoperative stages.

Preoperative nutritional intervention

Evidence suggests that 25–40% of all patients are malnourished on hospital admission (Kruizenga *et al.*, 2005). A low admission body mass index (BMI) increases the relative risk of death from cardiac procedures in the older age group (Rapp-Kesek *et al.*, 2004). The nutritional risk increases in many patients during their hospital stay (Kyle *et al.*, 2005) and up to a third of postsurgical patients experience clinically significant weight loss (Fettes *et al.*, 2002). Many patients presenting for surgery may be malnourished as a consequence of underlying pathology, e.g. cancer related cachexia or Crohn's disease, or of associated symptoms such as diarrhoea, nausea or vomiting. All causes of excessive nutrient loss and/or increased metabolic needs will influence nutritional status. Nutritionally at risk patients include those who:

- Are of advanced age.
- Are currently or predicted to eat little or nothing for >5 days.
- Have taken <60% of nutritional requirements over the previous 10 days.
- Are unable to eat the normal hospital diet.
- Have increased but unmet nutritional needs.

These groups of patients are deemed at risk of malnutrition and should be the focus of early nutritional support (Weimann *et al.*, 2006), as optimisation of nutritional status preoperatively reduces postoperative infectious complications (Windsor *et al.*, 2004) and enhances wound healing rates (see Chapter 7.17.6).

Nutritional screening

A variety of tools have been developed to assess the nutritional status of patients awaiting surgery, such as the Mini Nutritional Assessment (MNA), Subjective Global Index (SGI), Nutritional Risk Index (NRI), and Malnutrition Universal Screening Tool ('MUST') (see Chapter 7.17.2). Whilst the sensitivity and specificity of the tools vary, the consistency of the predictive value for each tool means that any one can be used for nutritional risk assessment (Kuzu *et al.*, 2006). It is recommended that all surgical inpatients should be screened for nutritional and physical status on admission, and reviewed weekly thereafter (NICE, 2006).

Preoperative nutritional support

Active nutritional support by provision of oral nutritional supplements or enteral feeding should be routinely considered in patients with a BMI of <18.5 kg/m² or those who present with unintentional weight loss within the last 3 months of >10% of body weight. A BMI below 20 kg/m² with unintentional weight loss of >5% of body weight within the previous 3–6 months is also predictive of malnutrition (NICE, 2006).

Fasting guidelines

Prolonged preoperative fasting has until recently been a time honoured tradition, although over 100 years ago the British surgeon Joseph Lister (1827–1912) stated, '*While it's desirable that there should be no solid matter in the stomach when chloroform is administered, it will be found very salutary to give a cup of tea or beef-tea about two hours previously*'. The need for a short period of starvation has recently come to the forefront, with work suggesting better postoperative recovery with oral fluid intake up to 2 hours before surgery.

The rationale for preoperative fasting is to reduce the volume and acidity of gastric contents, thus reducing the risks of intraoperative regurgitation and aspiration of gastric contents into the lungs, yet evidence supporting this rationale is lacking. '*Nil by mouth from midnight*' is a slowly changing practice as evidence increases that patients fasted from liquids and solids for an average of 12–14 hours have a compromised fluid and nutritional intake (Crenshaw & Winslow, 2002). Patients remain exposed to unnecessary starvation, suboptimal stress reduction and intravenous fluid overload preoperatively (Lassen *et al.*, 2005).

Guidelines from the American Society of Anesthesiologists (ASA, 1999) have revised these recommendations, allowing consumption of clear liquids (including fruit juices without pulp) up to 2 hours before elective surgery, a light breakfast, e.g. tea and toast, 6 hours before the procedure and a heavier meal 8 hours beforehand. These newer practices improve patient comfort and reduce adverse outcomes (Saqr & Chambers, 2006).

The recent Royal College of Nursing guidelines (RCN, 2005) for preoperative fasting in the UK permit low risk patients to take water, clear tea and black coffee up to 2 hours before anaesthetic induction, and milky drinks and food up to 6 hours before induction. Patients considered at high risk of aspiration (those who are obese, diabetic or with gastrointestinal reflux) can follow a similar fasting regimen, but this should be at the anaesthetist's discretion (Maltby *et al.*, 2004; Jellish *et al.*, 2005).

Carbohydrate loading

Carbohydrate loading has gained widespread popularity in the preoperative management of major surgical patients over the past decade. The surge in popularity is due to its integral role in the ERAS Programme. The use of carbohydrate rich drinks prior to surgery has been shown to alter the metabolic state from fasted to fed. This modulates the postoperative insulin response by improving the insulin sensitivity, leading to improved muscle strength and mass in particularly lean body tissue (Ljungqvist & Søreide, 2003), which is thought to help with early mobilisation and rehabilitation (Yuill *et al.*, 2005; Melis *et al.*, 2006a). A detailed review of the physiological action of the mechanism of carbohydrate and insulin resistance is given by Ljungqvist & Søreide (2003). However, carbohydrate rich drinks given prior to laparoscopic procedures such as cholecystectomy produce conflicting outcomes (Bisgaard *et al.*, 2004; Hausel *et al.*, 2005).

The use of preoperative carbohydrates has a positive effect on patient experience, reducing anxiety, thirst and hunger. Practically, carbohydrate solutions should be administered 4–12 hours preoperatively. Caution is required for diabetics due to possible impaired glycaemic control and impaired gastric emptying.

Postoperative nutritional support

The routine use of early nutritional support remains a controversial postoperative, therapeutic intervention in surgical patients; however, the advent of the ERAS programme seems to be resolving this controversy. Commencement of enteral or oral feeding within 24 hours of surgery is associated with optimal clinical outcome (Allison, 2005). Immediate postoperative enteral feeding, commenced within 6–12 hours post procedure, is associated with a significant reduction in postoperative complications, reducing both intensive care unit (ICU) and total hospital length of stay (Gabor *et al.*, 2005; Kreymann *et al.*, 2006). The recommendation to commence early enteral feeding is often tempered by the possibility of postoperative complications.

Several meta analyses have suggested that normal food intake or enteral nutrition (EN) may be beneficial in reducing infective complications and hospital stay in general surgical patients (Møiniche *et al.*, 1995; Schilder *et al.*, 1997; Marik & Zaloga, 2001). However, the issue of the early introduction of oral food intake in patients with an upper gastrointestinal tract anastomosis is not straightforward. Lassen *et al.* (2005) advocated the use of early oral food after upper gastrointestinal tract resection at will; however, for many patients this may not be the preferred method. This may not be a viable option for patients with anorexia or who lack confidence with eating in the first few days postoperatively. The use of jejunostomy feeding for immediate early EN has been reported to be safe, well tolerated and to have advantages over traditional management with intravenous fluids or parenteral nutrition (PN) (Aiko *et al.*, 2001; Sand *et al.*, 1997). For a detailed review of the proposed mechanism of action of early EN, see Kudsk (2002) and Genton & Kudsk (2003).

Early enteral feeding post surgery reduces the risk of anastomotic dehiscence, pneumonia, wound infection and intra-abdominal abscess (Lewis *et al.*, 2001). This has been reiterated in a recent study (Barlow *et al.*, 2011). The recommendation for clinical practice should be to use EN (either oral or enteral tube feeding) where the gastrointestinal tract is accessible and functioning. Nutritional support intervention in the perioperative period has been evaluated using standard oral nutritional supplements in mixed patient populations (Beattie *et al.*, 2000; Macfie *et al.*, 2000; Smedley *et al.*, 2004). In these trials, oral nutritional intervention positively influenced the clinical course by reducing postoperative complications. There is evidence to support the integration of nutrition into the care pathway for colorectal cancer (CRC) patients (see Chapter 7.15.3).

Immunonutrition

Immune enhancing supplementation is an expensive alternative to standard formula products. Although benefit from these has been demonstrated, their cost currently prohibits large scale implementation into routine practice in the preoperative period for elective surgical patients. Several studies on the use of immune nutrition perioperatively have indicated that immune enhanced EN is superior to EN in lowering incidence of infections and complications (Daly *et al.*, 1995; Braga *et al.*, 1999; 2002; Gianotti *et al.*, 2002).

The use of preoperative immune enhancing oral supplementation has been shown to reduce complication rates in CRC patients (Waitzberg *et al.*, 2006). A recent study (Burden *et al.*, 2011) concluded that there is no advantage in providing routine immune nutritional supplements to all patients, but did suggest these may be beneficial in patients who are weight losing preoperatively (see Chapter 7.11.1).

Route of feeding

Jejunostomy

Jejunostomy is a surgical procedure by which a tube is situated in the lumen of the proximal jejunum, primarily to administer nutrition, fluid and medication (Sarr, 1988), reducing the need for central venous access for administration of nutrition and drugs (see Chapter 6.4). Delany *et al.* (1973) inserted the first needle catheter jejunostomy (NCJ) in 1973. They described the delivery of feeding and fluids via a NCJ in patients undergoing upper gastrointestinal tract surgery. Since this, many cohort and feasibility studies have reviewed jejunostomy feeding, with many reporting serious and occasionally life threatening complications (Biffi *et al.*, 2000; Eddy *et al.*, 1996; Ryan *et al.*, 2006). The complications seen with jejunostomy can be classified into:

- *Mechanical* – such as tube dislocation, occlusion or migration.
- *Surgical* – such as cutaneous or intrabdominal abscesses, enterocutaneous fistulae, pneumatosis, small bowel obstruction and intestinal ischaemia.
- *Infectious* – can occur such as aspiration pneumonia or contamination of the enteral feed.
- *Gastrointestinal intolerance* to jejunal feeding is reported to be between 2.3% and 6.8% and includes abdominal distension, colic, constipation, nausea and vomiting.
- *Metabolic* – including hyperglycaemia, hypokalaemia, water and electrolyte imbalance, hypophosphataemia and hypomagnesaemia.

The largest prospective study over 9 years was reported by Braga *et al.* (2002) who studied 650 patients undergoing gastrointestinal tract surgery. All patients had either a NCJ (61.8%) or nasojejunal feeding tube (NJT) (38.2%). Severe jejunostomy related complications were noted in 1.7% of patients and EN related mortality was 0.1%. Refractory intolerance of the enteral feed was reported in

48% of patients. The authors recommended that intolerance could be minimised with a slow increase in feed rate in the first postoperative week and close monitoring. They concluded that EN was safe, well tolerated and not detrimental to anastomotic healing. The authors suggested that intolerance of EN was an early predictor of impending surgical complications.

In a recent study Ryan *et al.* (2006) prospectively studied 205 patients post oesophagectomy. They concluded that early EN via a NCJ was tolerated in 92% of patients. Patients were fed on average for 15 days, with 26% requiring long term nutritional support, i.e. for longer than 20 days. Serious complications were reported in 1.4% of patients, all of whom required repeat laparotomy. There was one death directly attributed to jejunostomy feeding.

Clearly, the choice of feeding jejunostomy is crucial and it may be a major factor in the development of complications, alongside the insertion technique used by the surgeon. The use of aggressive feeding, such as using high rates to initiate the enteral feed, coupled with the rapid increase in rate of the feed and the osmolarity of the feed, are all important (Melis *et al.*, 2006b). The too rapid delivery of EN coupled with the overzealous use of opioids, which slow gastrointestinal peristalsis, could lead to increased intra-abdominal pressure and exacerbate gastrointestinal oedema, reducing splanchnic blood flow and increasing the likelihood of gastrointestinal ischaemia (Melis *et al.*, 2006b). The volume of EN delivered is vital. A study by Watters *et al.* (1997) reported that EN delivered to nutritional requirements within 3 days in major surgical patients lead to respiratory problems secondary to increased abdominal distension.

Parenteral nutrition

Parenteral nutrition is discussed in Chapter 6.5.

Postoperative gastrointestinal motility

The three most common reasons for the delay of feed commencement are the absence of bowel sounds (with presumed ileus), risk of gastrointestinal anastomoses dehiscence and haemodynamic instability, especially in the ICU patient, but evidence does not support the necessity for delay.

After surgery, postoperative gastrointestinal dysfunction or ileus is commonly reported to occur. It is thought to occur in 90% of patients undergoing intra-abdominal surgery. Livingston & Passaro (1990) defined ileus as '*The inhibition of propulsive bowel motility, irrespective of pathological mechanisms*'.

Ileus is characterised by the development of nausea, vomiting, delayed gastric emptying, bowel distension, decreased bowel sounds, delay in passage of stools and pain after a surgical procedure. The pathogenesis of ileus is multifactorial; however, it is thought to stem from the high concentration of inflammatory mediators following any injury to the intestinal muscularis of the gastrointestinal tract. These act locally to initiate morphological

changes in the bowel wall. In addition, these immunological cells cause an increase in free radical production, which disrupts the membrane ion channels (potassium and calcium) that regulate smooth muscle contraction and rhythm. The result is a decrease in circular muscle contraction and thus a reduced intestinal transit time (Livingston & Passaro, 1990). Subsequently, systemic cytokines, prostaglandins and catecholamines are released that activate the autonomic nervous system. This produces inhibitory effects that alter motility and reduce mesenteric blood flow.

There are many other factors that have been linked to ileus, such as nitric oxide, nasogastric intubation, gum chewing, use of laparoscopic procedures, and pharmacological agents such as non-steroidal anti-inflammatory drugs, prokinetics such as metaclopramide hydrochloride, erythromycin, ceruletide and octreotide, a somatostatin analogue that inhibits the secretion of gastrointestinal hormones. These factors were reviewed extensively by Mythen (2005).

Traditionally, it has been considered that ileus prevents the safe delivery of EN. Barium studies have demonstrated that small bowel motility continues in the postoperative phase, despite delayed gastric emptying taking 24–48 hours to recover and colonic motility taking 3–5 days to return (Livingston & Passaro, 1990). Clinicians often use the traditional practice of auscultation of bowel sounds to gain information on intestinal function and motility. However, bowel sounds have not been shown to correlate with motor patterns of function or dysfunction (Madsen *et al.*, 2005). The administration of EN has been shown to promote gastrointestinal motility in several studies (Stewart *et al.*, 1998; Beier-Holgersen & Boesby, 1996). Delivery of EN in clinical practice is not simple. Attention to the feed rate of EN delivery is important, as failure to increase this may not produce a postprandial motility response and without this there will be no normal small bowel contraction and peristalses, resulting in undigested EN passing into the colon.

Nutrition requirements

It is important to remember that the aim of nutritional support in the surgical patient is to reduce postoperative complications, whilst optimising recovery and quality of life. Postsurgical energy requirements vary according to the degree of trauma and concurrent clinical factors. After minor surgical procedures, normal energy expenditure will hardly be affected, whereas major procedures with resultant sepsis and high output stoma or drain losses potentially increase energy and protein requirements. Postoperative management of head and neck cancer patients has been shown to be improved if a dietitian is part of the multidisciplinary team (Wood, 2005).

The quality of nutritional support rather than the quantity is now considered the more relevant for postsurgical patients. An intake of 25–35 kcal/kg/day of total energy with 0.8–1.5 g of protein (0.13–0.24 g of nitrogen)/kg/day is a starting point. However, overzealous, aggressive nutritional support is not helpful if it leads to complications.

Fluid requirements can be met by 30–35 mL/kg/day, with additional fluid provided to compensate for pyrexia and increased drain, fistulae or stoma losses. Serum biochemistry and anthropometry are usually the only tools available to estimate the nutritional adequacy of a prescribed regimen, but it should be noted that these may not be representative of nutritional status in the postsurgical patient (Bachrach-Lindstrom *et al.*, 2001).

It is widely known that postoperative fluid and electrolyte balance has been traditionally suboptimal (Lobo *et al.*, 2001). Optimal fluid balance is central to the return of normal physiological function postoperatively. Suboptimal fluid balance can impair respiratory function and wound healing by affecting tissue oxygenation due to interstitial oedema. A positive fluid balance causes gut oedema. Lobo *et al.* (2001) concluded that fluid and sodium restriction in patients undergoing major colonic resection significantly reduced the duration of ileus and improved gut perfusion. Additionally, disturbances in acid–base balance, glucose or electrolytes affect gut function and motility, presumably due to altered cellular mechanics (Wilkes *et al.*, 2001). The British Consensus Guidelines on Intravenous Fluid Therapy for Adult Surgical Patients (GIFTASUP) (Powell-Tuck *et al.*, 2011) provide a useful consensus for the recommendations for perioperative fluid management, and these are now being incorporated into many hospital surgical and critical care units.

Glycaemic control

Postoperative insulin resistance and hyperglycaemia aggravate the inflammatory response, enhancing cytokine production and contributing to the surgical stress that negatively impacts on morbidity and mortality (Ljungqvist *et al.*, 2005). Tight glycaemic control using sliding scale insulin therapy improves outcome (see Chapter 7.17.1). This appears to be due to a direct effect of insulin on blood glucose and an indirect effect of insulin in correcting abnormal serum lipid profile and downregulation of the catabolic state evoked in the surgically stressed patient (Vanhorebeek *et al.*, 2005). Many ICUs adopting tight glycaemic control protocols require a 24-hour feed schedule to minimise the risk of catastrophic hypoglycaemia.

Nutritional management of surgical complications

Complications of feeding the surgical patient may relate to the presence of the underlying pathology (such as Crohn's disease, cachexia, pancreatitis or diabetes), the planned surgical outcome (such as ileostomy formation) or an adverse effect as a result of surgery (wound dehiscence, fistula formation, infection and pyrexia). The use of bariatric surgery as a method of weight management has increased dramatically in recent years and brings its own nutritional problems (Edwards *et al.*, 2006), including late developing deficiencies of iron, vitamin B₁₂, calcium and vitamin D, in addition to protein energy malnutrition and fat malabsorption (Malinowski, 2006).

The immediate perioperative nutritional input for common complications of surgery is described below. Long term management of each condition may require a different approach.

Wound healing

Nutritional aspects of wound healing are discussed in Chapter 7.17.6. Malnutrition and recent nutritional intake are key factors in the complex mechanism of wound healing (Clark *et al.*, 2000). However, up to date literature is scarce. Malnutrition has been linked to impaired wound healing in surgical patients. Even acute starvation for a few days is detrimental to wound healing (Hunt & Williams-Hopf, 1996). Goodson *et al.* (1987) showed that even 1–2 days of inadequate nutrient intake decreased hydroxyproline synthesis, one of the main components of collagen. Preoperative oral food intake is also important in wound healing (Windsor *et al.*, 1988). The authors found a positive correlation between preoperative nutritional intake and improved postoperative wound healing. This is important as in clinical practice it is not uncommon for patients to have numerous radiological interventions and hence prolonged periods of nil by mouth in the week prior to surgical intervention.

Recent studies of the role of nutritional support in wound healing in surgical patients are limited; the majority are over 20 years old. Schroeder *et al.* (1991) concluded that EN in patients after gastrointestinal resection, compared with to nil by mouth and intravenous fluids, improved collagen synthesis and promoted wound strength. More recently, a meta analysis (Lewis *et al.*, 2001) demonstrated that anastomotic dehiscence rates were reduced in patients receiving EN. A study by Braga *et al.* (2002) also suggested that EN is not detrimental to anastomotic healing even when early direct passage of nutrients over a fresh intestinal suture has occurred.

