The provision of adequate energy and other nutrients and nutrition education should be one part of an overall interdisciplinary plan to assist children and their families. Attempts should be made to increase children's appetites and modify the environment to ensure optimal intake. Frequent small meals and snacks should be offered at regular times, using developmentally appropriate, nutrient-dense foods. This optimizes the smaller stomach capacity of the young child and provides structure and predictability for the eating environment. Families should receive support for positive parent-child interactions, with respect for the division of responsibility in feeding and avoidance of any pressure or coercion on the child's eating. Severe malnutrition may require carefully planned interventions and close monitoring to prevent refeeding syndrome.

Chronic constipation can result in poor appetite, diminished intake, and FTT. Ensuring adequate fluid and fiber intake can help relieve constipation, improve appetite, and eventually promote weight gain. Because the fiber intake of children is often low, especially in children who are picky eaters, fiber intake always should be addressed in the evaluation. Fiber can be increased by adding legumes, fruits (especially dried fruits), vegetables, high-fiber breakfast cereals, bran muffins, or all of these to the diet.

Iron Deficiency

Iron deficiency is one of the most common nutrient disorders of childhood. The highest prevalence of anemia in children occurs in those younger than 2 years of age (Gupta et al, 2017). Iron deficiency is less of a problem among older preschool and school age children.

Infants with iron deficiency, with or without anemia, tend to score lower on standardized tests of mental development and pay less attention to relevant information needed for problem solving. Poorer cognitive performance and delayed psychomotor development have been reported in infants and preschool children with iron deficiency. Deficiency can have long-term consequences, as demonstrated by poorer performance on developmental tests in late childhood and early adolescence (Lozoff et al, 2007). Iron intake should be considered during assessments of individual diets and in policy decisions intended to address the nutrition needs of low-income, high-risk children.

In addition to growth and the increased physiologic need for iron, dietary factors also play a role. For example, a 1-year-old child who continues to consume a large quantity of milk and excludes other foods may develop anemia. Some young preschool children do not eat much meat, so most of their iron is consumed in the nonheme form from fortified cereals, which is absorbed less efficiently (see Chapter 31).

Dental Caries

Nutrition and eating habits are important factors affecting oral health. An optimal nutrient intake is needed to produce strong teeth and healthy gums. The composition of the diet and an individual's eating habits (e.g., dietary carbohydrate intake, eating frequency) are significant factors in the development of dental caries (see Chapter 24).

Allergies

Food allergies during infancy and childhood are more likely when a child has a family history of allergies. Allergic symptoms are seen most often as respiratory or gastrointestinal responses as well as skin responses but may include fatigue, lethargy, and behavior changes. There can be confusion about the definitions of *food allergy*, *food intolerance*,

and *food sensitivity*, and some tests for food allergies are unspecific and equivocal. See Chapter 25 for management of food allergies in children.

Attention-Deficit/Hyperactivity Disorder (ADHD) and Autism Spectrum Disorder

ADHD and Autism Spectrum Disorder are two common neurological disorders of childhood that affect behavior, socialization, and communication. Both can affect eating behaviors and nutrient intake which can manifest as food aversions, hypersensitivity to textures and flavors, and inadequate intake. See Chapter 43 for more details about assessment and MNT for these conditions.

PREVENTING CHRONIC DISEASE

The roots of chronic adult diseases such as heart disease, cancer, diabetes, and obesity are often based in childhood—a phenomenon that is particularly relevant to the increasing rate of obesity-related diseases such as type 2 diabetes. To help decrease the prevalence of chronic conditions in Americans, government and nonprofit agencies have been promoting healthy eating habits for children. Their recommendations include the Dietary Guidelines for Americans, the USDA MyPlate, the National Cholesterol Education Program (NCEP), and the National Cancer Institute Dietary Guidelines (see Chapter 10).

Cardiovascular Health

Compared with their counterparts in many other countries, American children and adolescents have higher blood cholesterol levels and higher intakes of saturated fatty acids and cholesterol. Early coronary atherosclerosis begins in childhood and adolescence. Risk factors include family history, breastfeeding and perinatal factors, nutrition and diet, physical activity, tobacco exposure, hypertension, hyper- and dyslipidemia, overweight and obesity, and diabetes. These were explored by an expert panel ([National Heart Lung and Blood Institute, 2011](#)); selected recommendations with nutrition implications are briefly summarized as follows:

For most healthy children limiting total fat to 30% of total energy, saturated fat to 7% to 10%, and dietary cholesterol to 300 mg/day is recommended. A balanced energy intake, increased intake of fruits and vegetables, and limiting “extra calories” to 5% to 15% total intake also is recommended for most children. Fiber intake of at least “age + 5 grams” (e.g., for a 4-year-old, $4 + 5 = 9$ g per day) or 14 g fiber/1000 kilocalories is suggested.

For children with dyslipidemia, who are overweight or obese, or who have “risk factor clustering” or high-risk medical conditions, the Expert Panel recommends consideration of the Cardiovascular Health Integrated Lifestyle Diet (CHILD-1) as the first stage in dietary change ([National Heart Lung and Blood Institute, 2011](#)). This is a DASH-style pattern with emphasis on fat-free/low-fat dairy and increased intake of fruits and vegetables.

For all children, the approach to modifying risk factors, especially related to dietary fat intake, should be individualized (see Chapter 32).

Calcium and Bone Health

Osteoporosis prevention begins early by maximizing calcium retention and bone density during childhood and adolescence, when bones are growing rapidly and are most sensitive to diet and the important effects of physical activity (see Chapter 23). However, mean dietary intakes of calcium are lower than the AI, with 20% to 30% of pubertal girls having intakes less than 500 mg/day. One longitudinal study of white children from infancy to 8 years of age found that bone mineral content was positively correlated with intake of protein and several

minerals, suggesting that many nutrients are related to bone health in children ([Bounds et al, 2005](#)). Because food consumption surveys show that children are drinking more soft drinks and noncitrus juices and less milk, education is needed to encourage young people to consume an appropriate amount of calcium from food sources and possibly supplements (see Appendix 39).

Fiber

Education about dietary fiber and disease prevention has mainly been focused on adults, and only limited information is available on the dietary fiber intake of children. Dietary fiber is needed for health and normal laxation in children. National survey data indicate that preschool children consume a mean of 11 to 12 g/day of dietary fiber; school age children consume approximately 14 to 15 g/day ([USDA, 2014](#)). This is lower than the DRI for children, which is based on the same 14 g/1000 kcal as adults because of lack of scientific evidence for the pediatric population ([Otten et al, 2006](#)). Generally, higher fiber intakes are associated with more nutrient-dense diets in young children ([Kranz et al, 2012](#); [Papanikolaou et al, 2017](#)).

The Gut Microbiome

The gut microbiome is an emerging topic in nutrition, including pediatric nutrition. It is clear that dietary and other factors affect the number and type of bacteria that colonize the gut. Factors that can affect the gut microbial community include dietary fiber, prebiotics, probiotics, and the use of antibiotic medication (see Chapter 1).

The gut bacteria profile seems to be associated with short- and long-term health outcomes. In addition to effects on GI disorders, research continues to explore the relationship between the gut microbiome and short- and long-term health outcomes, including obesity, digestive disorders, inflammation, and cancers ([Peregrin, 2013](#)).

Physical Activity

Children should be physically active each day, including play as well as structured activities, depending on age and developmental level. Decreased levels of physical activity are still seen in one third of children 4 to 11 years of age, with almost two thirds of the same group having high screen time ([Anderson et al, 2008](#)). Regular physical activity helps control excess weight gain and improves musculoskeletal health and fitness and components of cardiovascular health ([Janssen and Leblanc, 2010](#)). Physical activity may also improve the child’s mental health, blood pressure, and lipid profile ([Janssen and Leblanc, 2010](#)).

Current physical activity recommendations for those ages 6 through 17 years of age are 60 minutes or more of physical activity every day with the majority at a moderate or vigorous aerobic intensity. Children and adolescents should do vigorous intensity activity at least 3 days per week and include muscle-strengthening and bone-strengthening activity on at least 3 days per week. Information regarding activities that will meet these recommendations and are appropriate for children is available ([U.S. Department of Health and Human Services \[USDHHS\], 2008](#)). Strategies to increase activity in preschool and childcare settings, schools, and the community include more activity breaks, increased time outside, and improved walking/biking path infrastructure ([USDHHS, 2012](#)). Screen time (active games, exercise or dance videos, or TV exercise programs) can be a beneficial source of activity for youth. Three in 10 youth ages 9 to 18 engaged in at least 1 hour of active screen time weekdays, and 4 in 10 youth did the same on weekends ([Wethington et al, 2013](#)). MyPlate’s *Eat Smart to Play Hard* materials promote the recommendation for 60 minutes of physical activity each day ([Fig. 16.6](#)). The Dietary Guidelines for Americans and MyPlate also have been applied to children and their parents.

Eat Smart To Play Hard

Use **MyPlate** to help you fuel up with foods from each food group.

Choose **MyPlate.gov**

Keep on Moving!

You need at least **60 minutes** of physical activity each day. Whether that's skateboarding, tossing a ball, or playing tag, every little bit counts!

FRUITS Fuel Up With Fruits at Meals or Snacks
Oranges, pears, berries, watermelon, peaches, raisins, and applesauce (without extra sugar) are just a few of the great choices. Make sure your Juice is 100% fruit juice.

VEGETABLES Color Your Plate With Great-Tasting Veggies
Try to eat more dark-green, red, and orange vegetables, and beans and peas.

GRAINS Make at Least Half Your Grains Whole Grains
Choose whole-grain foods, such as whole-wheat bread, oatmeal, whole-wheat tortillas, brown rice, and light popcorn, more often.

PROTEIN Vary Your Protein Foods
Try fish, shellfish, beans, and peas more often. Some tasty ways include a bean burrito, hummus, veggie chili, fish taco, shrimp or tofu stir-fry, or grilled salmon.

DAIRY Get Your Calcium-Rich Foods
Choose fat-free or low-fat milk, yogurt, and cheese at meals or snacks. Dairy foods contain calcium for strong bones and healthy teeth.

Know Your "Sometimes" Foods Look out for foods with added sugars or solid fats. They fill you up so that you don't have room for the foods that help you eat smart and play hard.

Fig. 16.6 Eat smart to play hard. (From United States Department of Agriculture: *Eat Smart to Play Hard* (website): <http://www.fns.usda.gov/sites/default/files/eatsmartminiposter.pdf>, 2012.)

CLINICAL CASE STUDY

Brian is a 7-year, 4-month-old white male who gained 15 pounds during the past school year. His height is 50½ inches, and his weight is 75 pounds. Brian moved to a new home and began a new school a year ago after his parents' divorce. After-school care has been provided by a retired neighbor, who loves to bake for Brian. He has few friends in the neighborhood, and his main leisure activities have been watching television and playing video games. When he gets bored, he often looks for a snack. His mother reports that they often rely on take-out and fast-food meals because of the time constraints of her full-time job, and she has gained weight herself. She recently started an aerobics class with a friend and is interested in developing healthier eating habits for herself and Brian.

After joint sessions with Brian and his mother, the following goals were identified by the family: (1) explore after-school care at the local community center, which has a physical activity component; (2) alter grocery and menu selection to emphasize the MyPlate and low-fat choices while still meeting the family's time and resource constraints; (3) begin to incorporate physical activities (Brian identified swimming and bicycling as things he would like to do) on the weekends; and (4) limit television and video games to no more than 2 hours daily.