Enterocutaneous fistulae

These fistulae are tracts leading from the bowel to the skin surface. Low residue enteral feeds are well tolerated and do not contribute to losses from distal bowel fistula. Sodium and magnesium replacement may be necessary if the fistula drains small bowel contents. The use of antidiarrhoeal or antisecretory drugs may reduce fistula losses sufficient to allow healing. Enteral feeding with predigested formula may also be successful if a somatostatin analogue (octreotide) is given to reduce gastrointestinal secretions. Nutritional support decreases or modifies the composition of the gastrointestinal secretions and is considered to have a primary therapeutic role in the management of patients with a fistula (Dudrick *et al.*, 1999).

Chylothorax

Chylothorax is the outcome of a rare but serious complication of thoracic surgery or major neck dissection, resulting in damage to the thoracic duct. Drainage of

chyle from the thoracic duct injury into the pleural cavity results in chylothorax, which is relieved by chest drain insertion.

Most nutrients, including medium chain triglycerides (MCTs), are absorbed across the gastrointestinal tract into the portal circulation for transport to the liver. Dietary fats are insoluble in aqueous solutions such as blood, so are packaged into chylomicrons within the intestinal cells and then travel as chyle (fat rich lymph fluid) in the interstitial fluid within the lymphatic system. Chyle also contains quantities of protein, e.g. albumin, lymphocytes and antibodies and has an electrolyte composition similar to that of plasma. Chyle flow is reduced by fasting and increased by oral fluids, especially those high in long chain fatty acids. Intravenous fluids have no effect on chyle flow.

Chylothorax can be managed conservatively by following a very low fat diet (ideally providing <15 g of fat/day) and substituting MCTs for longer chain fatty acids in enteral or oral diets, or by bypassing the thoracic duct completely and using PN (which can contain long chain fatty acids). A chest drain relieves the chyle collection. If conservative management fails, ligation of the thoracic duct, traditionally carried out by thoracotomy is required. The advent of video assisted thoracoscopic surgery (VATS) permits a laparoscopic approach to ligation of the thoracic duct (Kumar *et al.*, 2004).

Acute pancreatitis

Early EN modulates the stress response, promotes more rapid resolution of pancreatitis and results in a better outcome compared to PN (McClave *et al.*, 2006). Enteral nutrition attenuates inflammation, reduces the incidence of septic complications and provides a more cost effective approach to postsurgical feeding than PN (Louie *et al.*, 2005) (see Chapter 7.4.5). The use of antioxidants has been shown to improve outcome (Braganza *et al.*, 2011), but this remains an area of controversy,

Open abdomen

Occasionally, patients undergoing abdominal surgery develop abdominal compartment syndrome (ACS); a massive intestinal oedema following abdominal laparotomy that renders the abdomen difficult to close surgically. Closure of the abdomen increases intra-abdominal pressure to such an extent that cardiovascular, respiratory and renal function is compromised. The abdomen is therefore left open but covered until swelling subsides and surgical closure can be achieved. It is possible to enterally feed a patient with an open abdomen without complication (Cothren *et al.*, 2004).

High output stomas and intestinal failure

The small intestine is initially maladapted to the uptake of sodium and water; a process usually confined to the large bowel. Net secretion occurs in the upper small intestine to increase the sodium content of luminal fluid

and will have the effect of increasing stoma losses. Restricting the intake of salt poor fluids to <500 mL/day and sipping sodium rich oral rehydration solution, e.g. WHO rehydration solution or double strength Dioralyte or Rehydrat, can reduce small intestine secretions, minimise the fluid load through the small intestine and increase the chance of absorption. Alternatively, patients can take oral salt tablets *pro rata* with salt poor fluids for a similar effect (see Chapter 7.4.9).

The enhanced recovery after surgery programme

Traditionally, the use of nutritional support was a controversial postoperative therapeutic intervention. Perioperative use of nutritional support was reported to be *ad hoc* in many UK hospitals (Murphy *et al.*, 2006), with many patients remaining nil by mouth for the first week postoperatively. Parenteral nutrition was frequently used to provide nutritional support postoperatively. However, its use tended to be delayed and initiated only after the development of major surgical complications.

Over the past decade, the development of the ERAS programme has revolutionised the care of major elective surgical patients across Europe and the UK. This patient centred method optimises surgical outcome by improving clinical outcomes and patient experience. The ERAS programme was first described by Kehlet & Mogensen (1999) and it aims to improve the quality of care provided to patients who undergo major surgery. With improved care quality and reduced harm, it is assumed that the hospital stay will become more efficient and hospitals should benefit from the programme by savings in bed days (NHS Wales, 2010).

Enhanced recovery is sometimes referred to as fast track or accelerated surgery, and is supported by a growing base of clinical and research evidence (see the ESRA Society UK web site, www.erasuk.org). Enhanced recovery principles include:

- Optimising the patient's health/medical condition preoperatively.
- Assessing risk and fitness for surgery at preoperative assessment.
- Reducing starvation by using carbohydrate loading drinks up to 2 hours before surgery.
- Using minimally invasive surgery where possible.
- Using a clear and structured approach to postoperative management, including pain relief.
- Early mobilisation and early nutrition.

Enhanced recovery is dependent on the engagement, commitment and involvement of all members of the multidisciplinary team at all stages of the patient's care, starting at general practice surgery and continuing through the hospital stay and during recuperation in the patient's own home. Nutritional screening, assessment and early EN are key components of the ERAS pathway. The NHS enhanced recovery surgical pathway is shown in Figure 7.17.5; this is now embedded within the NHS.

7.17.6 Wound healing, tissue viability and pressure sores

Christina Merryfield

Key points

- Malnutrition impairs wound healing.
- Micronutrient status should be checked and deficiencies corrected.
- There is no additional benefit for supplemental intakes of micronutrients in the absence of deficiency.
- It is important to identify other local and systemic factors that may delay or impede healing, e.g. medication, anaemia, smoking and age.

In the early 1990s wound care gained importance with a rapid expansion of outpatient clinics and the emergence of multidisciplinary team experts in wound care (Peirce, 2007). Today's clinical setting has a critical dependence on technology and rapid advancement of healthcare practice. Nutrition continues to be essential in dealing with wound care management; it was Florence Nightingale who defined the nursing role as *'preparing the patient for the most favourable condition for healing'* (Hurd, 2003).

A wound may be described in many ways; by its aetiology, anatomical location and whether it is acute or chronic (Enoch & Price, 2004). A wound is a breakdown in the protective function of the skin, with the loss of continuity of epithelium with or without loss of underlying connective tissue (muscle, bone, nerves) (Leaper & Harding, 1998). Wounds occur following injury to the skin, underlying tissues or organs caused by surgery, trauma, cuts, chemicals, heat or cold, friction, shear force, pressure or disease, such as leg ulcers or carcinomas (Hutchinson, 1992). A pressure ulcer is defined as a localised injury to the skin and/or underlying tissue, usually over a bony prominence as a result of pressure, or pressure in combination with shear and/or friction. A number of contributing or confounding factors are also associated with pressure ulcers; the significance of these factors has yet to be elucidated. Wound healing can be defined as the physiology by which the body replaces and restores function to damaged tissues (Shipperley & Martin, 2002).

Diagnostic criteria and classification

Skin wounds will commonly result in the exposure of dermal tissues to the environment, haemorrhage, and loss of body fluids (water and plasma), micronutrients and metabolites, thus disturbing intercellular relationships (Lansdown, 2001). Wounds are often divided into acute or chronic and heal by primary or secondary intention. Acute wounds result from surgery or trauma and usually have a relatively short, uneventful healing time. Chronic wounds such as leg ulcers, pressure ulcers, diabetic foot ulcers and malignant wounds have prolonged healing times, are prone to episodes of infection and may

have increased levels of exudate due to prolonged inflammation (Gray *et al.*, 2006). Common types of chronic wounds are venous, arterial, neuropathic and pressure. Other important causes include malignancy, drug induced ulcers and vasculitis (Fan Wai-Ping *et al.*, 2010).

A pressure ulcer is an area of damage that is caused by unrelieved pressure, friction and/or shear forces. Currently there are four stages of pressure ulcers, plus two additional stages for deep tissue injury and unstageable pressure ulcers (Black *et al.*, 2007). Stage I and II ulcers generally are considered the least severe and stage IV ulcers are considered the most severe, but a broad range of skin damage or necrosis may be represented within the stage III classification. A stage III wound may appear shallow and superficial or as a full thickness wound (Tempest *et al.*, 2010).

Process of wound healing

The process of wound healing can be divided into three overlapping phases:

- Inflammatory.
- Proliferation.
- Maturation and remodelling.

Some wounds heal with routine wound care; however, those with rough edges and tissue deficit are likely to take longer to heal. The inflammatory stage occurs during the first few days and the wound area attempts to restore homeostasis by constricting blood vessels to control bleeding. Platelet aggregation and thromboplastin make a clot and inflammation occurs. The proliferative stage lasts 3 or more weeks. Granulation occurs and collagen is formed to fill the wound and new blood vessels are formed. The maturation and remodelling stage may last up to 2 years during which time new collagen is synthesised and eventually scar tissue is formed (RCN, 2005) (Figure 7.17.6).

Healing of wounds, whether from accidental injury or surgical intervention, involves the activity of an intricate network of blood cells, tissue types, cytokines and growth factors. This results in increased cellular activity, which intensifies the metabolic demand for nutrients (MacKay

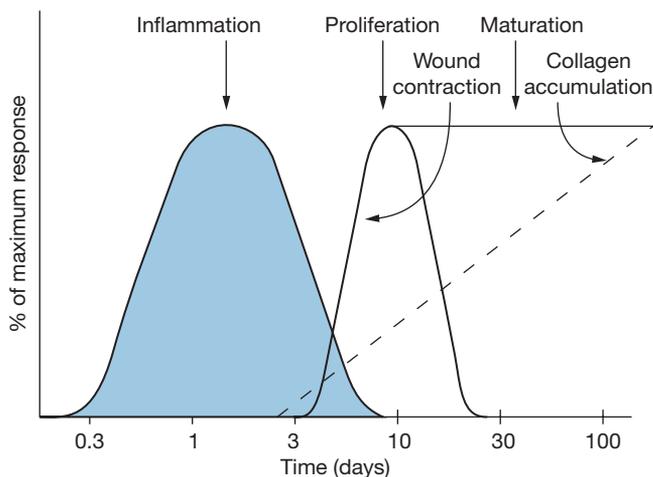

Figure 7.17.6 Stages of wound healing (source: Royal College of Nursing, 2005, figure 1, p. 30. Reproduced with permission of the Royal College of Nursing)

& Miller, 2003). The aim of wound healing management is to achieve a stable wound that has healthy granulation tissue tone characterised by a well vascularised wound bed. Good management should remove, or at least minimise, factors that delay healing (Enoch & Harding, 2003).

Disease consequence and public health

In the UK, chronic wounds represent a significant burden to patients and the NHS; approximately 200 000 patients have a chronic wound. Common symptoms of ulceration include pain, exudate and odour, and these symptoms are frequently associated with poor sleep, loss of mobility and social isolation. The cost of chronic wound care in an average general district hospital has been estimated to be £600 000 to £3 million per year (NHS Institute for Innovation and Improvement, 2009). It is estimated that one in five hospitalised patients have a pressure ulcer; this represent at least 20 000 hospital patients in the UK at any time (Posnett & Franks, 2008). Trends in patients with chronic wounds in the UK are likely to increase due to an ageing population. Care of pressure ulcers in nursing homes has been estimated to account for 4% of the NHS annual spending on budget (Bennett *et al.*, 2004). The scale of wound care in terms of the personnel and beds required per health district has been reported to be equivalent to 88.5 whole time equivalent nurses and up to 87 hospital beds (Drew *et al.*, 2007).

Good nutritional status is essential for wound healing to take place. Ignoring nutritional status may compromise the patient's ability to heal and subsequently prolong the stages of wound healing (Russell, 2001). Malnutrition is frequently undetected and untreated, causing a wide range of adverse consequences such as impaired wound healing and subsequently increased length of hospital stay. In 2010 34% of patients were found to be at risk of malnutrition (BAPEN, 2010), which is higher than the overall prevalence found in the 2008 and 2007 surveys. This represents a considerable number of people at risk of poor wound healing (see Chapter 6.2). The use of

nutritional screening or assessment tools appears to be more prevalent in managing patients at risk of pressure ulcers. However, they should not replace clinical judgement (EPUAP, 2003).

Assessment

Assessment should include the following (see Chapter 2.2 and Chapter 2.3).

Anthropometry

This should include weight, height and calculated body mass index (BMI). Mid upper arm circumference (MUAC) is a useful alternative indicator of nutritional status if it is not possible to measure height or weight. Impaired hand grip strength has been shown to be a popular marker of nutritional status and is an indicator of increased postoperative complications, increased length of hospitalisation, higher rehospitalisation and decreased physical status (Norman *et al.*, 2011). It is essential that patients and care home residents be screened for the risk of malnutrition as recommended by the National Institute for Health and Care Excellence (NICE, 2006).

Biochemical assessment

In general, it is unlikely that biochemical measurements will provide more information than other indicators such as undesired weight loss, although there may be an association between albumin level and pressure ulcers.

Clinical assessment

Assessment tools such as the Waterlow pressure ulcer risk assessment tool is frequently used in the UK; it incorporates a scoring system and provides guidance associated with levels of risk status (Waterlow, 2005). The assessment incorporates BMI and a malnutrition screening tool such as the Malnutrition Universal Screening Tool ('MUST') (see Chapter 6.2).

Dietary assessment

It is fundamental to assess whether the patient has an optimum nutritional status to allow wounds to heal. A diet history and/or food chart at ward level will help to assess the patient's intake.

Clinical investigation and management

Factors that may delay or prevent wound healing can be localised or systemic throughout the body, as shown in Table 7.17.19.

An individual's potential to develop pressure ulcers may be influenced by various factors (NICE, 2005), including:

- Reduced mobility or immobility.
- Sensory impairment.
- Acute illness.
- Level of consciousness.

Table 7.17.19 Factors that may delay or impede wound healing (Gottrup *et al.*, 2007)

Local factors	Systemic factors
Primary Blood supply (tissue perfusion) Tissue oxygen tension	Pivotal Haemodynamic conditions (perfusion, hypovolaemia, hypoxia, pain, etc.)
Secondary Tissue damage Mechanical stress of the tissue Hypothermia Pain Radiation Infection Surgical technique Suture technique and materials Others (vasculitis, immunological, etc.)	Important Age Smoking Medication Diseases Nutritional status Anaemia Alcoholism Radiation Others (immunological, etc.)

- Extremes of age.
- Vascular disease.
- Severe chronic or terminal illness.
- Previous history of pressure damage.
- Malnutrition and dehydration.

Wound healing assessment is critical for the planning and evaluation of care, and should include (Gottrup *et al.*, 2007):

- Medical history.
- Cause of tissue damage.
- Medication and allergies.
- Other diseases, e.g. diabetes, vascular disease and immune compromise.
- Lifestyle and environment – obesity, tobacco and/or alcohol use.
- Impaired mobility.
- Inadequate social network, carer support.
- Psychological problems.

An infected pressure ulcer will also increase tissue damage, causing further strain, a deeper ulcer and an increase in nutritional demands (Hurd, 2003). The infection requires treatment in order for the wound to heal.

Nutritional management

Nutritional requirements increase in the presence of a chronic wound and if the demand is not met, this can have a significant impact on wound healing. Metabolic demand rises in the presence of a wound due to greatly increased cell activity in the region (Casey, 1998). Optimum nutrition is a key factor in maintaining all phases of wound healing. Protein energy malnutrition (PEM) in the presence of a wound will lead to the loss of lean body tissue or protein stores, which will impede the healing process (Demling, 2009). A balance of all food groups is required to meet the essential nutrient needs for wound healing. The role of specific nutrients in wound healing is shown in Table 7.17.20.

Macronutrients

Metabolic or energy demands rise significantly in the presence of a wound. It has been estimated that the basal metabolic rate rises by up to 10% following even minor surgery and can rise by 100% or more in the presence of severe burns (White & Baxter, 1998). It is estimated that an individual may require a minimum of 30–35 kcal/kg of body weight/day (EPUAP, 2003). Activation of the immune system and the action of white blood cells demand higher levels of energy. Intake of insufficient energy will lead to a decrease in fat stores and the loss of protective cushioning, thus increasing the likelihood of pressure injuries (Todorovic, 2003). Also, low energy intake is usually associated with a lower intake of micronutrients and resultant deficiencies may impact wound healing (Thomas, 2001).

Carbohydrates together with fats are the primary source of energy in the wound healing process. Glucose is the major source of fuel used to provide energy for new tissues and prevent depletion of protein (Guo & DiPietro, 2010). Fat has a role in cell membrane structure and function. n-3 Fatty acids may have a role in increasing proinflammatory cytokine production at wound sites and therefore have the potential to affect wound healing during the inflammatory stage (McDaniel *et al.*, 2010). There is also some evidence that n-3 fatty acids may have a benefit when administered pre- and post-operatively as immune feeds (Moskovitz & Kim, 2002).

There is a direct correlation between wounds that are non-healing and the indication of PEM. Therefore, wound healing depends on good wound management along with the reversal of PEM (Hurd, 2003). Protein malnutrition delays wound healing by impairing collagen synthesis and deposition, and decreasing scar strength (Arnold & Barbul, 2006). Prolonged inadequate protein intake may promote tissue oedema, which delays healing by slowing oxygen diffusion from capillaries to cell membranes. Available nutrients will be drawn to the wound site initially, with lean muscle mass used to provide the amino acids necessary for wound healing. A 15% or greater loss of lean body mass is associated with impaired wound healing; a 30% or greater loss is associated with development of new wounds (Demling, 2009). Minor surgery may not significantly increase protein requirement; however, if the patient is already malnourished, wound healing will be adversely affected unless dietary protein intake is increased (MacKay & Miller, 2003). Studies have shown that increasing the protein in the diet of patients with chronic ulcers leads to faster healing times when compared with low protein diets (Hurd, 2003).

There have been mixed results on the impact of using glutamine in burns patients. However, in some experimental studies there seems to be some positive impact on wound healing (Robert & Demling, 2009).

Micronutrients

Micronutrients serve a vital role in wound healing and metabolic functions. Vitamins A, B₁, B₂ and B₆ are vital to energy production and collagen deposition (Woodward

Table 7.17.20 Role of key nutrients in tissue viability and wound healing (Johnston, 2007)

Nutrient	Function	Comments
Fat	Energy Cell membrane component Involved in formation of inflammatory mediators and clotting components	
Carbohydrate	Energy	
Protein	Tissue synthesis and repair	Excess protein can stress the liver and kidney
Vitamin A	Enhances immune response Antioxidant Promotes collagen synthesis and epithelialisation	Excess toxic
Vitamin C	Antioxidant Promotes collagen synthesis and angiogenesis Enhances iron absorption Promotes immune function	Additional vitamin C not beneficial unless deficient
Selenium	Antioxidant	Deficiency relatively common
Copper	Collagen cross linkage	Deficiency rare
Manganese	Component of enzymes needed for tissue Regeneration	Deficiency rare Magnesium can substitute for manganese when manganese status is poor
Zinc	Fibroblast proliferation Component of enzyme systems Collagen synthesis Immune function	Zinc supplement will not accelerate healing if not deficient in patients Can cause toxicity
Iron	Promotes collagen synthesis Improves O ₂ , nutrient and components of healing delivery to tissue Component of many enzyme systems	Blood loss can lead to anaemia
B vitamins	Efficient energy usage Collagen formation Component of enzyme systems	
Vitamin E	Antioxidant Enhances immune response	Excess can impair wound healing
Vitamin K	Blood clotting	Deficiency very rare

et al., 2009). Copper, zinc and selenium have a role in immune function and can be lost in significant amounts in patients with wounds, particularly in the burn exudate and urine of patients with severe burns. Patients with total body surface area burns of 30% or greater should be given intravenous supplementation for the first 8 days from admission and serum levels monitored on a weekly basis (Berger *et al.*, 1998).