After 4 months, Brian has enrolled in the local community center's afterschool program and participates in organized soccer and "pick-up" basketball. Weekends are a challenge. Brian and his mother have not yet incorporated physical activity into their weekend routine, and Brian finds it tough to limit screen time to 2 hours on the weekends. Brian has lost 4 pounds and is taller; he is 51 inches tall and weighs 66 pounds.

Nutrition Diagnostic Statement

- Overweight/obesity related to infrequent physical inactivity, sedentary lifestyle, and estimated excessive energy intake as evidenced by BMI-for-age above the 95th percentile.

Nutrition Care Questions

1. Calculate and plot Brian's BMI over time. Discuss the changes.
2. What recommendations should be made to prevent Brian and his mother from resuming their old habits?
3. What other activities can Brian try to help him avoid or reduce the tendency to eat when he is not hungry?
4. What would you suggest to promote a positive feeding relationship between Brian and his mother, considering his age and level of development?
5. What recommendations can you make to decrease Brian's energy intake and make it more consistent with MyPlate recommendations? Consider ideas to alter Brian's favorite recipes (e.g., his favorite meal is fried chicken with gravy, mashed potatoes, and ice cream), select healthy options from take-out or fast-food options, and modify snack options.
6. Are there any nutrient-related concerns because Brian's diet is being altered to help with weight management? Or because of his age? Or other factors?

pubarche
puberty

sexual maturity rating (SMR)
Tanner staging
thelarche

Adolescence is one of the most exciting yet challenging periods in human development. Generally thought of as the period of life that occurs between 12 and 21 years of age, adolescence is a period of tremendous physiologic, psychological, and cognitive transformation during which a child becomes a young adult. The gradual growth pattern that characterizes early childhood changes to one of rapid growth and development, affecting physical and psychosocial aspects of health. Changes in cognitive and emotional functioning allow teens to become more independent as they mature. Peer influence and acceptance may become more important than family values, creating periods of conflict between teens and parents. Because all of these changes have a direct effect on the nutrient needs and dietary behaviors of adolescents, it is important that health care providers develop a full understanding of how these developmental changes of adolescence can affect nutritional status.

GROWTH AND DEVELOPMENT

Puberty is the period of rapid growth and development during which a child physically develops into an adult and becomes capable of reproduction. It is initiated by the increased production of reproductive hormones such as estrogen, progesterone, and testosterone and is characterized by the outward appearance of secondary sexual characteristics, such as breast development in females and the appearance of facial hair in males.

Psychological Changes

The physical growth of puberty transforms the teen body into an adult-like form, leading adults to believe that adolescent development is complete. However, the social and emotional development of adolescence lags behind. The mismatch between how teens look and how they act may lead adults to deduce that adolescents are “not acting their age.” The rebellion that is associated with the teen years is actually the manifestation of their search for independence and a sense of autonomy. Food can be, and often is, used as a means of exerting autonomy. Adolescents may choose to become vegetarian as a way to differentiate themselves from their meat-eating parents

or to express their moral and ethical concerns over animal welfare or the environment.

Cognitive and emotional development may vary greatly among adolescents, with some adolescents maturing faster than others. In general, adolescence is a time of impulsivity as a result of slow development in regions of the brain that govern cognitive control combined with a heightened reward response. Cognitive ability, including abstract reasoning, expands during adolescence; however, teens are more likely to base decisions on emotional as opposed to rational contexts (Steinberg, 2016). Psychosocial development can affect health and nutritional status in many ways, including the following:

- Preoccupation with body size, body shape, and **body image** (the mental self-concept and perception of personal body size), resulting from the rapid growth and development that has occurred, may lead to dieting and possibly disordered eating behaviors
- Diminishing trust and respect for adults as authority figures, including nutrition and health professionals
- Strong influence of peers and social media, especially around areas of body image and appearance, with the influence of a few select peers becoming more important than that of large groups as adulthood approaches
- More pronounced social, emotional, and financial independence, leading to increased independent decision making related to food and beverage intake
- Significant cognitive development as abstract reasoning is nearly complete and egocentrism decreases; however, teens may still revert to less complex thinking patterns when they are stressed
- Development of future orientation, which is required to understand the link between current behavior and chronic health risks
- Development of social, emotional, financial, and physical independence from family as teens leave home to attend college or seek employment
- Development of a core set of values and beliefs that guides moral, ethical, and health decisions

The psychosocial development of adolescents has a direct bearing on the foods and beverages they choose. Food choices are more likely to be based on taste, cost, convenience, and peer behaviors than on health benefits because these influences satisfy an adolescent's innate preference for immediate reward. Nutrition education and counseling that addresses topics adolescents care about such as improving athletic or scholastic performance and improving energy can be particularly effective in influencing health behavior change. Although many adolescents are concerned with their physical appearance, it is important to address this topic with caution and sensitivity so as not to reinforce negative biases or increase a sense of shame.

Sexual Maturity

Sexual maturity rating (SMR), also known as **Tanner staging**, is used to assess clinically the degree of sexual maturation during puberty (Tanner, 1962). Among males SMR is based on genital and pubic hair development (Fig. 17.1 and Table 17.1). Among females SMR is assessed by breast and pubic hair development. SMR is measured through a series of five stages, with stage 1 marking prepubertal development and stage 5 marking the completion of physical growth and development (see Appendix 4). The five stages of SMR correlate with other markers of growth and development during puberty, such as alterations in height, weight, body composition, and endocrine functioning. A thorough understanding of the relationship

between physical growth and development and SMR enables health care professionals to assess an adolescent's potential for future growth.

The timing of pubertal development is dependent on gender, ethnic/racial background, and between individuals within population subgroups. Puberty typically begins earlier for females, between the ages of 8 and 12 years, and begins between 9 and 14 years for males (Abreu and Kaiser, 2016). There is evidence that African American and Hispanic females tend to enter puberty and experience menarche earlier than non-Hispanic white females; variation in timing is notable for both **thelarche** (breast development stage 2) and **pubarche** (pubic hair stage 3). For example, data from the National Health and Nutrition Examination Study III (NHANES III, 1988–1994) shows that the median age of menarche is 12.2 years in African American females, 12.2 years in Hispanic females, and 12.6 years in non-Hispanic white females (Ramnitz and Lodish, 2013). Similarly, breast development occurs at a mean age of 9.5 years in African American females, 9.7 years in Hispanic females, and 10.3 years in non-Hispanic white females. Evidence regarding ethnic/racial differences in the timing of puberty for males is supported by fewer studies and is less consistent. However, NHANES III data shows that the timing of Tanner stage 2 genital development tends to be earlier for African American males (9.2 years) than for Hispanic males (10.3 years), but not different in comparison with non-Hispanic white males (10 years) (Ramnitz and Lodish, 2013).

Individual variation in the timing of puberty within population subgroups is influenced by genetic, environmental, and nutrition factors. There is strong evidence that a minimum body weight is needed for pubertal development to progress and also consistent evidence that obesity may contribute to early onset of puberty in females (Abreu and Kaiser, 2016; Li et al, 2017). An analysis of data from five cohort studies showed that the number of females with early puberty was greater in the group with a body mass index (BMI) in the 95th percentile or higher than that in the group with lower BMIs. The difference in puberty timing was specifically related to thelarche; elevated BMI was not linked to **menarche** (the onset of menses or menstruation). Evidence regarding an association between obesity and the onset of puberty in males is inconsistent (Li et al, 2017). Likewise, evidence regarding the influence of other specific nutritional factors is limited and, as yet, inconsistent. One example of a factor being investigated is animal foods; some research suggests that higher intake of animal foods is related to earlier sexual development, whereas vegetable protein intake has been related to later maturation (Villamor and Jansen, 2016). Evidence for the influence of other nutritional factors including prenatal nutrition, infant feeding practices, and childhood intake of fat, carbohydrate, and micronutrients is mixed (Villamor and Jansen, 2016).

In summary, many factors impact the timing of puberty and there is great variation across and within population subgroups. Secular trend data suggest that the age of pubertal development in U.S. females has declined since the late 1800s and may have continued to decline since the mid-1900s; however, data are insufficient to establish a similar trend among males and there continues to be much normal variation in timing (Abreu and Kaiser, 2016). Secular declines in the average age of menarche are likely due in part to improvements in general health and nutrition over time among the population (Ramnitz and Lodish, 2013). For individuals, it is further important to recognize that menarche increases the micronutrient requirements of females and the timing of menarche should therefore be evaluated during a full nutrition assessment.

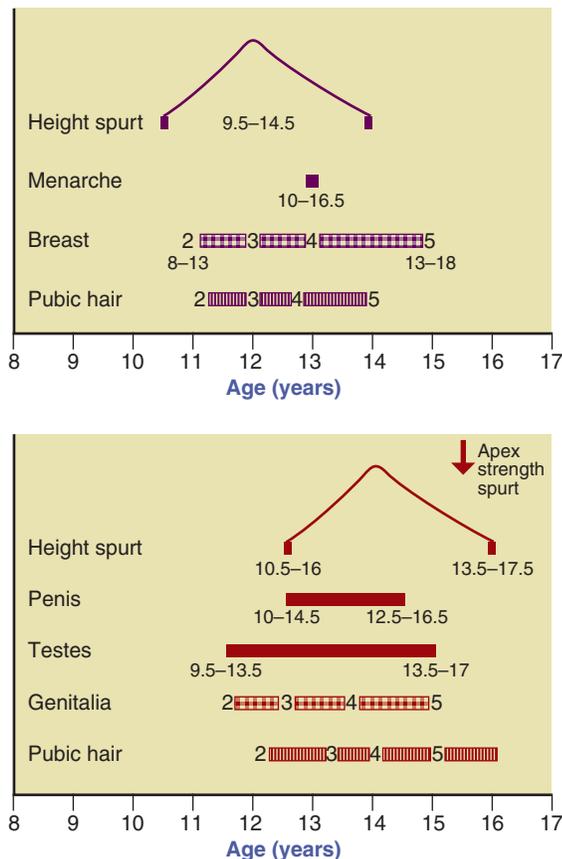

Fig. 17.1 Sequence of events during puberty in females (upper chart) and males (lower chart). Breast, genitalia, and pubic hair development are numbered 2 to 5 based on the Tanner developmental stages. (From Marshall WA, Tanner JM: Variations in the pattern of pubertal changes in males, *Arch Dis Child* 45:13, 1970.)

TABLE 17.1 Ratings of Sexual Maturation*

	Pubic Hair	Genitalia	Corresponding Changes
Males			
Stage 1	None	Prepubertal	
Stage 2	Small amount at outer edges of pubis, slight darkening	Beginning penile enlargement Testes enlarged to 5-mL volume Scrotum reddened and changed in texture	Increased sweat gland activity
Stage 3	Covers pubis	Penis longer Testes enlarged to 8-10 mL Scrotum enlarged	Voice changes Faint mustache and facial hair Axillary hair Beginning of peak height gain velocity (growth spurt of 6-8 inches)
Stage 4	Adult type, does not extend to thighs	Penis wider and longer Testes enlarged to 12 mL Scrotal skin darker	End of peak height gain velocity More facial hair Darker hair on legs Voice deeper Possibly severe acne
Stage 5	Adult type, spreads to thighs	Adult penis Testes enlarged to 15 mL	Significantly increased muscle mass
Females			
Stage 1	None	No change from childhood	
Stage 2	Small amount, downy, on medial labia	Breast buds	Increased sweat gland activity Beginning of peak height gain velocity (growth spurt of 3-5 inches)
Stage 3	Increased, darker, curly	Larger, but no separation of the nipple and the areola	End of peak height gain velocity Beginning of acne Axillary hair
Stage 4	More abundant, coarse texture	Larger Areola and nipple form secondary mound	Possibly severe acne Menarche begins
Stage 5	Adult, spreads to medial thighs	Adult distribution of breast tissue, continuous outline	Increased fat and muscle mass

*See Appendix 4.