Vitamin C is essential for collagen formation and critical for wound healing. An eight-fold increase in wound dehiscence has been reported in patients who had depleted concentrations of vitamin C compared with those who had adequate concentrations (Zaloga, 1994). It has been suggested that patients with stage III or IV pressure ulcers may benefit from supplementation with 500 mg twice daily for 14 days (Castellanos *et al.*, 2003). However, discretion must be used when recommending vitamin C supplementation as toxicity may occur in patients who are at risk for oxalate stone formation, although the risk is low (Posthauer, 2006; Flanigan, 1997). To maximise wound healing but minimise soft tissue damage in patients with renal failure, a suggested maximum recommended intake is 100 mg/day (Winkler,

2000; Clark, 2002). Doses over 200 mg/day are not usually required as tissue saturation occurs at this level (Woodward *et al.*, 2009). Some studies have shown that vitamin C supplementation at 60–200 mg/day only helps a pressure ulcer to heal if the patient is deficient in vitamin C. Vitamin C supplementation in non-deficient patients has not been shown to accelerate wound healing (Ringsdorf & Cheraskin, 1982).

Adequate concentrations of vitamin A appear to influence the body's therapeutic inflammatory response to wounds (Arnold & Barbul, 2006). Vitamin A plays a role in cell division, cell differentiation and immune system function (National Institutes of Health, 2009). Depletion of vitamin A, although rare, can result in impaired wound healing and susceptibility to infection (Ross, 2002).

Zinc has an identifiable role in all stages of wound healing (Bradbury, 2006). Deficiency has been associated with delayed wound healing by reducing the rate of epithelialisation, and decreasing scar strength and collagen synthesis (Andrews *et al.*, 1999). Although zinc supplementation is often recommended, it does not appear to aid the healing of leg ulcers, although it may be beneficial in those with venous leg ulcers and low serum zinc

(Wilkinson, 2012). A suggested supplementation for non-healing pressure ulcers is 15 mg/day and 20–25 mg/day for larger non-healing wounds, but this should be limited to 14 days (Woodward *et al.*, 2009). It has been acknowledged that excess zinc in animals can have a detrimental effect on wound healing (Lim *et al.*, 2004). In humans, excess zinc has been shown to induce both copper and iron deficient anaemia, which could result in decreased oxygen delivery to the wound (Gray, 2003). There appears to be more support for supplementing zinc deficient patients in order to improve wound healing rather than routine zinc supplementation (Bradbury, 2006).

Iron

Iron is necessary for the formation of collagen and to support tissue oxygenation at the wound site. Low haemoglobin levels need to be corrected before healing can continue effectively (McClemont, 1984). Iron also provides oxygen to the site of the wound (Woodward *et al.* 2009).

Fluid

Adequate fluid is required to maintain good skin tone and blood flow to wounded tissues, which is critical for the prevention of skin breakdown. A general guide of 30–35 mL/kg of body weight/day (minimum of 1500 mL/day) is recommended, but should be adjusted depending on the patient's clinical condition, such as cardiac and renal problems for which fluid may be restricted (Todorovic, 2003). Dehydration is also a major risk factor for the development of pressure sores as the skin becomes inelastic, fragile and more susceptible to breakdown (Horns *et al.*, 2004).

Drug–nutrient interactions

Medications may have a positive or negative effect on wound healing. Drugs that impair wound healing include those that are frequently used in the clinical setting. Corticosteroids inhibit fibroplasia and the formation of granulation tissue. High doses have a major effect on wound healing because of their interference with vascular proliferation and their effect of delaying epithelialisation. Antiplatelet drugs, including aspirin and other non-steroidal anti-inflammatory drugs, have a dose dependant effect as they act as inflammatory mediators. Anticoagulants such as warfarin and heparin inhibit proper coagulation and adversely affect wounds. Conversely, drugs such as prostacyclin can be used to promote healing in arterial and vasculitic ulcers. Calcium antagonists can help improve blood flow (Sussman, 2007).

Appendix A1 Generic framework for critical appraisal

Table A1.1 Generic framework for critical appraisal

Article section	Example questions that should be answered
Title	Is it accurate?
Introduction	Does it put the study entirely into context? Is the literature used to support statements? Is it contemporary? Do the authors use the literature to justify why they did the study and how it was done? Does the topic relate to your area of practice? Is the research question or aim of the study clearly stated?
Methods	Is the design logical and clearly described? Has the correct methodology been used? Is the study design able to answer the research question or achieve the aim? Is the study population and recruitment clearly described? What was the sampling strategy? Is there a sample size calculation? Was ethical approval given for the study if appropriate? If not, why not? Is there a clear, logical description of the study? Has the correct data been collected to answer the research question or achieve the aim? How were the data collated and analysed? Did the authors test to see if the data were normally distributed or not? What statistical tests were used? Are they appropriate? Was a statistician involved in the analysis? If the study is qualitative, how have the data been collated and analysed? Did the authors validate their interpretations? Is there a clear audit trail? Was an analysis package used?
Results	Are the results reported clearly and concisely? Do the results relate to the research question or aim and literature review? Are there results for all the data described in the methods? Are results given for data collection that was not described in the methods? Are the tables and figures used appropriately? Is the statistical analysis interpreted correctly? For qualitative research are the themes appropriate and clearly described with examples? Was the method of analysis appropriate?
Discussion	Does the discussion discuss the actual results or what the authors would like to have found? Are the results discussed in the context of the literature? Was the research question answered or aim achieved? How well? Are the weaknesses in design acknowledged?
Conclusion	Do they relate directly to the study? What are the implications for practice and further research?

Appendix A2 Micronutrients

Table A2.1 Vitamins

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Fat soluble vitamins					
A (retinol, beta-carotene)	Rhodopsin production in retinal rods, which are involved in adaptation of vision in the dark Growth Cell differentiation Embryogenesis Immune response	Retinol – liver and liver products, kidney and offal, oily fish and fish liver oils, eggs Beta-carotene – carrots, red peppers, spinach, broccoli, tomatoes	0–1 – years 350 µg of retinol/day 1–3 years – 400 µg of retinol/day 4–10 years – 500 µg of retinol/day 11–14 years – 600 µg of retinol/day Males 15+ years – 700 µg of retinol equivalent/day Females 15+ years – 600 µg of retinol equivalent/day Pregnancy – +100 µg of retinol equivalent/day Lactation – +350 µg of retinol equivalent/day	Eye changes – night blindness xerophthalmia (conjunctival xerosis, Bitot's spots, corneal xerosis, corneal ulceration, corneal necrosis and scars) Epithelial tissues – skin keratinisation (horny plugs block the sebaceous glands, follicular hyperkeratosis Immunity – susceptibility to infectious diseases Can contribute to nutritional deficiency anaemia	Retinol Acute toxicity – >200 mg (0.7 mmol) adults; >100 mg children Vomiting, abdominal pain, anorexia, blurred vision, headache and irritability Chronic toxicity – >10 mg for >1 month Headache, muscle and bone pain, ataxia, skin disorders, alopecia, liver toxicity and hyperlipidaemia. Not all the chronic symptoms are reversible Pregnancy – teratogenic intakes >3 mg/day
D (calciferols)	Precursor of 1, 25-dihydroxyvitamin D controls calcium absorption and excretion; involved in bone mineralisation May inhibit cell proliferation in some forms of cancer	Cod liver oil Oily fish (salmon, mackerel, etc.) Milk Margarine Breakfast cereals Eggs Liver	0–6 months – 8.5 µg/day 7–12 months – 7.0 µg/day 1–3 years – 7.0 µg/day 4–65 years – 0* 65+ years – 10 µg/day Pregnancy – +10 µg/day Lactation – +10 µg/day *Certain at risk groups or individuals may require dietary vitamin D	Rickets (children) Osteomalacia (adults) Impaired immune function (corrected by the administration of vitamin D)	Excess D ₃ from sunlight is converted to inert products Excess from supplements leads to hypercalcaemia, thirst, anorexia, soft tissue calcification, urinary calcium stones

Table A2.1 (Continued)

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
E (tocopherols)	Protects cell membrane and lipoprotein from damages by free radicals Maintains cell membrane integrity Regulates prostaglandin synthesis DNA synthesis	Wheatgerm oil Almonds Sunflower seeds and oil Safflower oil Hazelnuts Peanuts and peanut butter Corn oil	Requirements are influenced by PUFA; 0.4 mg of α -tocopherol/g of dietary PUFAs intake is required Average UK adult diet has 7% energy from PUFAs; therefore, vitamin E requirement is 6 mg for women and 8 mg for men Milk formulae should not be <0.3 mg of α -tocopherol equivalents/100 mL of reconstituted feed and not <0.4 mg of α -tocopherol equivalents/g of PUFA	Reduced tendon reflexes by age 3–4 years In adolescence – loss of touch and pain sensations, unsteady gait, impaired coordination and eye movement Supplementation can reduce similar symptom experiences by those with chronic/severe fat malabsorption, cystic fibrosis, cholestatic liver disease and abetalipoproteinaemia (particularly in children)	At high doses vitamin E acts as an antagonist to vitamins A, D and K >900 mg/kg of diet leads to headaches, nausea, muscle weakness, double vision, creatinuria, gastrointestinal disturbances
K	Synthesis of gamma-carboxyglutamic acid in the liver Essential for blood coagulation and other proteins, including osteocalcin	Green leafy vegetables (spinach, broccoli, cabbage and kale) Vegetable oils especially soyabean oil Eggs Meat Dairy products	No RNI as it is difficult to induce deficiency by dietary manipulation Suggested requirements are 0.5–1.0 μ g/kg/day	Poor blood clotting – low prothrombin activity Newborns are given vitamin K injection at birth (infants do not have bacteria producing vitamin K) Obstructive jaundice (lack of bile leading to poor absorption) Warfarin and dicoumarol (anticoagulants) – block enzymes that recycle vitamin K in the liver	Synthetic preparation of vitamin K ₃ (menadione) – used to treat intracranial and pulmonary haemorrhage in premature infants Overdosage – liver overload and brain toxicity Supplements containing vitamin K should not be taken with anticoagulant drugs
Water soluble vitamins					
C (ascorbic acid)	Powerful reducing agent (antioxidant) Synthesis of collagen Hydroxylation of dopamine to noradrenaline (norepinephrine) Production of carnitine Activation of peptide hormones and releasing factors Synthesis of bile Metabolism of drugs and carcinogens Enhances absorption of iron when consumed in the same meal	Kiwi fruit Citrus fruit (oranges, lemons, satsumas, etc.) Blackcurrants Guava Mango Papaya Pepper Brussels sprouts Broccoli Sweet potato	0–1 years – 25 mg/day 1–10 years – 30 mg/day 11–14 years – 35 mg/day Adults (15+ years) – 40 mg/day Pregnancy – +10 mg/day (last trimester only) Lactation – +30 mg/day Regular smokers – 80 mg/day	Scurvy Connective tissue abnormalities, poor wound healing, weakness, fatigue, bleeding gums (gingival), hyperkeratosis and skin haemorrhages	No evidence to support high doses (1–10 g/day) to prevent the common cold (although they may reduce symptom severity) Sudden cessation of high dose supplements may precipitate rebound scurvy High doses associated with diarrhoea and risk of kidney oxalate stone formation

(Continued)

Table A2.1 (Continued)

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Thiamine (B ₁)	Thiamine forms part of the coenzyme thiamine pyrophosphate (TPP) involved in decarboxylation steps ∴ Metabolism of fat, carbohydrate and alcohol	Cereal products Yeast and yeast products Pulses Nuts Pork and other meats Vegetables Milk	0–12 months – 0.3 mg/1000 kcal 1–50 years – 0.4 mg/1000 kcal No increment for pregnancy or lactation	Beriberi Wet – cardiac: high output cardiac failure, bounding pulse, warm extremities, peripheral oedema and cardiac dilatation Dry – neurological: peripheral neuropathy, foot drop, absent knee jerk reflexes Wernicke–Korsakoff syndrome – Wernicke’s encephalopathy and Korsakoff’s psychosis	>3 g/day – headache, irritability, insomnia, weakness, tachycardia, pruritus Regular large intakes can cause an allergic reaction
Riboflavin (B ₂)	Oxidation–reduction reactions in metabolic pathways Promotion of normal growth Assists the synthesis of steroids, red blood cells and glycogen Maintenance of mucous membrane, skin, eyes and nervous system Aids iron absorption	Eggs Milk and milk products Liver and kidney Yeast extract Fortified breakfast cereal	0–1 years – 0.4 mg/day 1–3 years – 0.6–1.0 mg/day 4–6 years – 0.8 mg/day 7–10 years – 1.0 mg/day Males 11–14 years – 1.4 mg/day Males 15+ years – 1.3 mg/day Females 11+ years – 1 mg/day Pregnancy – +0.3 mg/day Lactation – +0.5 mg/day	Mucosal lesions of the mouth, angular stomatitis, cheilosis, glossitis and magenta tongue Lesions of the genitalia, seborrhoeic skin lesions and vascularisation of the cornea Poor growth in the young/neonates	Low risk as only small amounts absorbed through the gastrointestinal tract in a single dose
Niacin (nicotinamide, nicotinic acid) (B ₃)	Incorporated into pyridine nucleotide coenzymes Nicotinamide adenine dinucleotide (NAD) Nicotinamide adenine dinucleotide phosphate (NADP) Glycolysis Fatty acid metabolism Tissue respiration Detoxification	Beef Pork Chicken Wheat flour Maize flour Eggs Milk	All ages – 6.6 mg/1000 kcal Pregnancy – no increment Lactation – +2.3 mg/day	Pellagra (the three Ds): Dermatitis – skin exposed to the sun becomes inflamed and pigmented, cracks and peels. Casal’s collar Diarrhoea – often accompanied by an inflamed tongue Dementia – ranging from mild confusion and disorientation to mania, occasionally psychoses	Nicotinic acid ≥200 mg/day leads to vasodilatation and hypotension (1–2 g/day are used in the treatment of hypertriglyceridaemia and hypercholesterolaemia) 3–6 g/day leads to reversible liver toxicity, changes in liver function, carbohydrate tolerance and uric acid metabolism

Table A2.1 (Continued)

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Folate (folic acid)	Involved in single carbon transfer reactions – synthesis of purines, pyrimidines, glycine and methionine Essential for the synthesis of DNA and RNA 5-methyl tetrahydrofolate (folate derivative) requires vitamin B ₁₂ to enable the use of methionine synthase in the synthesis of methionine and tetrahydrofolate	Rich sources (>100 µg/serving) – Brussels sprouts, kale, spinach. Good sources (50–100 µg/serving) – fortified bread and breakfast cereals, broccoli, cabbage, cauliflower, chickpeas, green beans, kidney, beans, peas, spring greens Moderate sources (15–15 µg/serving) – potatoes, most other vegetables, most fruit, most nuts, brown rice, wholegrain pasta, oats, bran, some breakfast cereals, cheese, yoghurt, milk, eggs, salmon, beef, game	0–1 years – 50 µg/day 1–3 years – 70 µg/day 4–6 years – 100 µg/day 7–10 years – 150 µg/day Adults (11+ years) – 200 µg/day Pregnancy – +100 µg/day Preconception and until 12th week of pregnancy – 400 µg/day (to prevent first occurrence of neural tube defects); 5000 µg/day (to prevent recurrence of neural tube defects)	Secondary deficiency (from malabsorption, certain drugs, late pregnancy and some disease states) Megaloblastic anaemia Infertility Diarrhoea	Low toxicity Folate supplements given to patients with developing vitamin B ₁₂ deficiency may obscure diagnosis Folate supplements in early pregnancy reduce neural tube defects Large doses (200 µg/day) reduce plasma homocysteine levels (raised plasma homocysteine – risk factor for cardiovascular disease)
Vitamin B ₆ (pyridoxine)	The three naturally occurring forms of vitamin B ₆ – pyridoxine, pyridoxal, and pyridoxamine – can be converted to the coenzyme pyridoxal-5-phosphate, which is involved in amino acid metabolism Also involved in the conversion of glycogen to glucose in muscles, the conversion of tryptophan to niacin, and in hormone metabolism	Meat Wholegrain cereals Fortified cereals Bananas Nuts Pulses	0–6 months – 8 µg/day 7–9 months – 10 µg/day 10–12 months – 13 µg/day 1–50+ years – 15 µg/day	Severe deficiency of vitamin B ₆ is rare. Patients suffering malabsorption, receiving dialysis or alcoholics are at risk of deficiency Deficiency symptoms – lesions of the lips and corners of the mouth, and inflammation of the tongue	Intakes of 500 mg/day and above have been associated with peripheral neuropathy The Department of Health recommends not to exceed a daily dose of 10 mg/day

(Continued)

Table A2.1 (Continued)

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Cobalamin (B ₁₂)	Recycles folate coenzymes. Normal myelination of nerves. Synthesis of methionine from homocysteine.	Meat and meat products Eggs Milk and dairy products Fish and fish products Yeast products and fortified vegetable extracts Fortified breakfast cereal	0–6 months – 0.3 µg/day 7–12 months – 0.4 µg/day 1–3 years – 0.5 µg/day 4–6 years – 0.8 µg/day 7–10 years – 1.0 µg/day 11–14 years – 1.2 µg/day 15+ years – 1.5 µg/day 19–50+ years – 1.5 µg/day Lactation – +0.5 µg/day	Malabsorption secondary to atrophy of the gastric mucosa leads to reduced intrinsic factor/ileum disease Pernicious (megaloblastic) anaemia and/or neurological problems such as loss of sensation	No reports in humans
Biotin (B ₇)	Coenzyme for several carboxylases including fatty acid synthesis and metabolism, gluconeogenesis, metabolism of branched chain amino acids	Liver Kidney Milk Eggs Dairy products	It is believed that intakes of between 10 and 200 µg/day are safe and adequate	Deficiency is rare. Reported in patients receiving total parenteral nutrition, when it should be added to the infusion solution Scaly dermatitis Glossitis Hair loss Anorexia Depression Hypercholesterolaemia Egg whites contain the protein avidin; eaten in great amounts this can bind with biotin and prevent absorption. Prevented by heating the egg whites	There have been no reports of biotin toxicity
Pantothenic acid (B ₅)	Part of coenzyme A (CoA) and is involved in the tricarboxylic acid cycle Essential for carbohydrate and lipid metabolism	Yeast Offal Peanuts Meat Eggs Green vegetables	Information is not available to derive recommended intakes, but intake of 3–7 mg/day is considered adequate	Spontaneous deficiency has not been described Deficiency symptoms – burning sensation in the feet, depression, fatigue, vomiting and muscle weakness	No specific toxic effects, although large doses may cause gastrointestinal symptoms, such as diarrhoea

PUFA, polyunsaturated fatty acid.