Modified from Tanner JM: *Growth at adolescence*, ed 2, Oxford, 1962, Blackwell Scientific Publications.

Linear Growth

The velocity of physical growth during adolescence is much higher than that of early childhood (Fig. 17.2). On average, adolescents gain about 20% of their adult height during puberty. There is a great deal of variability in the timing and duration of growth among adolescents as illustrated in Fig. 17.3 by a group of 13-year-old students.

Linear growth occurs throughout the 4 to 7 years of pubertal development in most teens; however, the largest percentage of height is gained during an 18- to 24-month period commonly referred to as the **growth spurt**. The fastest rate of growth during the growth spurt is labeled the **peak height gain velocity**. Although growth slows after the achievement of sexual maturity, linear growth and weight acquisition continue into the late teens for females and early 20s for males and young men. Most females gain no more than 2 to 3 inches after menarche, although females who have early menarche tend to grow more after its onset than do those having later menarche. Increases in height are accompanied by increases in weight during puberty. Teens gain 40% to 50% of adult body weight during adolescence. The majority of weight gain coincides with increases in linear height. However, it should be noted that teens may gain more than 15 pounds after linear growth has ceased. Changes in body composition accompany changes in weight and height. Males gain twice as much lean tissue as females, resulting in differentiation in percent body fat and lean body mass.

Body fat levels increase from prepuberty averages of 15% for males and 19% for females, to 15% to 18% in males and 22% to 26% in females. Differences in lean body mass and body fat mass affect energy and nutrient needs throughout adolescence and differentiate the needs of females from those of males.

Deviations from the normal patterns of growth described here may occur along with chronic conditions experienced in childhood or the medications prescribed to treat common conditions. For example, the prescription of stimulant medications for the treatment of attention-deficit/hyperactivity disorder (ADHD) and inhaled corticosteroids for the treatment of asthma have been investigated due to concerns regarding appetite suppression and growth deficits (Richardson et al, 2017). Short-term studies of stimulant treatment have shown dose-dependent growth deficits of 1 to 1.4 cm/year mainly in the first 2 years of treatment. Research evidence regarding the longer-term impact of stimulants on growth is mixed; studies have reported divergent effects on growth and many studies have shown no clinically significant height deficits by adulthood. Similarly, inhaled corticosteroids are associated with mild growth suppression in the short term (0.4 to 1.5 cm/year) but no clinically significant effects on adult height. While additional research is needed to evaluate these therapies, the examples highlight the importance of addressing the impact of medication use as part of pediatric nutritional assessments.

Fig. 17.3 These teens are all the same age, but their energy needs vary according to their individual growth rates. From www.istockphoto.com.

NUTRIENT REQUIREMENTS

The dietary reference intakes (DRIs) for adolescents are listed by chronologic age and gender (see inside cover). Although the DRIs provide an estimate of the energy and nutrient needs for an individual adolescent, actual need varies greatly between teens as a result of differences in body composition, degree of physical maturation, and level of physical activity. Therefore health professionals should use the DRIs as a guideline during nutritional assessment but should rely on clinical judgment and indicators of growth and physical maturation to make a final determination of an individual's nutrient and energy requirements.

Energy

Estimated energy requirements (EERs) vary greatly among males and females because of variations in growth rate, body composition, and physical activity level (PAL). EERs were established by the National Academy of Medicine, formerly the Institute of Medicine, and are calculated using an adolescent's gender, age, height, weight, and PAL, with an additional 25 kilocalories (kcal) per day added for energy deposition or growth (Institute of Medicine [IOM], 2006). To determine adequate energy intake, physical activity assessment is required. The energy requirements allow for four levels of activity (sedentary, low active, active, and very active), which reflect the energy expended in activities other than the activities of daily living. Tables 17.2 and 17.3 show the EER for each activity level based on PALs.

Adequacy of energy intake for adolescents is assessed best by monitoring weight and BMI. Excessive weight gain indicates that energy intake is exceeding energy needs, whereas weight loss or a drop in BMI below an established percentile curve suggests that energy intake is inadequate to support the body's needs. Groups of adolescents who are at elevated risk for inadequate energy intake include teens who "diet" or frequently restrict caloric intake to reduce body weight; individuals living in food-insecure households, temporary housing, or on the street; adolescents who frequently use alcohol or illicit drugs, which may reduce appetite or replace food intake; and teens with chronic health conditions such as cystic fibrosis, Crohn's disease, or muscular dystrophy.

Recent concerns about excessive energy intake among youth have centered on intake of solid fats and added sugars. The mean daily intake of solid fats and added sugars among young people ages 12 to 19 years represents 32% of total energy consumption (Bowman et al, 2016). On a given day, young people consume a mean of 38 grams of solid fats and 21.8 teaspoon equivalents of added sugars (Bowman et al, 2016). The main food and beverage sources of solid fats are milk, grain-based desserts, pizza, cheese, processed meats, and fried potatoes. Grain-based desserts are also a main source of added sugar intake along with sugar-sweetened beverages, candy and other sweet snacks, ready-to-eat cereals, dairy-based desserts, and sweeteners and syrups. Sugar-sweetened beverages are of particular concern as a source of added sugar intake; soft drinks contribute nearly 30% and fruit drinks contribute 15% of added sugars consumed by youth ages 2 to 18 years (Keast et al, 2013). NHANES data revealed that 64% of males and 61% of females consume a sugar-sweetened beverage on a given day (Rosinger et al, 2017). The proportion of energy from solid fats and added sugars is similar for foods and beverages obtained from stores (33%), schools (32%), and fast-food restaurants (35%) (Poti et al, 2014).