Table A2.2 Minerals

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Calcium (Ca)	Structural rigidity of bones and teeth, as hydroxyapatite Intracellular signalling control of muscles and nerves Blood clotting Cofactor for enzymes, e.g. lipase	Dairy sources – milk, cheese, yoghurt Cereals and cereal products, e.g. breakfast cereals, white bread Pulses e.g. baked beans, lentils, chickpeas	0–12 months – 525 mg/day 1–3 years – 350 mg/day 4–6 years – 450 mg/day 7–10 years – 550 mg/day Boys 11–18 years – 1000 mg/day Girls 11–18 years – 800 mg/day Men 19+ years – 700 mg/day Women 19+ years – 700 mg/day Lactation – +550 mg/day	Deficiency symptoms – Stunted growth in childhood, not reaching peak bone mass in early adulthood, higher risk of developing osteoporosis in later life	Tight homeostatic control of Ca generally prevents Ca accumulation in blood and tissues (hypercalcaemia) Intakes of up to 2 g of Ca/day have been shown to be safe Milk alkali syndrome (MAS) results from excessive intake of Ca and alkali as antacid tablets, Ca supplements and milk MAS has been reported as Ca carbonate intakes of ≥ 4 g/day or more. A rare cause of MAS is excessive intake of Ca by the ingestion of betel nut paste containing oyster shells
Phosphorus (P)	Skeletal rigidity – Ca compound hydroxyapatite Energy for metabolism – phosphate bonds in adenosine triphosphate (ADP) Constituent of phospholipids and membranes Constituent of nucleic acids	Milk and dairy products (except butter) Cereals and cereal products Meat and meat products Fish Nuts Fruit and vegetables	0–12 months – 525 mg/day 1–3 years – 350 mg/day 4–6 years – 450 mg/day 7–10 years – 550 mg/day Males 11–18 years – 1000 mg/day Females 11–18 years – 800 mg/day Adults 19+ years – 700 mg/day Lactation – +550 mg/day	Hypophosphataemia occurs in poorly managed parenteral nutrition and refeeding syndrome, sepsis, liver disease, alcoholism, diabetic ketoacidosis and excessive use of aluminium containing antacids Deficiency at birth possibly linked to rickets at a later age	>70 mg/kg leads to high serum levels that are above any likely to be taken in foods High intakes balanced by excretion in urine; disrupted in renal patients P:Ca ratio should not be above 2.2 mg of P to 1 mg of Ca
Iron (Fe)	As haemoglobin – transport of oxygen, cell respiration As myoglobin – oxygen storage in muscles Other functions – component of enzymes, including those involved in immune functions, and cytochromes, which are essential for energy production	Very good sources – meat, especially offal (but not during pregnancy due to high vitamin A level), fish, eggs, meat extracts Good sources – bread and flour, breakfast cereals, vegetables (dark green) and pulses, nuts and dried fruit (prunes, figs, apricots), yeast extract	0–3 months – 1.7 mg/day 4–6 months – 4.3 mg/day 7–12 months – 7.8 mg/day 1–3 years – 6.9 mg/day 4–6 years – 6.1 mg/day 7–10 years – 8.7 mg/day Boys 11–18 years – 11.3 mg/day Girls 11–18 years – 14.8 mg/day Men 19–50+ years – 8.7 mg/day Women: 19–50 years – 14.8 mg/day 50+ years – 8.7 mg/day	Deficiency symptoms Pallor of finger nails and mucous membranes in the mouth and under eyelids Koilonychia (spoon shaped nails) Tachycardia and in severe cases, oedema Fatigue, breathlessness on exertion, insomnia, giddiness, anorexia Paraesthesia of fingers and toes	Tight metabolic control prevents dietary excess. Toxicity due to Fe supplement overdose causing gastrointestinal symptoms, especially constipation. Absorption of other micronutrients, e.g. Zinc are reduced by high dose Fe supplements. The hereditary disease primary idiopathic haemochromatosis is characterised by high levels of Fe absorption and tissue deposition

(Continued)

Table A2.2 (Continued)

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Zinc (Zn)	Enzymes – alcohol dehydrogenase, alkaline phosphate, aldolase and RNA polymerase Involved in digestion, carbohydrate and bone metabolism, oxygen transportation Immune response Stabilising the structure of DNA, RNA and ribosomes	Rich sources – whole grains, pork, poultry, milk and milk products, eggs and nuts Very rich sources – lamb, leafy/ root vegetables, crab and shellfish, beef and offal	0–6 months – 4.0 mg/day 7–months–3 years – 5.0 mg/day 4–6 years – 6.5 mg/day 11–14 years – 9.0 mg/day Males 15+ years – 9.5 mg/day Females 15+ years – 7.0 mg/day Lactation: 0–4 months – +6 mg/day 4+ months – +2.5 mg/day	Deficiency symptoms Growth retardation Failure to thrive Delayed sexual maturation Sore throat and immune defects Circumoral and acral dermatitis Diarrhoea Alopecia and neuropsychiatric symptoms	Acute toxicity (>200 mg) – nausea, vomiting and fever 50 mg interferes with copper and iron metabolism 75–300 mg/day – symptoms of copper deficiency, e.g. microcytic anaemia and neutropenia
Copper (Cu)	Incorporated in many metalloenzymes	Offal Nuts Cereals and cereal products Meat and meat products	0–12 months – 0.3 mg/day 1–3 years – 0.4 mg/day 4–6 years – 0.6 mg/day 7–10 years – 0.7 mg/day 11–14 years – 0.8 mg/day 15–16 years – 1.0 mg/day 18+ years – 1.2 mg/day Pregnancy – +0.3 mg/day	Deficiency is rare; can occur in premature infants and in patients receiving total parenteral nutrition Associated with cystic fibrosis, coeliac disease and chronic diarrhoea in children Occurs in the hereditary condition Menkes disease where Cu transport is impaired Deficiency symptoms Failure to thrive in babies Oedema with low serum albumin Fe resistant anaemia Impaired immunity with low neutrophil count Fractures and osteoporosis Abnormal blood vessels due to defects in collagen and elastin Hair and skin hypopigmentation with steely, uncrimped (kinky) hair Neurological abnormalities May be a risk factor for coronary heart disease Associated with raised plasma cholesterol levels and heart related abnormalities	Contamination by Cu water pipes or cooking utensils. Deliberate ingestion of Cu salts Nausea, vomiting, and diarrhoea May be fatal in extreme cases Liver cirrhosis; infants and young children are particularly vulnerable Wilson's disease

Table A2.2 (Continued)

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Iodine	Maintain metabolic rate controlling energy production and oxygen consumption in cells Normal growth and development In foetus and neonate – normal protein metabolism in brain and central nervous system	Milk and dairy products Sea fish, e.g. haddock and cod Seaweed Iodised salt	0–3 months – 50 µg/day 4–12 months – 60 µg/day 1–3 years – 70 µg/day 4–6 years – 100 µg/day 7–10 years – 110 µg/day 11–14 years – 130 µg/day 15+ years – 140 µg/day	Goitre hypothyroidism symptoms include: lethargy, poor cold tolerance, bradycardia and myxoedema In foetus, causes cretinism. Symptoms include mental retardation, hearing and speech defect, squint, disordered stance and gait, growth retardation In infants and children, varying degrees of growth and mental retardation Associated with stillbirth, miscarriage and infertility	High doses lead to hyperthyroidism, toxic nodular goitre and weak association with thyroid cancer if taken at persistently high intakes
Selenium (Se)	Integral part of >30 selenoproteins Glutathione peroxidases – protect against oxidative damage Iodothyronine deiodinases – production of triiodothyronine from thyroxine Selenoprotein P – antioxidant and transport functions	Offal Fish Brazil nuts Eggs Poultry Meat and meat products	0–3 months – 10 µg/day 4–6 months – 13 µg/day 7–12 months – 10 µg/day 1–3 years – 15 µg/day 4–6 years – 20 µg/day 7–10 years – 30 µg/day 11–14 years – 45 µg/day Men: 15–18 years – 70 µg/day 19+ years – 75 µg/day Women 15+ years – 60 µg/day Lactation – +15 µg/day	Endemic causes – Keshan disease (cardiomyopathy), Kashin–Beck disease (musculoskeletal disorder) Iatrogenic causes – TPN, phenylketonuric patients receiving a semi synthetic diet Deficiency symptoms Cardiomyopathy Musculoskeletal disorders	Acute – hypersalivation, nausea, vomiting, garlic smelling breath, diarrhoea, hair loss, restlessness, tachycardia and fatigue Chronic (selenosis) – nail and hair changes, skin lesions and neurological effects; numbness, pain and paralysis Recommended maximum safe intake – 6 µg/kg/day
Magnesium (Mg)	Integral part of bones and teeth; 60% is found in the skeleton Intracellular energy metabolism; a cofactor for enzymes requiring ATP in the replication of DNA, and synthesis of protein and RNA Essential for phosphate transferring systems Muscle and nerve cell function	Green vegetables Pulses and wholegrain cereals Meat Hard drinking water	0–3 months – 55 mg/day 4–6 months – 60 mg/day 7–9 months – 75 mg/day 10–12 months – 80 mg/day 1–3 years – 85 mg/day 4–6 years – 120 mg/day 7–10 years – 200 mg/day 11–14 years – 280 mg/day 15–18 years – 300 mg/day Men 19+ years – 300 mg/day Women 19+ years – 270 mg/day Lactation +50 mg/d	In healthy adults, dietary deficiency is unlikely to occur Low serum Mg levels occur when there are renal losses, malabsorption or changes in tissue distribution due to disease or use of some drugs, e.g. diuretics, refeeding syndrome Deficiency symptoms Cardiac arrhythmias and cardiac arrest Very low levels of Mg are associated with hypocalcaemia	Hypermagnesaemia can occur in renal or adrenal disease

(Continued)

Table A2.2 (Continued)

Vitamin	Function	Food sources	Recommended nutrient intake (RNI)	Deficiency	Toxicity
Manganese (Mn)	Component of several metalloenzymes (e.g. arginase and pyruvate), Needed for enzyme activity such as glutamine synthetase, various hydrolases, kinases, decarboxylases and phosphotransferases	Cereals and cereal products Tea Vegetables	Infants and children – 16 µg/kg/day Men – 3.32 µg/day Women – 2.69 µg/day	In experimental studies, deficiency is linked to delayed growth of fingernails, reddened black hair and scaly dermatitis	Risk is low as high intakes are resolved by the excretion of manganese in bile and urine
Molybdenum (Mo)	Cofactor in xanthine oxidase, sulphite oxidase and aldehyde oxidase – metabolism of purines, pyrimidines, quinolines and sulphites	Offal Nuts Cereals Bread	No RNIs Safe intakes believed to be 50–400 µg/day	Not observed in humans, single case reported following prolonged TPN which lead to mental disturbance and coma Inborn error of metabolism results in abnormal production of the coenzyme leading to abnormal urinary metabolites, neurological and ocular problems Failure to thrive Most severe cases can be fatal at 2–3 years	Little data are available for dietary excess Intakes >100 mg/kg/day have been reported to cause diarrhoea, anaemia and high blood uric acid levels associated with gout
Chromium (Cr)	Believed to be part of the 'glucose tolerance factor' (GTF) – potentiates the action of insulin May participate in lipoprotein metabolism	Meat Wholegrains Legumes Nuts	There are no RNIs for Cr Theoretical requirements: Children – 0.1–1.0 µg/kg/day Adults – 25–30 µg/day	Only observed with long term TPN: impaired glucose tolerance, weight loss, neuropathy, elevated plasma fatty acids, depressed respiratory quotient and abnormal nitrogen metabolism	Hexavalent form is very toxic Two fatalities reported following acute ingestion of large doses as dichromate (75 mg/kg) and chromic acid (4.1 mg/kg). Acute – gastrointestinal haemorrhages, renal and liver abnormalities Chronic – renal failure, liver failure, haemolysis and anaemia

TPN, total parenteral nutrition.

Appendix A3 Dietary reference values

Energy

Table A3.1 Estimated average requirements (EARs) for energy of children 0–18 years (SACN, 2011)

Age	EAR [MJ/day (kcal/day)]	
	Boys	Girls
0–3 months	2.6	2.4
4–6 months	2.7	2.5
7–9 months	2.9	2.7
10–12 months	3.2	3.0
1–3 years	4.1	3.8
4–6 years	6.2	5.8
7–10 years	7.6	7.2
11–14 years	9.8	9.1
15–18 years	12.6	10.2

Table A3.2 Estimated average requirements (EARs) according to height and weight at body mass index (BMI) of 22.5 kg/m² and assuming a physical activity level (PAL) of 1.63 (SACN, 2011)

Age (years)	Height (cm)	Weight (kg) BMI = 22.5 kg/m ²	EAR (MJ/day)
Males			
19–24	178	71.5	11.6
25–34	178	71.0	11.5
35–44	176	69.7	11.0
45–54	175	68.8	10.8
55–64	174	68.3	10.8
65–74	173	67.0	9.8
75+	170	65.1	9.6
Females			
19–24	163	29.9	9.1
25–34	163	59.7	9.1
35–44	163	59.9	8.8
45–54	162	59.0	8.8
55–64	161	58.0	8.7
65–74	159	57.2	8.0
75+	155	54.3	7.7

Protein

Table A3.3 Reference nutrient intakes (RNIs) for protein (Department of Health, 1991)

Age	Weight (kg)	RNI (g/day)
0–3 months	5.9	12.5
4–6 months	7.7	12.7
7–9 months	8.8	13.7
10–12 months	9.7	14.9
1–3 years	12.5	14.5
4–6 years	17.8	19.7
7–10 years	28.3	28.3
Males		
11–14 years	43.0	42.1
15–18 years	64.5	55.2
19–50 years	74.0	55.5
50+ years	71.0	53.3
Females		
11–14 years	43.8	41.2
15–18 years	55.5	45.4
19–50 years	60.0	45.0
50+ years	62.0	46.5
Pregnancy		+6.0
Lactation		
0–4 months		+11.0
4+ months		+8.0

Vitamins

Table A3.4 Reference nutrient intakes (RNIs) for vitamins

Age	Thiamin (mg/day)	Riboflavin (mg/day)	Niacin ¹ (mg/day)	Vitamin B ₆ ² (mg/day)	Vitamin B ₁₂ (µg/day)	Folate (µg/day)	Vitamin C (mg/day)	Vitamin A (µg/day)	Vitamin D (µg/day)
0–3 months	0.2	0.4	3	0.2	0.3	50	25	350	8.5
4–6 months	0.2	0.4	3	0.2	0.3	50	25	350	8.5

¹Phosphorus (P) RNI is set to equal to calcium (Ca) in mmol values; 1 mmol Ca = 40 mg, 1 mmol P = 30.9.

²1 mmol = 23 mg sodium (Na): 1 g salt (NaCl) contains 17.1 mmol, Na.

³1 mmol = 39.1 mg.

⁴Intakes of dietary chloride should equal sodium intakes in molar terms. 1 mmol chloride = 35.5 mg.

⁵Supplements may be required if menstrual losses are high.

*No increment.

1 pint	568 mL	500 mL	17.6 fl oz
2 pints	1.1 L	750 mL	26.4 fl oz
3 pints	1.7 L	1000 mL	1.76 pints (1¾ pints)
4 pints	2.3 L		
5 pints	2.8 L		

Appendix A5 Dietary data

Conversion factors

Energy

1000 joules = 1 kJ

1000 kJ = 1 MJ

1 kcal = 4.184 kJ [The Royal Society (London)
recommended conversion factor]

1 kJ = 0.239 kcal

1 W = 1 joule/second

0.06 W = 1 kJ/min

86.4 W = 1 kJ/24 h

1 µg of retinol equivalent

= 1 µg of retinol or 6 µg of beta-carotene

1 IU of vitamin A

= 0.3 µg of retinol or 0.6 µg of beta-carotene

Vitamin D

1 µg of vitamin D = 40 IU

1 IU = 0.025 µg of vitamin D

Nicotinic acid/tryptophan

1 mg of nicotinic acid = 60 mg of tryptophan

Nicotinic acid content mg equivalents

= nicotinic acid (mg) + [tryptophan (mg)/60]

Vitamin E

Vitamin E activity is expressed as D-alpha-tocopherol equivalents. Activity is expressed as international units (IU): 1 IU is equivalent to 0.67 mg D-alpha-tocopherol.

Table A5.1 Nutrient energy yields

Nutrient	kcal/g	kJ/g
Protein	4	17
Fat	9	37
Carbohydrate	3.75	16
Sugar alcohols	2.4	10
Ethyl alcohol	7	29
Glycerol	4.31	18
Medium chain triglyceride (MCT)	8.4	35

Protein and nitrogen

Dietary protein (g) = dietary nitrogen (g) × 6.25

Dietary nitrogen (g) = dietary protein (g) ÷ 6.25

This conversion factor is only appropriate for a mixture of foods. For milk or cereals alone, the factors 6.4 or 5.7 should be used.

Vitamins

Vitamin A

The active vitamin A content of a diet is usually expressed in retinol equivalents.

Table A5.2 Mineral content of compounds and solutions

Solution/compound	Mineral content	
1 g of sodium chloride	393 mg of Na	17 mmol of Na
1 g of sodium bicarbonate	273 mg of Na	12 mmol of Na
1 g of potassium bicarbonate	524 mg of K	13.4 mmol of K
1 g of calcium chloride (hydrated)	273 mg of Ca	7 mmol of Ca
1 g of calcium carbonate	400 mg of Ca	10 mmol of Ca
1 g of calcium gluconate	93 mg of Ca	2.3 mmol of Ca
1 L of normal saline	3450 mg of Na	150 mmol of Na

Food exchange lists

Carbohydrate

Table A5.3 Food portions containing approximately 10g of carbohydrate (CHO)

Food	Weight (g)	Description
Wholemeal bread	25	1 thin slice/large loaf
White bread	20	1 thin slice/small loaf
Potatoes – boiled	60	1 size of hen's egg
Potatoes – mashed	60	1 scoop
Potatoes – roast	40	1 very small
Sweet potatoes – boiled	50	1 size of hen's egg
Rice – boiled, brown, white	30	$\frac{3}{4}$ tablespoon
Pasta – boiled, e.g. spaghetti, macaroni	50	1 tablespoon
Pulses, e.g. lentils	60	2 tablespoons
Peas – frozen	100	3 tablespoons
Parsnip – boiled	80	1 medium
Sweetcorn – boiled	50	2 tablespoons
Thick soup, e.g. tinned vegetable	100	1 small tin
Thin soup, e.g. minestrone	250	1 standard mug
Sausages	100	2 large sausages
Beefburger, economy	100	1 economy burger
Beefburger, 100% meat = no CHO	–	–
Fish fingers	60	2 fish fingers
Breakfast cereals, e.g. branflakes	15	2 tablespoons
Breakfast cereals, e.g. wheat bisk type	20	1 bisk
Muesli, no added sugar	15	$\frac{3}{4}$ tablespoon
Porridge – made with water	125	Small average portion
Biscuits – plain digestive	15	1 digestive
Apple, pear	100	1 medium
Orange	120	1 small
Banana	45	$\frac{1}{2}$ small banana
Melon – galia, honeydew	200	1 medium slice
Pineapple, fresh	100	1 large slice
Grapes	70	15 large grapes
Orange juice – no added sugar	110	$\frac{1}{2}$ average glass
Apple juice – no added sugar	100	$\frac{1}{2}$ average glass
Cranberry juice	70	$\frac{1}{3}$ average glass
Milk – full fat, semi or skimmed	200	1 average glass
Yogurt – low fat, fruit	70	$\frac{1}{2}$ small pot
Yogurt – low fat, plain	135	1 small pot
Ice cream – plain dairy, vanilla	50	1 small scoop
Lemonade	170	1 small glass
Lucozade®	60	$\frac{1}{3}$ average glass
Cola	90	$\frac{1}{2}$ average glass
Beer – best bitter	450	$\frac{3}{4}$ pint glass
Lager – premium	400	$\frac{3}{4}$ pint glass
Wine – medium white	330	2 $\frac{1}{2}$ small wine glasses
Wine – red contains 0.2g CHO/100 mL	–	–
Crisps	20	$\frac{3}{4}$ small packet
Peanuts – dry roasted	100	1 large packet

Protein

Table A5.4 Food portions containing approximately 6g or 2g of protein

Food	Portion size	Protein per portion (g)	Approximate energy per portion (kcal)
Milk	180 mL	6	115 (full-fat) 85 (semi skimmed) 60 (skimmed)
Cheddar cheese	25 g	6	100
Yoghurt	125 g	6	125
Egg	50 g (one average hen's egg)	6	70
Meat/poultry lean cooked	25 g	6	40
White fish	35 g	6	30
Baked beans	120 g	6	100
Peas	100 g	6	70
Bread (1 large thin slice)	25 g	2	50
Pasta (boiled)	50 g	2	50
Rice (boiled)	100 g	2	140
Most breakfast cereals	25 g	2	90
Digestive biscuits	15 g (one biscuit)	2	70
Potatoes	140 g	2	100
Crisps	30 g	2	160

Potassium

Table A5.5 Food portions containing approximately 4 mmol of potassium

Food	Portion size providing approximately 4 mmol potassium
Milk	100 mL
Yoghurt	60 g
Cheddar cheese	130 g
Egg	100 g (2 small eggs)
Meat/fish	50 g
White flour	120 g
Wholemeal flour	45 g
White bread	160 g
Wholemeal bread	70 g
Apple	125 g
Orange with skin	100 g
Grapes / Orange without skin	50 g
Potato boiled	50 g
Orange juice	100 mL
Tomato juice	60 mL

Sodium

Table A5.6 No added salt and 40 mmol of sodium diets

No added salt	40 mmol of sodium diet
<p>This restricts sodium intake to <100 mmol of Na⁺/day. A pinch of salt may be used in cooking, but none should be added to food at the table.</p> <p>The following foods must be avoided:</p> <ul style="list-style-type: none"> • Bacon, ham, sausages, pâté • Tinned fish and meat • Smoked fish and meat • Fish and meat pastes • Tinned and packet soups • Sauce mixes • Tinned vegetables • Bottled sauces and chutneys • Meat and vegetable extracts, stock cubes • Salted nuts and crisps • Soya sauce • Monosodium glutamate • Cheese – up to 100 g/week • Bread – up to 4 slices/day 	<p>In addition to the foods listed opposite, the following restrictions apply:</p> <ul style="list-style-type: none"> • No salt to be used in cooking or at table • Salt free butter or margarine must be used • Milk should be restricted to 300 mL/day • Breakfast cereals must be salt free

E number classification system (see Chapter 4.5)

E100–180	Colours
E200–283	Preservatives
E300–321	Antioxidants
E322–495	Emulsifiers, stabilisers, acidity regulators, thickeners
E950–969	Artificial sweeteners

Table A5.7 Commonly used additives

Type of additive	E number	Chemical name
Colours		
Natural and nature identical colours	E101	Riboflavin (yellow)
	E100	Curcumin (yellow)
	E120	Cochineal (red)
	E140	Chlorophyll (green)
	E150a	Plain caramel (brown/black)
	E153	Carbon (black)
	E160a	Alpha-, beta- and gamma-carotene (yellow/orange)
	E160b	Annatto (yellow/red)
	E160c	Capsanthin (paprika extract) (red/orange)
	E160d	Lycopene (red extract from tomatoes)
	E162	Beetroot red (betanin) (purple/red)
	E163	Anthocyanins (red/blue/violet)
	Synthetic colours	E102
E104		Quinoline Yellow*
E110		Sunset Yellow FCF*
E122		Carmoisine (Azorubine)* (red)
E123		Amaranth* (purple red)
E124		Ponceau 4R* (red)
E127		Erythrosine* (pink/red)
E128		Red 2 G*
E129		Allura Red AC*
E132		Indi go carmine (Indigotine) * (blue)
E142		Green S*
E150 b–d		Caustic sulphite caramel; ammonia caramel; sulphite ammonia caramel (brown/black)
E151		Black PN*
E154		Brown FK*
E155	Brown HT*	
E180	Litholrubine BK (Pigment Rubine; Rubine)*	
Preservatives		
Sorbic acid and its derivatives	E200	Sorbic acid
	E201–203	Sodium, potassium and calcium sorbates
Benzoic acid and derivatives	E210	Benzoic acid
	E211–213	Sodium, potassium and calcium benzoates
	E214 – E219	Ethyl, methyl or propyl hydroxybenzoates
Sulphur dioxide and derivatives	E220	Sulphur dioxide
	E221	Sodium sulphite
	E222	Sodium hydrogen sulphite (sodium bisulphite)
	E223	Sodium metabisulfite
	E224	Potassium metabisulphite
	E226	Calcium sulphite
	E227	Calcium hydrogen sulphite (calcium bisulphite)
Nitrites and nitrates	E249	Potassium nitrite
	E250	Sodium nitrite
	E251	Sodium nitrate
	E252	Potassium nitrate
Acetic, lactic and propionic acid derivatives	E260–E263	Acetic acid and acetates
	E270	Lactic acid
	E280–E283	Propionic acid and propionates

(Continued)

Table A5.7 (Continued)

Type of additive	E number	Chemical name
Antioxidants		
Ascorbic acid and derivatives	E300	Ascorbic acid (vitamin C)
	E301–304	Ascorbates and ascorbyl palmitate
Tocopherols	E306	Vitamin E
	E307–309	Synthetic tocopherols
Gallates	E310–312	Propyl, octyl and dodecyl gallates
BHA/BHT	E320	Butylated hydroxyanisole (BHA)
	E321	Butylated hydroxytoluence (BHT)
Emulsifiers and stabilisers		
Emulsifier	E322	Lecithins
Acidity regulators, buffers, stabilisers	E325–327	Sodium, potassium and calcium lactate
	E330–333	Citric acid; sodium, potassium and calcium citrates
	E334–337	Tartaric acid; sodium and potassium tartrates
	E338–341	Phosphoric acid; sodium, potassium and calcium phosphates and orthophosphates
Gelling agents	E350–352	Sodium, potassium and calcium malates
	E401–405	Sodium, ammonium, potassium and calcium alginates
	E406	Agar
Gums	E407	Carrageenan
	E410	Locust bean gum
	E412	Guar gum
	E413	Tragacanth
	E414	Gum arabic
Emulsifiers/stabilisers	E415	Xanthan gum
	E471–E477	Esters and glycerides of fatty acids, e.g. mono- and di-glycerides of fatty acids or glyceryl monostearate and distearate

*Azo dye.

Appendix A6 Body mass index (BMI)

Table A6.1 BMI ready reference table

BMI	Weight (kg)																							
Morbidly obese (BMI > 40)	45	102	104	107	110	113	116	119	121	124	127	131	134	137	140	143	146	150	153	156	159	163	170	173

Appendix A7 Anthropometric data

Demiquet and Mindex

These can be used as an index of adiposity in elderly people (see Chapter 2.2).

$$\text{Demiquet} = \frac{\text{Weight (kg)}}{\text{Demispan (m)}^2}$$

$$\text{Mindex} = \frac{\text{Weight (kg)}}{\text{Demispan (m)}}$$

Table A7.1 Distribution of Demiquet and Mindex in a normal population over the age 65 years [data derived from Lehmann *et al.* (1991)]

	Percentiles				
	10th	30th	50th	70th	90th
Men (Demiquet kg/m ²)					
64–74 years	87.6	99.6	106.7	117.1	130.7
75+ years	84.5	98.9	106.3	113.4	125.0
Women (Mindex kg/m)					
64–74 years	68.3	77.8	84.8	92.3	110.6
75+ years	63.1	73.6	81.7	88.4	102.2

Upper arm anthropometry

For measurement techniques and discussion see Chapter 2.2.

Table A7.2 Triceps skinfold thickness (TSF) [data derived from Bishop *et al.* (1981)]

	Centiles							
	Mean (mm)	5th	10th	25th	50th	75th	90th	95th
Men								
18–74 years	12.0	4.5	6.0	8.0	11.0	15.0	20.0	23.0
18–24 years	11.2	4.0	5.0	7.0	9.5	14.0	20.0	23.0
25–34 years	12.6	4.5	5.5	8.0	12.0	16.0	21.5	24.0
35–44 years	12.4	5.0	6.0	8.5	12.0	15.5	20.0	23.0

Estimating height from ulna length (see Figure A7.1)

Table A7.5 Estimates of height from ulna length (Elia, 2003)

Men		Ulna length (cm)	Women	
Height (m)			Height (m)	
<65 years	>65 years		<65 years	>65 years
1.94	1.87	32.0	1.84	1.84
1.93	1.86	31.5	1.83	1.83
1.91	1.84	31.0	1.81	1.81
1.89	1.82	30.5	1.80	1.79
1.87	1.81	30.0	1.79	1.78
1.85	1.79	29.5	1.77	1.76
1.84	1.78	29.0	1.76	1.75
1.82	1.76	28.5	1.75	1.73
1.80	1.75	28.0	1.73	1.71
1.78	1.73	27.5	1.72	1.70
1.76	1.71	27.0	1.70	1.68
1.75	1.70	26.5	1.69	1.66
1.73	1.68	26.0	1.68	1.65
1.71	1.67	25.5	1.66	1.63
1.69	1.65	25.0	1.65	1.61
1.67	1.63	24.5	1.63	1.60
1.66	1.62	24.0	1.62	1.58
1.64	1.60	23.5	1.61	1.56
1.62	1.59	23.0	1.59	1.55
1.60	1.57	22.5	1.58	1.53
1.58	1.56	22.0	1.56	1.52
1.57	1.54	21.5	1.55	1.50
1.55	1.52	21.0	1.54	1.48
1.53	1.51	20.5	1.52	1.47
1.51	1.49	20.0	1.51	1.45
1.49	1.48	19.5	1.50	1.44
1.48	1.46	19.0	1.48	1.42
1.46	1.45	18.5	1.47	1.40

Figure A7.1 How to measure ulna length
Measure between the point of the elbow (olecranon process) and the mid point of the prominent bone of the wrist (styloid process) (left side if possible)

Table A7.7 Waist measurements in adults as a predictor of health risk (WHO, 2008)

	Men	Asian men	Women	Asian women
Waist circumference				
Increased risk	≥94 cm		≥80 cm	
Substantially increased risk	≥102 cm	≥90 cm	≥88 cm	≥80 cm
Waist to hip ratio				
Increased risk	≥0.9		≥0.85	

Table A7.6 Classification of body mass index (BMI) and risk of comorbidities in adults (WHO, 1998; 2004)

Classification	BMI (kg/m ²)	BMI (kg/m ²) Asian origin	Risk of comorbidities
Underweight	<18.5	<18.5	Low (but risk of other clinical problems increased)
Normal range	18.5–24.9	18.5–22.9	Average
Overweight	25.0–29.9	23–27.4	Increased risk
Obese class I	30.0–34.9	27.5–32.4	Moderate
Obese class II	35.0–39.9	32.5–37.4	Severe
Obese class III	>40.0	>37.5	Morbid obesity

Appendix A8 Predicting energy requirements

For a discussion on stress factors and physical activity levels (PALs) in clinical practice, see Chapter 6.1 and the specific clinical chapters in Section 7 for detailed discussion as appropriate.

In 2011, the Scientific Advisory Committee on Nutrition (SACN) published the report *Dietary Reference Values for Energy*. Energy requirements for the UK were last reviewed by the Committee on Medical Aspects of Food Policy (COMA) in their 1991 report *Dietary Reference Values for Food and Energy and Nutrients for the United Kingdom*. Following careful consideration of the evidence, SACN has recommended a revision to the estimated average requirements (EAR) for food energy for infants, children, adolescents and adults. However, these are intended only for use in healthy populations and not individuals or groups who require clinical management. Although exclusive breastfeeding is recommended for about the first 6 months of life, it is recognised that infants are fed in a variety of ways. Therefore, separate recommendations have been made for exclusively breast-fed infants, breast milk substitute fed infants and those for whom the method of feeding is mixed or unknown. For the full report, refer to SACN (2011), particularly Tables 14 and 15.

Table A8.1 Basal metabolic rate (BMR) [Henry, (2005); as recommended by SACN (2011)]

	Age (years)	BMR prediction equation (MJ/day)
Males	<3	0.255 (w) – 0.141
	3–10	0.0937 (w) + 2.15
	10–18	0.0769 (w) + 2.43
	18–30	0.0669 (w) + 2.28
	30–60	0.0592 (w) + 2.48
	>60	0.0563 (w) + 2.15
Females	<3	0.246 (w) – 0.0965
	3–10	0.0842 (w) + 2.12
	10–18	0.0465 (w) + 3.18
	18–30	0.0546 (w) + 2.33
	30–60	0.0407 (w) + 2.90
	>60	0.0424 (w) + 2.38

w, weight in kg.

Appendix A9 Clinical chemistry

Conversion calculations

$$\text{mg to mmol} \quad \frac{\text{mg}}{\text{atomic weight}}$$

$$\text{mmol to mg} \quad \text{mmol} \times \text{atomic weight}$$

Milliequivalents (mEq)

$$1 \text{ mEq} = \frac{\text{atomic weight (mg)}}{\text{valency}}$$

To convert

$$\text{mg to mEq} \quad \frac{(\text{mg} \times \text{valency})}{\text{atomic weight}}$$

$$\text{mEq to mg} \quad (\text{mEq} \times \text{atomic weight})/\text{valency}$$

For minerals with a valency of 1, mEq = mmol

For minerals with a valency of 2, mEq = mmol × 2

Table A9.1 Atomic weights and valencies

Mineral	Atomic weight	Valency
Sodium	23.0	1
Potassium	39.0	1
Phosphorus	31.0	2
Calcium	40.0	2
Magnesium	24.3	2
Chlorine	35.4	1
Sulphur	32.0	2
Zinc	65.4	2

Table A9.2 Mineral content of compounds and solutions

Solution/compound	Mineral content	
1 g sodium chloride	393 mg Na	(17.1 mmol Na ⁺)
1 g sodium bicarbonate	274 mg Na	(12 mmol Na ⁺)
1 g potassium bicarbonate	390 mg K	(10 mmol K ⁺)
1 g calcium chloride (dihydrate)	273 mg Ca	(6.8 mmol Ca ²⁺)
1 g calcium carbonate	400 mg Ca	(10 mmol Ca ²⁺)
1 g calcium gluconate	89 mg Ca	(2.2 mmol Ca ²⁺)
1 litre normal saline	3450 mg Na	(150 mmol Na ⁺)

Table A9.3 Conversion factors for mmol/mg/mEq

Mineral	mg/mmol		mg/mEq		mmol/mEq	
	mg=	mmol=	mg=	mEq=	mmol=	mEq=
Sodium	mmol × 23	mg ÷ 23	mEq × 23	mg ÷ 23	mEq	mmol
Potassium	mmol × 39	mg ÷ 39	mEq × 39	mg ÷ 39	mEq	mmol
Phosphorus	mmol × 31	mg ÷ 31	mEq × 15.5	mg ÷ 15.5	mEq ÷ 2	mmol × 2
Calcium	mmol × 40	mg ÷ 40	mEq × 20	mg ÷ 20	mEq ÷ 2	mmol × 2
Magnesium	mmol × 24.3	mg ÷ 24.3	mEq × 12.15	mg ÷ 12.15	mEq ÷ 2	mmol × 2
Chlorine	mmol × 35.4	mg ÷ 35.4	mEq × 35.4	mg ÷ 35.4	mEq	mmol
Sulphur	mmol × 32	mg ÷ 32	mEq × 16	mg ÷ 16	mEq ÷ 2	mmol × 2
Zinc	mmol × 65.4	mg ÷ 65.4	mEq × 32.7	mg ÷ 32.7	mEq ÷ 2	mmol × 2

Osmolarity and osmolality

Osmolality is the number of osmotically active particles (milliosmoles) in a *kilogram* of solvent. Osmolarity is the number of osmotically active particles in a *litre* of solution (i.e. solvent + solute).

In body fluids, there is only a small difference between the two. However, in commercially prepared feeds, osmolality is always much higher than osmolarity. Osmolality is therefore the preferred term for comparing the potential hypertonic effect of liquid diets (although, in practice, it is often osmolarity which is stated).

The osmolality of a liquid feed is considerably influenced by the content of amino acids and electrolytes such as sodium and potassium. Carbohydrates with a small particle size (e.g. simple sugars) increase osmolality more than complex carbohydrates with a higher molecular weight. Fats do not increase the osmolality of solutions because of their insolubility in water.

The osmolality of plasma is normally in the range 280–300 mosmol/kg and the body attempts to keep the osmolality of the contents of the stomach and intestine at an isotonic level. It does this by producing intestinal secretions which dilute a concentrated meal or drink. If enteral feeds with a high osmolality are administered, large quantities of intestinal secretions will be produced rapidly in order to reduce the osmolality. In order to avoid diarrhoea, it is therefore important to administer such feeds slowly; the number of mosmoles given per unit of time is more important than the number of mosmoles per unit of volume.

Biochemical and haematological reference ranges

The results of laboratory tests are interpreted by comparison with reference or normal ranges. These are usually defined as the mean ± 2 SD (standard deviation), which assumes a Gaussian or normal (symmetrical) type distribution (Figure A9.1). Unfortunately, most biological data have a skewed rather than a symmetrical distribution and more complex statistical calculations are required to define the reference ranges.

The reference ranges as defined usually include approximately 95% of the normal 'healthy' population; consequently, 5% of this population will have values outside the reference range but cannot be said to be abnormal. The use of reference ranges may be illustrated by taking the reference range of blood urea as 3.3–6.7 mmol/L. Approximately 95% of the normal 'healthy' population would come within these limits. However, it would be wrong to interpret a value of 6.4 mmol/L as normal while assuming a value of 7.0 mmol/L to be abnormal. Nature 'abhors abrupt transitions', so there is no clear-cut division between 'normal' and 'abnormal'. This applies equally well to body weight and height and also to measurements undertaken in the laboratory.