Counseling related to excessive energy intakes among adolescents should focus on intake of discretionary calories, especially those from added sweeteners consumed through soft drinks and candy and from solid fats consumed through snack foods and fried food. Tips should be provided for selecting nutrient-dense foods and beverages at all locations where teens spend their time.

Protein

During adolescence protein requirements vary with degree of physical maturation. The DRIs for protein intake are estimated to allow for adequate pubertal growth and positive nitrogen balance (IOM, 2006). Table 17.4 illustrates the protein requirements for adolescents. Actual protein needs are best determined based on a per kilogram of body weight method during puberty to account for differences in rates of growth and development among teens.

Insufficient protein intake is uncommon in the U.S. adolescent population. However, as with energy intake, food security issues, chronic illness, frequent dieting, and substance use may compromise

TABLE 17.2 Estimated Energy Requirements for Adolescent Males

Age	Reference Weight (kg [lb])	Reference Height (m [in])	ESTIMATED ENERGY REQUIREMENTS (KCAL/DAY)			
			Sedentary PAL*	Low Active PAL*	Active PAL*	Very Active PAL*
9	28.6 (63.0)	1.34 (52.8)	1505	1762	2018	2334
10	31.9 (70.3)	1.39 (54.7)	1601	1875	2149	2486
11	35.9 (79.1)	1.44 (56.7)	1691	1985	2279	2640
12	40.5 (89.2)	1.49 (58.7)	1798	2113	2428	2817

TABLE 17.4 Protein: Estimated Average Requirements and Recommended Dietary Allowances for Adolescents

Age (yr)	EAR (g/kg/day)	RDA (g/kg/day)
9-13	0.76	0.95 or 34 g/day*
14-18 Males	0.73	0.85 or 52 g/day*
14-18 Females	0.71	0.85 or 46 g/day*

*Based on average weight for age.

EAR, Estimated average requirement; RDA, recommended dietary allowance.

Data from Institute of Medicine, Food and Nutrition Board: *Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids*, Washington, DC, 2002, National Academies Press.

protein intakes among adolescents. Teens who follow vegan or similarly restrictive diets are also at elevated risk for inadequate protein intake.

When protein intake is inadequate, alterations in growth and development are seen. In the still-growing adolescent, insufficient protein intake results in delayed or stunted increases in height and weight. In the physically mature teen, inadequate protein intake can result in weight loss, loss of lean body mass, and alterations in body composition. Impaired immune response and susceptibility to infection also may be seen.

Carbohydrates and Fiber

Carbohydrate requirements of adolescents are estimated to be about 130 g/day (IOM, 2006). The requirements for carbohydrates, as for most nutrients, are extrapolated from adult needs and should be used

as a starting point for the determination of an individual adolescent's actual need. Adolescents who are very active or actively growing need additional carbohydrates to maintain adequate energy intake, whereas those who are inactive or have a chronic condition that limits mobility may require fewer carbohydrates. Whole grains are the preferred source of carbohydrates because these foods provide vitamins, minerals, and fiber. Intake of carbohydrate is adequate in most teens; data from the 2013–2014 What We Eat in America survey, a component of the NHANES, suggest that average daily intakes of carbohydrate are 298 g for teenage males and 220 g for females (U.S. Department of Agriculture [USDA], Agricultural Research Service [ARS], 2016b).

However, fiber intakes of youth are low because of poor intake of whole grains, fruits, and vegetables. The adequate intake (AI) values for fiber intake among adolescents are 31 g/day for males 9 to 13 years old, 38 g/day for males 14 to 18 years old, and 26 g/day for 9- to 18-year-old females. These values are derived from calculations that suggest that an intake of 14 g/1000 kcal provides optimal protection against cardiovascular disease (CVD) and cancer (IOM, 2006). Adolescents who require less energy intake because of activity restrictions may have needs that are lower than the AI values.

What We Eat in America survey data suggest that average daily intakes of fiber are 16.4 g for teenage males and 12.5 g for females (USDA, ARS, 2016b). The disparities between fiber recommendations and actual intakes suggest that more emphasis must be placed on making optimal sources of carbohydrates, including whole grains, fruits, vegetables, and legumes, readily available and appealing choices in the settings where adolescents make food choices.

Fat

DRI values for total fat intake have not been established for adolescents. Instead it is recommended that total fat intakes not exceed 30% to 35% of overall energy intake, with no more than 10% of calories coming from saturated fatty acids. Specific recommendations for intakes of omega-6 and omega-3 fatty acids have been set in an attempt to ensure that teens consume adequate essential fatty acids to support growth and development, as well as to reduce chronic disease risk later in life. The AI for omega-6 polyunsaturated fatty acids (linoleic acid) is 12 g/day for 9- to 13-year-old males, 10 g/day for 9- to 13-year-old females, 16 g/day for 14- to 18-year-old males, and 11 g/day for 14- to 18-year-old females. Estimated requirements for omega-3 polyunsaturated fatty acids (alpha-linolenic acid) among teens are 1.2 g/day for 9- to 13-year-old males, 1 g/day for 9- to 13-year-old females, 1.6 g/day for 14- to 18-year-old males, and 1.1 g/day for 14- to 18-year-old females (IOM, 2006).

Minerals and Vitamins

Micronutrient needs of youth are elevated during adolescence to support physical growth and development. The micronutrients involved in the synthesis of lean body mass, bone, and red blood cells are especially important during adolescence. Vitamins and minerals involved in protein, ribonucleic acid, and deoxyribonucleic acid synthesis are needed in the greatest amounts during the growth spurt. Needs decline after physical maturation is complete; however, the requirements for vitamins and minerals involved in bone formation are elevated throughout adolescence and into adulthood, because bone density acquisition is not completed by the end of puberty.

In general, adolescent males require greater amounts of most micronutrients during puberty, with the exception of iron. Micronutrient intakes during adolescence are often inadequate among some subgroups of teens, especially among females and young people of non-Hispanic black race (Moore et al, 2012; Papanikolaou et al, 2015). Data from the National Growth and Health Study, which followed a cohort

of more than 2300 girls over 10 years, suggest that the majority of teenage girls have inadequate intakes of calcium, magnesium, potassium, and vitamins D and E (Moore et al, 2012). The proportion of girls with inadequate intakes tends to increase with age. What We Eat in America survey data also can be used to monitor the adequacy of micronutrient intakes among U.S. adolescents. Compared with DRI recommendations this survey data suggests intakes of vitamin E and calcium are often too low among males and females (Tables 17.5 and 17.6) (USDA, ARS, 2016b).

Calcium

Because of accelerated muscular, skeletal, and endocrine development, calcium needs are greater during puberty and adolescence than during childhood or the adult years. Bone mass is acquired at much higher rates during puberty than any other time of life. In fact, females accrue approximately 37% of their total skeletal mass from ages 11 to 15 years, making adolescence a crucial time for osteoporosis prevention (IOM, 2011).

The recommended dietary allowance (RDA) for calcium is 1300 mg for all adolescents with an upper level intake of 3000 mg/day (IOM, 2011). Calcium intake declines with age during adolescence, especially among females. Research suggests that high soft drink consumption in the adolescent population contributes to low calcium intake by displacing milk consumption (Ranjit et al, 2010); conversely, adolescents who report more often having milk served at dinner tend to have lower intakes of sugar-sweetened beverages (Watts et al, 2018). Interventions to promote calcium consumption among young people should be

TABLE 17.5 Mean Intakes of Select Nutrients Compared with DRIs: Adolescent Males

	Mean Intake	9- to 13-year-old RDA/AI	14- to 18-year-old RDA/AI

initiated early and focus not only on increasing dairy product intake but also on decreasing intakes of soft drinks and increasing intakes of nondairy foods that are rich in calcium. Nondairy sources of calcium are particularly important for young people who may not consume milk for health or cultural reasons. Examples of nondairy calcium sources include calcium-fortified orange juice, soy milk, rice milk, and almond milk; calcium-fortified ready-to-eat cereals; enriched breads and other grains; some legumes (e.g., white beans) and dark green vegetables (e.g., kale, broccoli); and tofu prepared with calcium sulfate.

Iron

Iron requirements are increased during adolescence to support the deposition of lean body mass, increase in red blood cell volume, and need to replace iron lost during menses among females. Iron needs are highest during periods of active growth among all teens and are especially elevated after the onset of menses in adolescent females. The DRI for iron among females increases from 8 mg/day before age 13 (or before the onset of menses) to 15 mg/day after the onset of menses (IOM, 2006). Among adolescent males recommended intakes increase from 8 to 11 mg/day, with higher levels required during the growth spurt. Iron needs remain elevated for women after age 18 but fall back to prepubescent levels in men once growth and development are completed (IOM, 2006).

Median intakes of iron among adolescents in the United States are less than desirable. Increased needs for iron, combined with low intakes of dietary iron, place adolescent females at risk for iron deficiency and anemia. Rapid growth may temporarily decrease circulating iron levels, resulting in **physiologic anemia of growth**. Other risk factors

BOX 17.1 Risk Factors for Iron Deficiency

Inadequate Iron Intake/Absorption/Stores

- Food insecurity or living in poverty
- Malabsorption diseases (e.g., celiac disease)
- Unbalanced vegetarian eating styles, especially vegan diets
- Restrictive diets that eliminate entire food groups
- Low intakes of meat, fish, poultry, or iron-fortified foods
- Low intake of foods rich in ascorbic acid
- Frequent dieting or restricted eating
- Chronic or significant weight loss
- Meal skipping
- Substance abuse
- History of iron-deficiency anemia
- Recent immigration from developing country
- Special health care needs

Increased Iron Requirements and Losses

- Heavy or lengthy menstrual periods
- Rapid growth
- Pregnancy (recent or current)
- Inflammatory bowel disease
- Chronic use of aspirin, nonsteroidal antiinflammatory drugs (e.g., ibuprofen), or corticosteroids
- Participation in endurance sports (e.g., long-distance running, swimming, cycling)
- Intensive physical training
- Frequent blood donations
- Parasitic infection

for iron deficiency anemia are listed in **Box 17.1**. During adolescence, iron deficiency anemia may impair the immune response, decrease resistance to infection, and decrease cognitive functioning and short-term memory (see Appendix 42).

Folate

The DRI for folate intake among adolescents is 300 mcg/day for 9- to 13-year-old males and females, increasing to 400 mcg/day for 14- to 18-year-olds (IOM, 2006). The need for folate increases during later adolescence to support accretion of lean body mass and to prevent neural tube defects among females of reproductive age. Food sources of folate should include naturally occurring folate, found in dark green leafy vegetables and citrus fruit, and folic acid found in fortified grain products (see Appendix 31).

Average intakes of folate reported in the 2013–2014 What We Eat in America survey suggest that adolescent females are at greater risk for inadequate intake than are males (USDA, ARS, 2016b). This is a cause for concern among adolescent females who have achieved menses and are sexually active, as having adequate folate status before conception is important for the prevention of birth defects such as spina bifida (see Chapter 14).

Vitamin D

Vitamin D plays an important role in facilitating calcium and phosphorus absorption and metabolism, which has important implications for bone development during adolescence (IOM, 2011). There is also some evidence that suggests vitamin D may play a role in

cardiometabolic health, immunity, preventing chronic disease, and protecting against certain types of cancer; however, given the state of this evidence the current RDA is based solely on benefits for bone health (Golden and Carey, 2016). The RDA for vitamin D requirements among adolescents is 600 IU/day (15 µg/day) (IOM, 2011). See Appendix 38 for dietary sources.