The majority of the normal 'healthy' population will have results close to the mean value for the population as a whole and all values will be distributed around

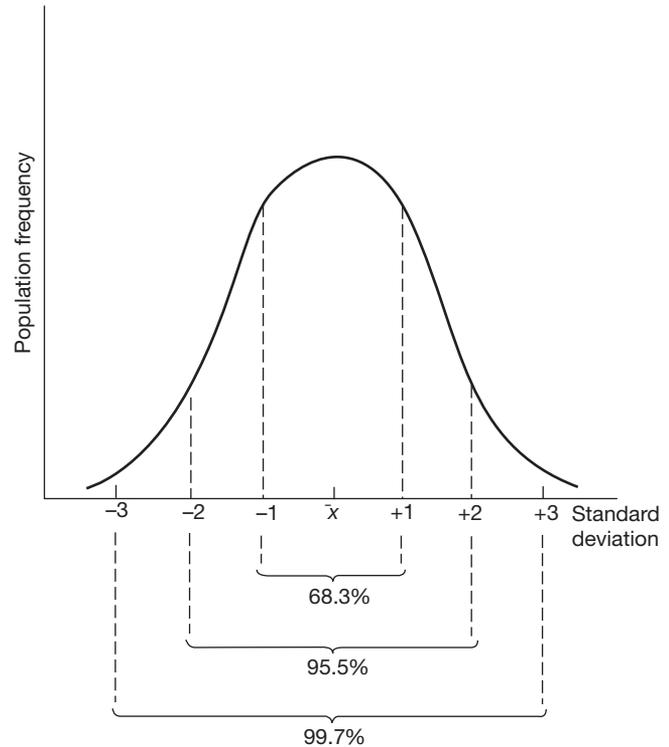

Figure A9.1 Normal distribution curve

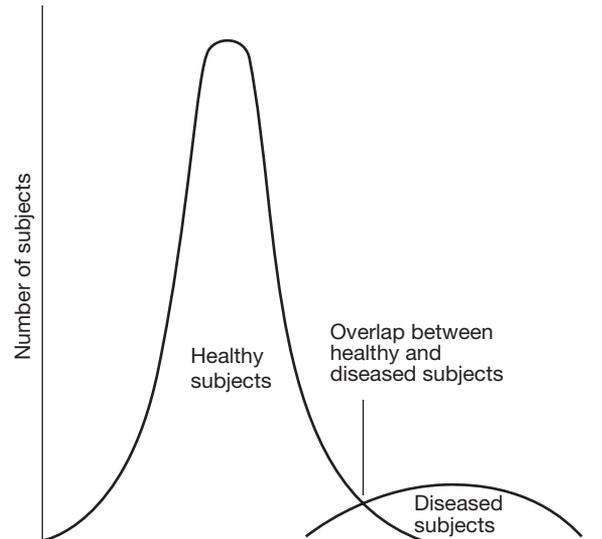

Figure A9.2 Theoretical distribution of values in health and disease

that mean. Therefore, the probability that a value is abnormal increases the further it is from the mean value (Figure A9.2).

A variety of factors can cause variation in the biochemical and haematological constituents present within the blood. These can be conveniently divided into factors causing variation within an individual and those causing variation between groups of individuals.

Variations within individuals

The following factors can cause significant variation in clinical biochemical and haematological data and should be considered when interpreting individual results.

Diet

Variation in diet can affect the levels of triglycerides, cholesterol, glucose, urea and other blood constituents.

Drugs

These can have significant effects on a number of biochemical determinations, often resulting from secondary effects on sensitive organs, e.g. liver, kidney and endocrine glands. Steroids, including oral contraceptives, can cause variations in a number of biochemical and haematological parameters, including a reduction in albumin, increases in several carrier proteins, e.g. transcortin, thyroxine-binding globulin, caeruloplasmin and transferrin, and also increases in coagulation factors, e.g. fibrinogen, factor VII and factor X.

Menstrual cycle

Several biochemical constituents show marked variations with the phase of the cycle; these include the pituitary gonadotrophins, ovarian steroids and their metabolites. There is also a marked fall in plasma iron just before and during menstruation. This is probably caused by hormonal changes rather than blood loss.

Muscular exercise

Moderate exercise can cause increases in levels of potassium, together with a number of enzymes including aspartate transferase, lactate dehydrogenase, creatine kinase and hydroxybutyrate dehydrogenase.

Posture

Significant differences in the concentration of many blood constituents may be obtained by collecting blood samples from ambulant compared with recumbent individuals. The red cell and white cell counts, together with the concentration of proteins (e.g. albumin, immunoglobulins) and protein-bound substances (e.g. calcium, cholesterol, T₄, cortisol), may decrease by up to 15% following 30 minutes of recumbency. This is probably due to fluid redistribution within the body. Hospitalised patients usually have their blood samples collected early in the morning following overnight recumbency, and consequently have significantly lower values than the normal ambulant (outpatient) population.

Stress

Both emotional and physical stress can alter circulating biochemical constituents, causing increases in the levels of pituitary hormones [e.g. adrenocorticotrophic hormone (ACTH), prolactin, growth hormone] and adrenal steroids (cortisol).

Time of day

Some substances exhibit a marked circadian (diurnal) variation which is independent of meals or other activi-

ties, e.g. serum cortisol, iron and the amino acids tyrosine, phenylalanine and tryptophan. Cortisol levels are at their highest in the morning (9 am) and at their lowest levels at midnight, while iron concentration may decrease by 50% between the morning and evening. Plasma phenylalanine levels are at their lowest after midnight and reach their highest concentrations between 8.30 and 10.30 am.

Variations between groups of individuals

Several factors influence the reference values quoted for individuals. These include age, sex and race.

Age

The blood levels of many biochemical and haematological constituents are age related; these include haemoglobin, total leucocyte count, creatinine, urea, inorganic phosphate and many enzymes, e.g. alkaline phosphatase, creatine kinase and γ -glutamyl transferase. Haemoglobin levels and total leucocyte counts are highest in the newborn and gradually decrease through childhood, reaching the adult reference range at puberty. As creatinine is related to muscle mass, paediatric reference ranges are lower than those of adults. Urea levels rise slightly with age but this may well indicate impaired renal function. Alkaline phosphatase activity and inorganic phosphate levels are at their highest during childhood, reaching peak levels at puberty.

Gender

Many biochemical and haematological parameters show concentration differences which are sex dependent, including creatinine, iron, urea, and the various sex hormones. Ferritin, haemoglobin and red cell counts are slightly higher in males than in females. Creatinine and urea levels are 15–20% lower in premenopausal females than in males. Premenopausal females also have lower serum iron levels than males, but after the menopause iron levels are similar in both sexes.

Race

Racial differences have been reported in some biochemical constituents, including cholesterol and protein. The reference ranges for cholesterol are higher in Europeans than in similar groups of Japanese. Similarly, the Bantu Africans have higher serum globulins than corresponding Europeans. African and Middle-Eastern individuals have lower total leucocyte and neutrophil counts than other races. Some of these racial differences are probably genetic in origin, although the environment and diet may also be contributory factors.

Laboratory variations

Methods of analysis and standardisations vary considerably from laboratory to laboratory. These differences will influence the quoted reference ranges, and therefore readers are advised to use only those quoted by their local laboratory. Local reference ranges may be at variance with the levels quoted in the following tables.

Correction of serum calcium for low albumin

Corrected serum calcium level (mmol/L)

$$= \frac{\text{measured serum calcium (mmol/L)}}{40} + \left(\frac{40 - \text{measured albumin}}{40} \right)$$

An alternative (and possibly more accurate) equation is:

Corrected serum calcium level (mmol/L)

$$= \frac{\text{measured serum calcium (mmol/L)}}{40} + \left[\left(\frac{40 - \text{measured albumin}}{40} \right) \times 0.02 \right]$$

To be even more accurate, the serum protein level should also be considered:

Corrected serum calcium level (mmol/L)

$$= \frac{\text{measured serum calcium (mmol/L)}}{40} + \left[\left(\frac{72 - \text{measured protein}}{72} \right) \times 0.02 \right]$$

This corrected calcium value should be added to that obtained from the correction for low albumin, and a mean of the two levels obtained, calculated to two decimal places.

Table A9.4 Adult normal values [adapted from Provan (2005)] Oxford Handbook of Clinical and laboratory investigation, 2nd edn

Substance	Value	Substance	Value
Albumin	32–50 g/L	Red cell count	
Bicarbonate	20–29 mmol/L	Males	4.5–6.5 × 10 ¹² /L
Bilirubin	<17 μmol/L	Females	3.8–5.8 × 10 ¹² /L
Calcium	2.15–2.55 mmol/L	Mean cell haemoglobin (MCH)	27–32 pg
Chloride	97–107 mmol/L	Mean cell volume (MCV)	77–95 fl
Total cholesterol	<5 mmol/L	Mean cell haemoglobin concentration	32–36 g/dL
Creatinine	60–125 mmol/L	White blood count (WBC)	4.0–11.0 × 10 ⁹ /L
Glucose (fasting)	<6.1 mmol/L	Neutrophils	2.0–7.5 × 10 ⁹ /L
Phosphate	0.7–1.5 mmol/L	Eosinophils	0.04–0.4 × 10 ⁹ /L
Magnesium	0.7–1.0 mmol/L	Monocytes	0.2–0.8 × 10 ⁹ /L
Osmolality	278–305 mOsmol/kg	Basophils	0.0–0.1 × 10 ⁹ /L
Potassium	3.5–5.0 mmol/L	Lymphocytes	1.5–4.5 × 10 ⁹ /L
Sodium	135–150 mmol/L	Platelets	150–400 × 10 ⁹ /L
Total protein	63–80 g/L	Erythrocyte sedimentation rate	2–12 mm/1st hour
Triglycerides	0.55–1.90 mmol/L	Ferritin (varies with age)	14–200 μg/L
Urate	0.14–0.46 mmol/L	Premenopausal women	14–148 μg/L
Urea	3.0–6.5 mmol/L	Serum B ₁₂	150–700 ng/L
Haemoglobin		Serum folate	2.0–11.0 μg/L
Males	13.0–18.0 g/dL	Red cell folate	150–700 μg/L
Females	11.5–16.5 g/dL	Prothrombin time (PT)	12–14 s
Haematocrit (PCV)		Activated partial thromboplastin	26.0–33.5 s
Males	0.40–0.52	time (APTT)	
Females	0.36–0.47	Thrombin time (TT)	+3 s of control

Table A9.5 Normal adult urine values

Substance	Value
Albumin	<20 mg/24 hours
Calcium	<7.5 mmol/24 hours
Creatinine	9–15 mmol/24 hours
Phosphate	15–50 mmol/24 hours
Osmolality	50–1500 mOsmol/24 hours
Potassium	14–120 mmol/24 hours
Protein	<150 mg/24 hours
Sodium	100–250 mmol/24 hours
Urate	<3.0 mmol/24 hours
Urea	250–600 mmol/24 hours

Table A9.6 Normal adult faecal values

Substance	Value
Faecal fat	<18 mmol/24 hours
Nitrogen	70–140 mmol/24 hours

Appendix A10 Nutritional supplements and enteral feeds

Patients at risk of malnutrition may be prescribed oral nutritional supplements (ONS) or enteral feeds as long as they have a functional gastrointestinal tract. Many of these products are prescribed only in specified clinical circumstances defined by the Advisory Committee on Borderline Substances (ACBS); they are termed ACBS prescribable. Standard ACBS indications are disease related malnutrition, intractable malabsorption, preoperative preparation of malnourished patients, dysphagia, proven inflammatory bowel disease, following total gastrectomy, short bowel syndrome and bowel fistula. The following tables provide a guide to the range of proprietary supplements, feeds and other nutritional support products currently available in the UK.

Product composition within a particular category will differ; some products may be more appropriate than others in particular clinical circumstances. Ongoing

product development by the manufacturers inevitably means that over time the availability and composition of some products may change and new products will appear. The information given here is for guidance only and product details should be checked before clinical usage.

For current product availability, composition and prescribing indications, consult the *British National Formulary (BNF)*, the *Monthly Index of Medical Specialities (MIMS)* or the manufacturers (for web addresses, see Table A10.1.11 and Table A10.2.6). Information on which products are suitable for special diets, e.g. kosher, halal, gluten free, lactose free, vegetarian or vegan, can also be obtained directly from the manufacturers.

Appendix A10.1 Adult nutritional supplements and enteral feeds

Table A10.1.1 Prescribable liquid (sip feed) supplements

Note: Many sip feed supplements are available in a variety of flavours to offset taste fatigue. Some, but not all, are nutritionally complete; check compositional details before use. Some products can also be used for tube feeding.

Product type	Product name (manufacturer) Quantity	Per bottle/can			
		kJ	kcal	Protein (g)	Fibre (g)

Table A10.1.4 Single nutrient component supplements

Component	Product name (manufacturer)	Notes, ACBS indications and nutritional values			
Carbohydrate	Caloreen (Nestlé) Powder	1640 kJ (390 kcal)/100 g	Disease related malnutrition or malabsorption states or other conditions requiring fortification with a high or readily available carbohydrate supplement		
	Maxijul Liquid (SHS) Liquid	850 kJ (200 kcal)/100 mL			
	Maxijul Super Soluble (SHS) Powder	1615 kJ (380 kcal)/100 g			
	Polycal (Nutricia Clinical) Powder	1630 kJ (384 kcal)/100 g			
	Polycal Liquid (Nutricia Clinical) Liquid	1050 kJ (247 kcal)/100 mL			
	Resource Optifibre (Nestlé) Powder	323 kJ (76 kcal) and 78 g of fibre/100 g			
	S.O.S. 10, 15, 20, 25 (Vitaflo) Powder	1590 kJ (380 kcal)/100 g			
	Vitajoule (Vitaflo) Powder	1610 kJ (380 kcal)/100 g			
	Fat	Calogen (Nutricia Clinical) Liquid (100% LCTs fat emulsion)		1850 kJ (450 kcal)/100 mL	Disease related malnutrition or malabsorption states or other conditions requiring fortification with a high fat supplement
		Fresubin 5kcal Shot (Fresenius Kabi) Liquid		2100 kJ (500 kcal)/100 mL	
Liquigen (SHS) Liquid (97% MCTs)		1850 kJ (450 kcal)/100 mL	Steatorrhoea associated with cystic fibrosis (pancreas), intestinal lymphangiectasia, intestinal surgery, chronic liver disease/cirrhosis and other proven malabsorption syndromes		
Medium-Chain Triglyceride (MCT) Oil (SHS) Liquid (100% MCTs)		3515 kJ (855 kcal)/100 mL			
Protein		Casilan 90 (Heinz) Powder (90% protein)		1572 kJ (370 kcal)/100 g	
	Protifar (Nutricia Clinical) Powder (89% protein)	1580 kJ (373 kcal)/100 g			
	Vitapro (Vitaflo) Powder (75% protein)	1506 kJ (360 kcal)/100 g	Protein energy malnutrition or malabsorption states, hypoproteinaemia and as a protein source in modular feed		

LCTs, long chain triglycerides; MCTs, medium chain triglycerides.

Table A10.1.5 Multiple nutrient component supplements

Components	Product name (manufacturer)	Notes, ACBS indications and nutritional values
Fat/ carbohydrate	MCT Duocal (SHS) Powder	Conditions requiring extra calories, e.g. fat malabsorption or where assimilation of LCTs is impaired 50g in 150 mL of water provides 1041 kJ (249 kcal), 36 g of CHO and 11.6 g of fat
	Duocal (SHS) Liquid	Conditions requiring extra calories Per 100 mL: 695 kJ (166 kcal), 23.7 g of CHO and 7.9 g of fat (30% MCTs)
Protein/ carbohydrate	ProSource (Nutrinovo) Liquid	Protein energy malnutrition and patients on a fluid restricted diet Per 30 mL: 420 kJ (100 kcal), 10 g of protein and 15 g of CHO
	Calogen Extra (Nutricia Clinical) Liquid	High energy fat emulsion with protein, carbohydrate, vitamins and minerals Per 100 mL: 1650 kJ (400 kcal), 5.0 g of protein, 4.5 g of CHO and 40.3 g of fat
Protein/fat/ carbohydrate	Calshake (Fresenius Kabi) Powder	For increased energy requirements, e.g. patients with cystic fibrosis, cancer or HIV/AIDS 87-g sachet + 240 mL of whole milk provides approx. 2495 kJ (596 kcal), 11.6 g of protein, 68.4 g of CHO and 30.8 g of fat
	Enshake (Abbott) Powder	High energy, high protein drink for patients with involuntary weight loss 96.5-g sachet + 240 mL of whole milk provides approx. 2519 kJ (600 kcal), 16 g of protein, 78.4 g of CHO and 24.7 g of fat
	Pro-Cal (Vitaflo) Powder	Disease related malnutrition or malabsorption states and other conditions requiring fortification with energy and protein, e.g. burns 15-g sachet provides 418 kJ (100 kcal), 2 g of protein, 4 g of CHO and 8.4 g of fat
	Pro-Cal Shot (Vitaflo) Liquid	Per 30 mL: 418 kJ (100 kcal), 2 g of protein, 4 g of CHO and 8.5 g of fat
	QuickCal (Vitaflo) Powder	13-g sachet provides 418 kJ (100 kcal), 0.6 g of protein, 2.2 g of CHO and 10 g of fat
	Scandishake Mix (Nutricia Clinical) Powder	High energy supplement for disease related malnutrition based on skimmed milk powder, carbohydrate and fat 85-g sachet + 240 mL of whole milk provides 2457 kJ (588 kcal), 11.7 g of protein, 66.8 g of CHO and 30.4 g of fat
	Vitasavoury 200 (Vitaflo) Powder Vitasavoury 300 (Vitaflo) Powder	Low volume, high energy supplements for disease related malnutrition or malabsorption states or other conditions requiring additional energy and protein 33-g sachet provides 855 kJ (200 kcal), 4 g of protein, 7.4 g of CHO and 17.2 g of fat 50-g sachet provides 1295 kJ (300 kcal), 6 g of protein, 11.3 g of CHO and 26.0 g of fat

CHO, carbohydrate; MCTs, medium chain triglycerides; LCTs, long chain triglycerides.

Table A10.1.6 Food and fluid thickeners

For thickening of food and drinks of patients with dysphagia.

Type of product	Product name (manufacturer)
Modified maize starch powder*	Multi Thick (Abbott)
	Nutlis (Nutricia Clinical)
	Resource ThickenUp (Nestlé)
	Thick and Easy (Fresenius Kabi)
	Thixo-D (Sutherland)
	Vitaquick (Vitaflo)
Maltodextrin and xanthan gum	Resource ThickenUp Clear (Nestlé)

*See individual manufacturer's recommendations for the quantities required to achieve various textures.

Table A10.1.7 Enteral feeds – standard indications

Product type	Product name (manufacturer)	Per 100 mL			
		kJ	kcal	Protein (g)	Fibre (g)
Standard energy (1 kcal/mL)	Fresubin Original (Fresenius Kabi)	420	100	3.8	0.0
	Fresubin Original Fibre (Fresenius Kabi)	420	100	3.8	2.0
	Isosource Fibre (Nestlé)	422	100	3.8	1.4
	Isosource Standard (Nestlé)	420	100	4.0	0.0

	Jevity Promote (Abbott)	427	101	5.6	1.7
	Novasource GI Control (Nestlé)	444	106	4.1	2.2
	40% MCTs				
	Nutrison (Nutricia Clinical)	420	100	4.0	0.0
	Nutrison MCT (Nutricia Clinical)	420	100	5.0	0.0
	61% MCTs				
	Nutrison Multi Fibre (Nutricia Clinical)	420	100	4.0	1.5
	Osmolite (Abbott)	424	100	4.0	0.0
	Nutritionally complete (1.0–1.2 kcal/mL)	Fresubin 1000 Complete (Fresenius Kabi) Complete in 1000 mL	420	100	5.5
Fresubin 1200 Complete (Fresenius Kabi) Complete in 1000 mL		500	120	6.0	2.0
Fresubin 1800 Complete (Fresenius Kabi) Complete in 1500 mL		500	120	6.0	2.0
Fresubin 2250 Complete (Fresenius Kabi) Complete in 1500 mL		630	150	5.6	2.0
Nutrison 1000 Complete Multi Fibre (Nutricia Clinical) Complete in 1000 mL		420	100	5.5	2.0
Nutrison 1200 Complete Multi Fibre (Nutricia Clinical) Complete in 1000 mL		505	120	5.5	2.0
Osmolite Plus (Abbott)		508	121	5.6	0.0
Medium energy (1.2–1.3 kcal/mL)	Jevity Plus (Abbott)	504	120	5.5	2.2
	Jevity Plus HP (Abbott)	547	130	8.1	1.5
	Nutrison Protein Plus (Nutricia Clinical)	525	125	6.3	0.0
	Nutrison Protein Plus Multi Fibre (Nutricia Clinical)	525	125	6.3	1.5
	Osmolite Plus (Abbott)	508	121	5.6	0.0
High energy (1.5–2.0 kcal/mL)	Ensure Twocal (Abbott)	838	200	8.4	1.0
	Fresubin Energy (Fresenius Kabi)	630	150	5.6	0.0
	Fresubin Energy Fibre (Fresenius Kabi)	630	150	5.6	2.0
	Fresubin HP Energy (Fresenius Kabi)	630	150	7.5	0.0
	Isosource Energy (Nestlé)	670	160	5.7	0.0
	Isosource Energy Fibre (Nestlé)	630	150	4.9	1.5
	Jevity 1.5 kcal (Abbott)	640	152	6.4	2.2
	Novasource GI Forte (Nestlé)	631	150	6.0	2.2
	Nutrison Energy (Nutricia Clinical)	630	150	6.0	0.0
	Nutrison Energy Multi Fibre (Nutricia Clinical)	630	150	6.0	1.5
	Osmolite 1.5 kcal (Abbott)	632	150	6.3	0.0
	Resource Energy (Nestlé)	630	150	5.6	<0.5

MCTs, medium chain triglycerides.

Table A10.1.8 Specialist indication enteral feeds and supplements

Product type	Product name (manufacturer)	Per 100 mL			
		kJ	kcal	Protein (g)	Fibre (g)
Amino acid liquid formula	Elemental 028 Extra (SHS) Sip feed	360	86	2.5	0.0
Low sodium liquid formula	Nutrison Low Sodium (Nutricia Clinical)	420	100	4.0	0.0
Peptide based liquid formula	Peptamen (Nestlé)	420	100	4.0	0.0
	Peptamen HN (Nestlé)	556	133	6.6	0.0
	Peptisorb (Nutricia Clinical)	425	100	4.0	0.0
	Perative (Abbott)	552	131	6.7	0.0
	Survimed OPD (Fresenius Kabi)	420	100	4.5	0.0
Soya protein liquid formula	Fresubin Soya Fibre (Fresenius Kabi)	420	100	3.8	2.0
	Nutrison Soya (Nutricia Clinical)	420	100	4.0	0.0
	Nutrison Soya Multi Fibre (Nutricia Clinical)	420	100	4.0	1.5

Table A10.1.9 Specialised formulae for specific clinical conditions

Condition	Product (manufacturer)	Notes and ACBS indications
Cancer	Forticare (Nutricia Clinical) Liquid	Pancreatic cancer Lung cancer undergoing chemotherapy
	Supportan (Fresenius Kabi) Liquid	
	ProSure (Abbott) Liquid	Pancreatic cancer Contains EPA
Crohn's disease	Alicalm (SHS) Powder	Crohn's disease
	Modulen IBD (Nestlé) Powder	Active Crohn's disease/nutritional support during Crohn's remission
	Can be flavoured with Flavour Mix (Nestlé) Powder	
Epilepsy	KetoCal (SHS) Powder	Part of ketogenic diet in management of drug therapy resistant epilepsy
Liver disease	Generaid (SHS) Powder	Whey protein + BCAA Chronic liver disease and/or portohepatic encephalopathy
Pulmonary disease	Oxepa (Abbott) Liquid	Acute lung injury, ARDS and SIRS
	Pulmocare (Abbott) Liquid	COPD, cystic fibrosis or respiratory failure
	Respifor (Nutricia Clinical) Liquid	Disease related malnutrition in COPD + BMI <20 kg/m ²
Renal disease	Nepro (Abbott) Liquid	Chronic renal failure with haemodialysis or continuous ambulatory peritoneal dialysis
	Renamil (KoRa) Powder	Cirrhosis Chronic renal failure
	Renapro (KoRa) Powder	Biochemically proven hypoproteinaemia Patients on dialysis
Renal/liver disease	Duocal Super Soluble (SHS) Powder	For use where a high energy, low fluid and low electrolyte diet is required
	Suplena (Abbott) Liquid	Chronic/acute renal failure without dialysis Chronic/acute liver disease with fluid restriction
	Elemental 028 Extra (SHS) Powder	Intractable malabsorption and proven irritable bowel disease
Short bowel syndrome	Elemental 028 Extra (SHS) Powder	
Synthetic diets	Metabolic Mineral Mixture (SHS) Powder	Mineral and trace element supplement for synthetic diets

ARDS, acute respiratory distress syndrome; BCAA, branched chain amino acids; COPD, chronic obstructive pulmonary disease; SIRS, systemic inflammatory response syndrome; BMI, body mass index; EPA, eicosapentaenoic acid.

Table A10.1.10 Nutritional supplements for metabolic diseases

Condition	Product (manufacturer)	Notes and ACBS indications
Glutaric aciduria	XLYS, TRY Glutaridon* (SHS) Powder	Type 1 glutaric aciduria
Glycogen storage diseases	Glycosade (Vitaflo) Powder	Plus other metabolic conditions where a constant glucose supply is essential
Homocystinuria	HCU cooler (Vitaflo) Liquid HCU Express (Vitaflo) Powder	Methionine free protein substitute
Hypermethioninaemia	HCU LV (SHS) Powder	And vitamin B ₆ non-responsive homocystinuria
Hypermethioninaemia or homocystinuria	XMET Homidon* (SHS) Powder XMET Maxamum (SHS) Powder	Essential and non-essential amino acids except methionine
Isovaleric acidaemia	XLEU Faladon (SHS) Powder	Essential and non-essential amino acids except leucine
Maple syrup urine disease	Isoleucine Amino Acid Supplement (Vitaflo) Powder Valine Amino Acid Supplement (Vitaflo) Powder MSUD Aid III (SHS) Powder MSUD cooler (Vitaflo) Liquid MSUD express (Vitaflo) Powder MSUD Maxamum (SHS) Powder	Use in low protein diets by mixing with protein substitute, adding to modular feeds, or incorporating into other permitted food or drink Essential and non-essential amino acids except isoleucine, leucine and valine
Methylmalonic acidaemia	XMTVI Asadon (SHS) Powder	Essential and non-essential amino acids except methionine, threonine, valine and low isoleucine
Propionic acidaemia	XMTVI Maxamum (SHS) Powder	
Other errors of protein metabolism	Cystine Amino Acid Supplement (Vitaflo) Powder Leucine Amino Acid Supplement (Vitaflo) Powder Phenylalanine Amino Acid Supplement (Vitaflo) Powder	Use in low protein diets by mixing with protein substitute, adding to modular feeds, or incorporating into other permitted food or drink
Other inborn errors of metabolism	DocOmega (Vitaflo) Powder KeyOmega (Vitaflo) Powder	n-3 supplement containing DHA n-3 and supplement containing AA and DHA
Phenylketonuria (PKU)	Add-Ins (SHS) Powder Easiphen (SHS) Liquid Lophlex (SHS) Powder L-Tyrosine (SHS) Powder Milupa PKU 3-advanta (Milupa) Powder Phlexy-10 Exchange System (SHS) Capsule/tablet/drink PK Aid-4 (SHS) Powder	Phenylalanine free protein substitute Ready to drink phenylalanine free liquid product Phenylalanine free drink mix For use in maternal PKU where there are low plasma tyrosine concentrations Phenylalanine free protein supplement Each unit (1 sachet, 10 tablets or 20 capsules) provides 10g of amino acids except phenylalanine Unflavoured blend of essential and non-essential amino acids

(Continued)

Table A10.1.10 (Continued)

Condition	Product (manufacturer)	Notes and ACBS indications		
	PKU cooler10 (Vitaflo) Liquid Provides 10g of protein equivalent	Ready to drink phenylalanine free protein substitutes, including n-3 LCPs, DHA and EPA		
	PKU cooler15 (Vitaflo) Liquid Provides 15g of protein equivalent			
	PKU cooler20 (Vitaflo) Liquid Provides 20g of protein equivalent			
	PKU express (Vitaflo) <i>powder</i> 1 × 25g sachet provides 15g of protein equivalent		Phenylalanine free protein substitute	
	PKU Lophlex LQ 10 (SHS) Liquid Provides 10g of protein equivalent		Phenylalanine free liquid containing a balanced mixture of essential and non-essential amino acids, carbohydrates, vitamins, trace elements and some minerals	
	PKU Lophlex LQ 20 (SHS) Liquid Provides 20g of protein equivalent			
	Tyrosine Amino Acid Supplement (Vitaflo) Powder		For use in low protein diets	
	XP Maxamum (SHS) Powder		Phenylalanine free protein substitute drink mix	
	Tyrosinaemia		TYR cooler (Vitaflo) Liquid	Ready to drink tyrosine and phenylalanine free protein substitute
			TYR express (Vitaflo) <i>powder</i> 25-g sachet provides 15g of protein equivalent	Unflavoured, powdered tyrosine and phenylalanine free protein substitute
XPHEN TYR Tyrosidon (SHS) Powder		Normal plasma methionine concentrations		
XPTM Tyrosidon (SHS) Powder		Above normal plasma methionine concentrations		
Urea cycle disorders	L-Arginine (SHS) Powder	Except arginase deficiency		
	Dialamine (SHS) Powder	Essential amino acid supplement		
	EAA Supplement (Vitaflo) Powder			
	Low protein milk replacement drinks	Loprofin PKU Drink (SHS) Liquid	Low protein, low phenylalanine drink based on cow's milk	
Milupa Ip-drink (Milupa) Powder		Suitable for dietary management of amino acid metabolism disorders		
ProZero (Vitaflo) Liquid		Liquid blend of carbohydrate and fat		
Sno-Pro (SHS) Liquid		Low protein, low phenylalanine drink based on milk extracts		
Vitamin and mineral component		Phlexy-Vits (SHS) Powder/tablet	For use with restricted diets for PKU and similar amino acid abnormalities	
	Flavouring preparations	FlavourPac (Vitaflo) Powder	For use with unflavoured protein substitutes	
Blackcurrant, lemon, orange, tropical, raspberry				
Modjul Flavour System (SHS) Powder				
	Blackcurrant, orange, pineapple			

*A source of vitamins, minerals and trace elements is also required, e.g. **Phlexy-Vits**.

AA, arachidonic acid; DHA, docosahexaenoic acid; EPA, eicosapentanoic acid; LCPs, long chain polyunsaturated fatty acids.

Appendix A10.2 Paediatric nutritional supplements and enteral feeds

This appendix was compiled as a guide; it is not definitive. For further details, see Shaw & Lawson (2007).

Table A10.2.1 Paediatric sip feeds

Product type	Product name (manufacturer)	Per 100 mL of ready to drink product/standard dilution				Notes
		kJ	kcal	Protein (g)	Fibre (g)	
Low energy (<1 kcal/mL)	Nutriprem 1 (Cow & Gate) Liquid	201	48	1.5	0.5	60-mL bottle, formula for low birth weight babies <1.8 kg only available in hospital
	Nutriprem 2 (Cow & Gate) Liquid	310	75	2.0	0.6	Catch-up growth in preterm infants (<35 weeks' gestation at birth) and small for gestational age infants up to 6 months corrected age
	SMA Gold Prem 2 (SMA Nutrition) Powder	305	73	1.9	0.0	250-mL carton, disease related malnutrition, malabsorption, growth failure from birth to 18 months
	SMA High Energy (SMA Nutrition) Liquid	382	91	2.0	0.0	
Standard energy (1 kcal/mL)	Clinutren Junior (Nestlé) Powder	420	100	3.0	0.0	Growth failure*†
	Infatrini (Nutricia Clinical) Liquid	415	100	2.6	0.8	100-mL bottle, failure to thrive, disease related malnutrition and malabsorption, from birth up to body weight of 8 kg
	Paediasure (Abbott) Liquid	422	100	2.8	0.0	200-mL bottle*†
	Paediasure Fibre (Abbott) Liquid	420	100	2.8	0.8	
	Paediasure Peptide (Abbott) Liquid	420	100	3.0	0.0	
	Similac High Energy (Abbott) Liquid	419	100	2.6	0.4	120-mL bottle, increased energy requirements, faltering growth and/or need for fluid restriction, body weight up to 8 kg

(Continued)

Table A10.2.1 (Continued)

Product type	Product name (manufacturer)	Per 100 mL of ready to drink product/standard dilution				Notes
		kJ	kcal	Protein (g)	Fibre (g)	
High energy (1.5 kcal/mL)	Fortini (Nutricia Clinical) Liquid	630	150	3.4	0.0	Disease related malnutrition and growth failure in children aged 1–6 years,* body weight 8–20 kg
	Fortini Multifibre (Nutricia Clinical) Liquid	630	150	3.4	1.5	
	Fortini Smoothie Multifibre (Nutricia Clinical) Liquid	625	150	3.4	1.4	
	Frebini Energy Drink (Fresenius Kabi) Liquid	630	150	3.8	0.0	Disease related malnutrition and growth failure in children aged 1–10 years,* body weight 8–30 kg
	Frebini Energy Fibre Drink (Fresenius Kabi) Liquid	630	150	3.8	1.1	
	Paediasure Plus (Abbott) Liquid	632	151	4.2	0.0	*†
	Paediasure Plus Fibre (Abbott) Liquid	626	150	4.2	1.1	*†
	Paediasure Plus Juce (Abbott) Liquid	638	150	4.2	0.0	Low fat*†
	Resource Junior (Nestlé) Liquid	630	150	3.0	0.0	For children aged 1–10 years*

*Not suitable for use in children under 1 year of age.

†For children aged 1–10 years, body weight 8–30 kg.

Table A10.2.2 Feed thickener

Product name (manufacturer)	Notes
Carobel Instant (Cow & Gate)	Instant thickening agent, prepared from carob seed flour, suitable from birth. Prescribable for thickening feeds in the treatment of habitual and recurrent vomiting

Table A10.2.3 Paediatric enteral feeds – standard indications

Product type	Product name (manufacturer)	Per 100 mL				Notes
		kJ	kcal	Protein (g)	Fibre (g)	
Low energy (<1 kcal/mL)	Nutrini Low Energy Multi Fibre (Nutricia Clinical) Liquid	315	75	2.1	0.8	For children aged 1–6 years, except bowel fistula, body weight 8–20 kg
Standard energy (1 kcal/mL)	Clinutren Junior (Nestlé) Powder	420	100	3.0	0.0	For growth failure*†
	Frebini Original (Fresenius Kabi) Liquid	420	100	2.5	0.0	
	Frebini Original Fibre (Fresenius Kabi) Liquid	420	100	2.5	0.8	
	Infatrini (Nutricia Clinical) Liquid	415	100	2.6	0.8	Failure to thrive, disease related malnutrition and malabsorption, from birth up to body weight 8 kg
	Nutrini (Nutricia Clinical) Liquid	420	100	2.8	0.0	For growth failure in children aged 1–6 years, body weight 8–20 kg*
	Nutrini Multi Fibre (Nutricia Clinical) Liquid	420	100	2.8	0.8	
	Paediasure (Abbott) Liquid	422	100	2.8	0.0	*†
	Paediasure Fibre (Abbott) Liquid	420	100	2.8	0.8	
	Similac High Energy (Abbott) Liquid	419	100	2.6	0.4	Increased energy requirements, faltering growth and/or need for fluid restriction, body weight up to 8 kg
	Tentrini (Nutricia Clinical) Liquid	420	100	3.3	0.0	For growth failure in children aged 7–12 years, body weight 21–45 kg
	Tentrini Multi Fibre (Nutricia Clinical) Liquid	420	100	3.3	1.1	
Medium energy (1.2 kcal/mL)	Isosource Junior (Nestlé) Liquid	512	122	2.7	0.0	For growth failure in children aged 1–6 years, body weight 8–20 kg*
High energy (1.5 kcal/mL)	Frebini Energy (Fresenius Kabi) Liquid	630	150	3.8	0.0	For growth failure in children aged 1–10 years, body weight 8–30 kg*
	Frebini Energy Fibre (Fresenius Kabi) Liquid	630	150	3.8	1.1	
	Nutrini Energy (Nutricia Clinical) Liquid	630	150	4.1	0.0	For growth failure in children aged 1–6 years, body weight 8–20 kg*
	Nutrini Energy Multi Fibre (Nutricia Clinical) Liquid	630	150	4.1	0.8	For children aged 1–6 years, body weight 8–20 kg* and total gastrectomy, not with bowel fistula
	Paediasure Plus (Abbott) Liquid	632	151	4.2	0.0	*†
	Paediasure Plus Fibre (Abbott) Liquid	626	150	4.2	1.1	
	Tentrini Energy (Nutricia Clinical) Liquid	630	150	4.9	0.0	For growth failure in children aged 7–12 years, body weight 21–45 kg
	Tentrini Energy Multi Fibre (Nutricia Clinical) Liquid	630	150	4.9	1.1	For children aged 7–12 years, body weight 21–45 kg and proven inflammatory bowel disease

*Not suitable for use in children under 1 year of age.

†For children aged 1–10 years, body weight 8–30 kg.

Table A10.2.4 Specialist paediatric formulae

Formula type	Product name (manufacturer)	Per 100 mL of ready to drink product (standard dilution)				Notes	
		kJ	kcal	Protein (g)	Fibre (g)		
Amino acid based	Emsogen (SHS) Powder	368	88	2.5	0.0	Short bowel syndrome, intractable malabsorption, proven inflammatory bowel disease, bowel fistula. Not suitable as sole source of nutrition for children aged 1–5 years* For children aged 1–12 years*	
	Neocate Active (SHS) Powder	418	100	2.8	0.0		
	Neocate Advance (SHS) Powder	420	100	2.5	0.0		
	Neocate LCP (SHS) Powder	293	70	1.9	0.0		‡
	Nutramigen AA (Mead Johnson) Powder	286	68	4.9	0.0		
Fructose based	Galactomin 19 (SHS) Powder	288	69	1.9	0.0	Conditions of glucose plus galactose intolerance	
Hydrolysate	Aptamil Pepti 1 (Allergy) (Milupa) Powder	280	67	1.6	0.6	Established cow's milk protein intolerance with or without secondary lactose intolerance [‡] Established cow's milk protein allergy or intolerance. Not suitable for children aged <6 months; suitable for children aged 6 months–12 years Disaccharide and/or whole protein intolerance, or where amino acids and peptides are indicated in conjunction with MCTs [‡] Disaccharide and/or whole protein intolerance where additional MCTs are not indicated [‡] Established disaccharide and/or whole protein intolerance where additional MCTs are not indicated. Not suitable for children aged <6 months; suitable for children aged 6 months–12 years For growth failure in children aged 1–6 years,* body weight 8–20 kg Disaccharide and/or whole protein intolerance [‡] Disaccharide and/or whole protein intolerance, or where amino acids or peptides are indicated in conjunction with MCTs. For children aged 1–12 years* Short bowel syndrome, intractable malabsorption, proven inflammatory bowel disease, bowel fistula, in children aged 1–10 years* Disaccharide and/or whole protein intolerance, or where amino acids or peptides are indicated in conjunction with MCTs and hydrolysed casein [‡]	
	Aptamil Pepti 2 (Allergy) (Milupa) Powder	285	68	1.6	0.6		
	Cow & Gate Pepti-Junior (Cow & Gate) Powder	275	66	1.8	0.0		
	Nutramigen Lipil 1 (Mead Johnson) Powder	280	68	1.9	0.0		
	Nutramigen Lipil 2 (Mead Johnson) Powder	285	68	1.7	0.0		
	Nutrini Peptisorb (Nutricia Clinical) Liquid	420	100	2.8	0.0		
	Pepdite (SHS) Powder	297	71	2.1	0.0		
	Pepdite 1+ (SHS) Powder	423	100	3.1	0.0		
	Peptamen Junior (Nestlé) Liquid	420	100	3.0	0.0		
	Pregestimil Lipil (Mead Johnson) Powder	280	68	1.9	0.0		
Low calcium	Locasol (SHS) Powder	278	66	1.9	0.0	Conditions of calcium intolerance requiring restriction of calcium and vitamin D intake [‡]	

Table A10.2.4 (Continued)

Formula type	Product name (manufacturer)	Per 100 mL of ready to drink product (standard dilution)				Notes
		kJ	kcal	Protein (g)	Fibre (g)	
MCT enhanced	Caprilon (SHS) Powder	277	66	1.5	0.0	Fat 3.6g (MCTs 75%) ^{d‡}
	MCT Pepdite (SHS) Powder	286	68	2.0	0.0	Fat 2.7g, (MCTs 75%) ^{d‡}
	MCT Pepdite +1 (SHS) Powder	381	91	2.8	0.0	Fat 3.6g, (MCTs 75%) ^d for children aged 1–12 years [*]
	Monogen (SHS) Powder	313	74	2.0	0.0	LCAD, CPTD, and primary and secondary lipoprotein lipase deficiency. Fat 2.1 g (MCTs 90%) [‡]
Peptide-based	Paediasure Peptide (Abbott) Liquid	420	100	3.0	0.0	* [†]
	Peptamen Junior (Nestlé) Liquid	420	100	3.0	0.0	Short bowel syndrome, intractable malabsorption, proven inflammatory bowel disease, bowel fistula ^{*†}
Pre-thickened infant feeds	Enfamil AR (Mead Johnson) Powder	285	68	1.7	0.0	Significant gastro-oesophageal reflux [‡]
	SMA Staydown (SMA Nutrition) Powder	279	67	1.6	0.0	
Residual lactose	Enfamil O-Lac (Mead Johnson) Powder	280	68	1.4	0.0	Proven lactose intolerance [‡]
	Galactomin 17 (SHS) Powder	295	70	1.7	0.0	Proven lactose intolerance in preschool children, galactosaemia and galactokinase deficiency [‡]
	SMA LF (SMA Nutrition) Powder	281	67	1.5	0.0	Proven lactose intolerance [‡]
Soya based	InfaSoy (Cow & Gate) Powder	275	66	1.6	0.0	Proven lactose and associated sucrose intolerance in preschool children, galactokinase deficiency, galactosaemia and proven whole cow's milk sensitivity [‡]
	SMA Wysoy (SMA Nutrition) Powder	280	66	1.8	0.0	

*Not suitable for use in children under 1 year of age.

†For children aged 1–10 years, body weight 8–30 kg.

‡Suitable from birth to 12 years of age.

^dDisorders in which a high intake of MCTs is beneficial (MCTs 75%).

MCT, medium chain triglycerides; LCAD, long chain acyl-CoA deficiency; CPTD, carnitine palmitoyl transferase deficiency.

Table A10.2.5 Nutritional supplements for metabolic diseases (products in italics are also listed in the adult Appendix A10.1)

Metabolic disease	Product name (manufacturer)	Age range	Notes
Glutaric aciduria (type 1)	GA1 Anamix Infant (SHS) Powder	Birth–3 years	Contains vitamins, minerals, trace elements, essential and non-essential amino acids except lysine and low tryptophan
	GA Gel (Vitaflo) Gel	1–10 years	
	XLYS, Low TRY, Maxamaid (SHS) Powder	1–8 years	
Glycogen storage disease	Glycosade (Vitaflo) Powder	>2 years	Also other metabolic conditions where a constant glucose supply is essential
Homocystinuria	Cystine Amino Acid Supplement (Vitaflo) Powder	>1 year	Methionine free protein substitutes for use as nutritional supplements
	<i>HCU cooler (Vitaflo) Liquid</i>	>3 years	
	<i>HCU Express (Vitaflo) Liquid</i>	>8 years	
	HCU gel (Vitaflo) Powder	1–10 years	
Hypermethioninaemia or homocystinuria	<i>XMET Homidon (SHS) Powder</i>	1–8 years	Methionine free, unflavoured, powdered drink mixes
	XMET Maxamaid (SHS) Powder		
	<i>XMET Maxamum (SHS) Powder</i>	>8 years	Methionine free, unflavoured, powdered drink mix with vitamins, minerals and trace elements
	HCU Anamix Infant (SHS) Powder	Birth–3 years	Essential and non-essential amino acids except methionine for proven vitamin B ₆ non-responsive homocystinuria or hypermethioninaemia
	<i>HCU LV (SHS) Powder</i>	>8 years	For hypermethioninaemia or vitamin B ₆ non-responsive homocystinuria
High energy fat/carbohydrate supplement	Energivit (SHS) Powder		For children requiring additional energy, vitamins, minerals and trace elements following a protein restricted diet
Hyperlysinaemia	HYPER LYS Anamix Infant (SHS) Powder	Birth–3 years	Essential and non-essential amino acids except lysine
	XLYS Maxamaid (SHS) Powder	1–8 years	
Isovaleric acidaemia	IVA Anamix Infant (SHS) Powder	Birth–3 years	Isovaleric acidaemia and other proven disorders of leucine metabolism <i>XLEU Faladon can be used as part of a modular feed or added as an amino acid supplement to XLEU Analog in the latter stages of weaning</i>
	<i>XLEU Faladon (SHS) Powder</i>		
	XLEU Maxamaid (SHS) Powder		
Low protein milk replacement drinks	Loprofin PKU Drink (SHS) Liquid	>1 year	Low protein, low phenylalanine drink based on cow's milk for use in PKU
	Low protein drink (Milupa) Powder	>1 year	For inborn errors of amino acid metabolism
	Milupa Ip-drink (Milupa) Powder	>1 year	For dietary management of amino acid metabolism disorders
	ProZero (Vitaflo) Liquid	>6 months	Liquid blend of carbohydrate and fat
	Sno-Pro (SHS) Liquid		Low protein, low phenylalanine drink based on milk extracts for PKU, chronic renal failure and other inborn errors of amino acid metabolism

Table A10.2.5 (Continued)

Metabolic disease	Product name (manufacturer)	Age range	Notes		
Maple syrup urine disease	<i>MSUD Aid III (SHS) Powder</i>		<i>Also related conditions where intake of branched chain amino acids must be limited</i>		
	MSUD Anamix Infant (SHS) Powder	Birth–3 years			
	MSUD Anamix Junior (SHS) Powder	1–10 years			
	MSUD Anamix Junior LQ (SHS) Liquid	1–10 years			
	<i>MSUD cooler (Vitaflo) Liquid</i>	>3 years			
	<i>MSUD express (Vitaflo) Powder</i>	>8 years			
	MSUD Gel (Vitaflo) Powder	1–10 years			
	MSUD Maxamaid (SHS) Powder	1–8 years			
	<i>MSUD Maxamum (SHS) Powder</i>	>8 years			
	Methylmalonic acidaemia and propionic acidaemia	MMA/PA Anamix Infant (SHS) Powder		Birth–3 years	Essential and non-essential amino acids except methionine, threonine, and valine, low isoleucine content
		XMTVI Asadon (SHS) Powder		<i>Infants and children</i>	
		XMTVI Maxamaid (SHS) Powder		1–8 years	
<i>XMTVI Maxamum (SHS) Powder</i>		>8 years			
Phenylketonuria (PKU) PKU		<i>Add-Ins (SHS) Powder</i>	>4 years	Essential and non-essential amino acids except phenylalanine	
	<i>Easiphen (SHS) Liquid</i>	>8 years			
	<i>Lophlex (SHS) Powder</i>	>8 years			
	Milupa PKU 2-prima (Milupa) Powder	1–8 years			
	Milupa PKU 2-secunda (Milupa) Powder	9–15 years			
	Milupa PKU 3-advanta (Milupa) Powder	>15 years			
	<i>Phlexy-10 Exchange System (SHS) Capsule/tablet/drink</i>	>8 years	<i>Each unit (1 sachet, 10 tablets or 20 capsules) provides 10g of amino acids except phenylalanine</i>		
	Phlexy-Vits (SHS) Powder/tablet	>11 years	Vitamin and mineral component of restricted therapeutic diets in PKU and similar amino acid abnormalities		
	PKU Anamix First Spoon (SHS) Powder	6 months–5 years	Contains DHA, essential and non-essential amino acids except phenylalanine		
	PKU Anamix Infant (SHS) Powder	Birth–3 years	Contains prebiotic oligosaccharides, AA and DHA		
	PKU Anamix Junior (SHS) Powder	1–10 years	Contains AA, DHA, vitamins and minerals		
	PKU Anamix Junior LQ (SHS) Liquid	1–10 years			
	<i>PKU cooler 10, 15, 20 (Vitaflo) Liquid</i>	>3 years	<i>Ready to drink phenylalanine free protein substitute containing DHA and EPA, vitamins, minerals and trace elements.</i>		

(Continued)

Table A10.2.5 (Continued)

Metabolic disease	Product name (manufacturer)	Age range	Notes
Phenylketonuria	<i>PKU express (Vitaflo) Powder</i>	>3 years	Contains essential and non-essential amino acids except phenylalanine, carbohydrate, vitamins, minerals and trace elements
	<i>PKU gel (Vitaflo) Powder</i>	1–10 years	
	<i>PKU Lophlex LQ 10, 20 (SHS) Liquid</i>	>4 years	<i>Ready to drink, phenylalanine free protein substitute containing essential and non-essential amino acids, carbohydrates, vitamins, trace elements and some minerals</i>
	<i>PKU Start (Vitaflo) Liquid</i>	<12 months	Ready to feed phenylalanine free infant formula containing essential and non-essential amino acids, carbohydrate, fat, vitamins, minerals, trace elements, AA and DHA
Tyrosinaemia	<i>XP Maxamaid (SHS) Powder</i>	1–8 years	Phenylalanine free drink mix containing essential and non-essential amino acids, carbohydrate, vitamins, minerals and trace elements
	<i>XP Maxamum (SHS) Powder</i>	>8 years	
	<i>Methionine-free TYR Anamix Infant (SHS) Powder</i>	Birth–3 years	For proven tyrosinaemia type 1
	<i>TYR Anamix Infant (SHS) Powder</i>	Birth–3 years	Proven tyrosinaemia where plasma methionine concentrations are normal
	<i>TYR Anamix Junior (SHS) Powder</i>	1–10 years	Proven tyrosinaemia
	<i>TYR Anamix Junior LQ (SHS) Liquid</i>	>1 year	Tyrosinaemia type 1 (when NTBC is used), type 2 and type 3
	<i>TYR cooler (Vitaflo) Liquid</i>	>3 years	Contains carbohydrates, minerals, trace elements and vitamins, essential and non-essential amino acids except tyrosine and phenylalanine
	<i>TYR express (Vitaflo) Powder</i>	>8 years	
	<i>TYR Gel (Vitaflo) Gel</i>	1–10 years	
	Flavouring preparations	<i>XPHEN TYR Maxamaid (SHS) Powder</i>	1–8 years
<i>FlavourPac (Vitaflo) Powder</i> <i>Modjul Flavour System (SHS) Powder</i>			<i>For use with unflavoured protein substitutes</i>

AA, arachidonic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; NTBC, nitisone.

Appendix A11 Nutrition screening tools

This appendix contains screening tools that are discussed in detail in the text; many other tools are available that are applicable to dietetic practice. For details on paediatric screening tools, refer to Shaw & Lawson (2007).

Reassess subjects identified at risk as they move through care settings

See The 'MUST' Explanatory Booklet for further details and The 'MUST' Report for supporting evidence.

Figure A11.1 Malnutrition Universal Screening Tool 'MUST' (from www.bapen.org.uk/pdfs/must/must_page3.pdf)

Patient's Name
NHS/ID No

Complete all boxes on admission and action as indicated by score

Estimated/reported Weight (kg)	Estimated/reported Height (m)	Body mass index (BMI) (use BMI chart to calculate)
--------------------------------	-------------------------------	--

Score each risk factor, using highest score if more than one is relevant.
Total up column scores to obtain final score and record below.

Weight loss in last 3 months <u>and</u> current BMI (choose highest score)	Age (years)	Level of SCI	Other medical conditions	Skin conditions	Diet	Intake	Ability to eat
0 'Minimal' (under 5%) MI $\geq 22.5 \text{ kg/m}^2$	1 18–30	1 S1–S5	0 None	0 Intact	0 Normal diet and fluids or established NG/PEG feed	0 Eating all meals or tolerating full enteral feed	0 Not applicable as on NG/PEG feed
1 'Some' (5–10%) BMI 18.5–22.5 kg/m ²	2 31–60	2 L1–L5	1 Chronic conditions, e.g. pain/substance abuse	1 Grade 1 ulcer	1 Introductory NG/PEG feed	1 Under half meal or NG/PEG feed tolerated	0 Able to eat independently
3 'Moderate' (11–15%) BMI 16.5–18.4 kg/m ²	3 >60	3 T1–T12	2 Acute trauma, e.g. head injury/fractures	2 Grade 2 ulcer	2 Modified texture diet	2 Minimal diet or enteral feed	2 Requires some help
4 'Marked' (>15%) BMI <16.4 kg/m ²	4 Under 18	5 C1–C8	3 Within 1 week of surgery/ongoing infection	3 Grade 3 ulcer	3 Nil by mouth for >5 days	3* Vomiting and diarrhoea or not tolerating NG/PEG feed	3 Needs to be fed
			4 Ventilated (non-invasive)	5 Grade 4 ulcer			
			5 Fully ventilated with tracheostomy			Investigate cause and treat	

Date	Column score	TOTAL SCORE							

Figure A11.2 Spinal nutritional screening tool

Transfer total score overleaf and choose appropriate action plan according to identified risk category.

Complete table below to update nutritional risk scores and document weight changes.

Date	Total score	Risk (L/M/H)	Latest weight Actual/estimate	Weight Change (\pm kg)	Variance and comments	Referred to dietitian	Review date	Nurse's signature

Follow local action plan according to risk score. Document actions in nursing notes.

Score	Risk	Action plan	
10 and under	Low Rehab	Encourage healthy food and drink choices Assist with feeding if needed	Monthly weight if possible Repeat score monthly
	Low Acute	Encourage appropriate menu choices If eating less than half meals complete 3-day food chart and offer two nutritional supplements /sip feeds* a day If no improvement in eating refer to dietitian	Weekly weight if possible Repeat score weekly
11–15	Moderate Rehab and Acute	Encourage appropriate menu choices Assist with feeding if needed Complete 3-day food chart. Implement 'Red Tray' Replace missed meals with nutritional supplements /sip feeds* a day If no improvement in eating refer to dietitian	Weekly weight if possible Repeat score weekly
Above 15	High Rehab and Acute	Encourage high energy/protein menu choices Assist with feeding if needed Complete 3-day food chart. Implement 'Red Tray' Replace missed meals with nutritional supplements as prescribed by doctor or dietitian Refer to dietitian	Weekly weight if possible Repeat score weekly

Patients N.B.M. for over 5 days or requiring NG/PEG feeding need automatic referral to dietitian. If 'out of hours' feeding regimens for the prevention of refeeding syndrome guidance is available on

*Supplement drinks; if the patient has diabetes monitor blood glucose levels and refer to dietitian and diabetes advisor.

If the patient has renal problems, monitor bloods closely and refer to dietitian and medical team.

If too much weight is being gained or BMI above 30 kg/m²: (1) give patient #Why Weight Matters' diet sheet, (2) Suggest patient attends 'drop-in' weight clinic to monitor weight trend and (3) offer referral to dietitian.

PLEASE RING EXT TO FORMALLY REFER PATIENTS TO DIETITIAN FROM NUTRITIONAL SCREENING

Figure A11.2 (Continued)

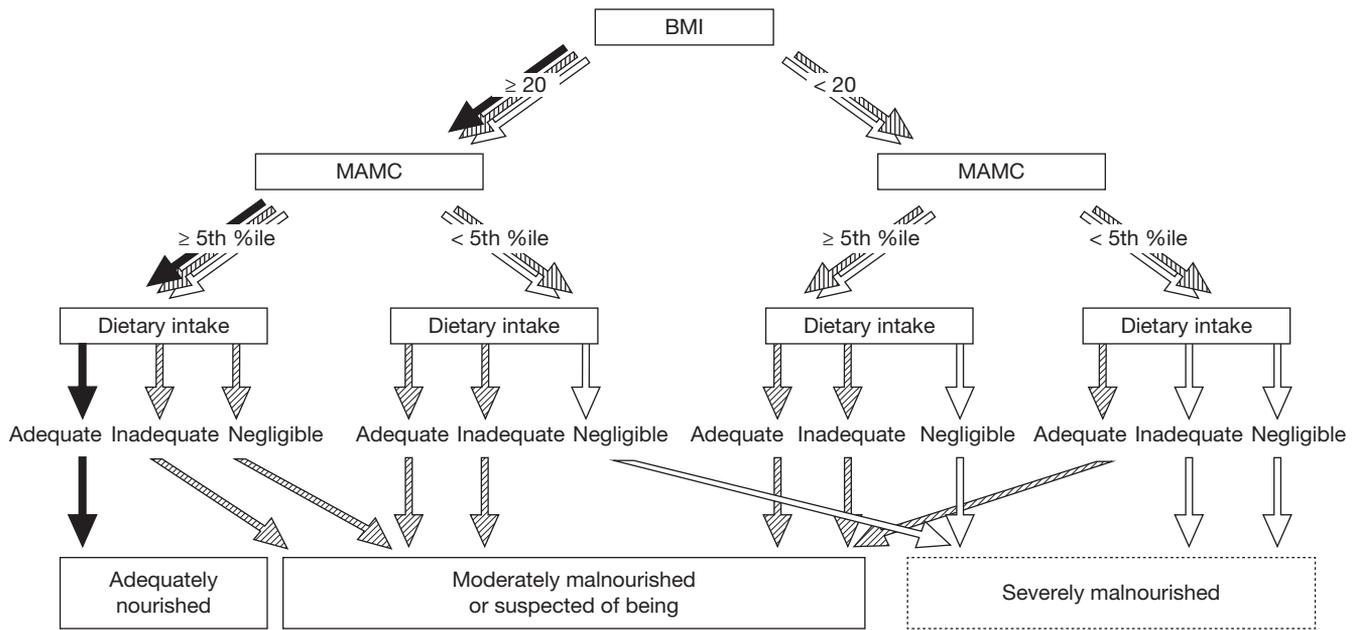

Figure A11.3 Royal Free Hospital Global Assessment (RFH-GA) scheme for determining nutritional status in patients with cirrhosis [from Morgan *et al.* (2006) Derivation and validation of a new global method for assessing nutritional status in patients with cirrhosis. *Hepatology* 44: 823–835]
 N.B. This Figure shows an assessment tool rather than a screening tool but is added for completeness.

Index