A recent IOM report concluded that a serum 25(OH)D level of 20 ng/mL covers the requirement of 97.5% of the population (IOM, 2011). However, it is recommended that individuals at risk for vitamin D deficiency maintain a higher level of 30 ng/mL and there is a need for additional research to resolve ongoing debate and controversy regarding cutoff values for adequate and optimal circulating levels (Smith et al, 2017).

Based on current guidelines, there is a high prevalence of vitamin D deficiency among U.S. adolescents. Among youth ages 14 to 18 years, approximately one third have serum 25(OH)D levels below 20 ng/mL and 43% have levels between 20 to 29 ng/mL (Moore and Liu, 2017). There also have been noted declines in vitamin D status over the past two decades. NHANES data collected during the preceding few decades established that serum 25(OH)D levels decreased by 15% to 16% (Ganji et al, 2012). The reductions were especially obvious among non-Hispanic black participants and those in the highest BMI quintile.

Several factors may contribute to the recent increases and prevalence of vitamin D deficiency (Fiscaletti et al, 2017). Increased use of topical sunblock lotions has been advocated to prevent premature aging of the skin and some skin cancers, but its use also decreases vitamin D synthesis. Some evidence suggests that individuals with a higher BMI more readily sequester cutaneous vitamin D in adipose tissue, making it less bioavailable. Further, overweight youth may be less likely to engage in regular physical activity outdoors and thus have less exposure to sunlight. Other risk factors for vitamin D deficiency include malabsorption syndromes such as cystic fibrosis, long-term use of medications that increase its catabolism (e.g., corticosteroids), lactose intolerance or milk allergy, darkly pigmented skin, and residence at northern geographic latitudes where youth may spend little time outdoors during colder months. Low vitamin D intake is an important health risk for adolescents and deserves attention during nutrition assessment, education, and intervention (see Appendix 38).

Supplement Use by Adolescents

The consumption of moderate portions of a wide variety of foods is preferred to nutrient supplementation as a method for obtaining adequate nutrient intake. Despite this recommendation, studies show that adolescents do not consume nutrient-dense foods and usually have inadequate intakes of many vitamins and minerals; thus supplements such as a multivitamin may be beneficial for many adolescents (Keast et al, 2013). For most vitamins and minerals, national survey data indicate that only a small percentage of adolescents (<15%) are supplement consumers (USDA, ARS, 2017). The adolescents most likely to use supplements are those in good health with a higher household income and health insurance (Dwyer et al, 2013).

The use of herbal and other nonvitamin, nonmineral dietary supplements is not well documented. National data suggest that 5% of adolescents consume nonvitamin, nonmineral supplements; however, this estimate is based on parental report and the actual prevalence of use is likely higher as adolescents may not disclose all supplement use to their parents (Wu et al, 2013). Adolescents most likely to use nonvitamin, nonmineral supplements are those who report non-Hispanic white race, a higher household income, activity limitations resulting from chronic health conditions, long-term prescription use, or relatively heavy use of physician services. Many adolescent athletes also use or may consider the use of dietary supplements to improve sport

performance (see Chapter 22). The short- and long-term effects of such nonnutritional supplement use by adolescents are not known. Health professionals should screen adolescents for supplement use and should counsel them accordingly (see Chapter 11).

FOOD HABITS AND EATING BEHAVIORS

Food habits of concern that are seen more frequently among adolescents than other age groups include irregular consumption of meals, excessive snacking, eating away from home (especially at fast-food restaurants), dieting, and meal skipping. Many factors contribute to these behaviors, including decreasing influence of family, increasing influence of peers, exposure to various forms of media, employment outside the home, greater discretionary spending capacity, and increasing responsibilities that leave less time for adolescents to eat meals with their families. Most adolescents are aware of the importance of nutrition and the components of a healthy diet; however, they may have many barriers to overcome. Among the most challenging barriers are household food insecurity, discrimination against some ethnic/racial groups, and weight-related concerns (Larson and Story, 2015; Waxman et al, 2015).

Teens perceive taste preferences, hectic schedules, the cost and accessibility of different foods, and social support from family and friends to be key factors that affect their food and beverage choices (Berge et al, 2012). For example, parents may positively influence the food and beverage choices of teens by modeling healthy eating habits, selecting healthy foods for family meals, encouraging healthy eating, and setting limits on the consumption of unhealthy snack foods. Friends influence each other through modeling and shared activities, such as eating out at fast-food restaurants and purchasing snacks at convenience stores near school.

Developmentally, many teens lack the ability to associate current eating habits with future disease risk. Teens often are more focused on “fitting in” with their peers. They adopt health behaviors that demonstrate their quest for autonomy and make them feel more like adults such as drinking alcohol, smoking, and engaging in sexual activity. Nutrition education and counseling should focus on short-term benefits that many adolescents care about, such as improving school and sports performance and having more energy. Although appearance is also important to many adolescents, this topic needs to be discussed carefully so as to not reinforce negative biases. Messages should be positive, developmentally appropriate, and concrete. Specific skills such as choosing water, unsweetened tea, or milk over sugar-sweetened drinks; ordering broiled rather than fried meats; and choosing baked rather than fried snack foods are key concepts to discuss.

Irregular Meals and Snacking

Meal skipping is common among adolescents. Meal skipping increases throughout adolescence as teens try to sleep longer in the morning, try to lose weight through calorie restriction, and try to manage their busy lives. Breakfast is the most commonly skipped meal. National data suggest that approximately one quarter of adolescents (12 to 19 years) skip breakfast on a given day (USDA, ARS, 2016a). Breakfast skipping has been associated with poor health outcomes, including higher BMI; poorer concentration and school performance; and increased risk of inadequate nutrient intake (Burrows et al, 2017). Adolescents who skip breakfast tend to have a higher intake of added sugars and poorer intake of key nutrients (e.g., calcium, vitamin A) compared with those who eat breakfast, especially when the breakfast meal is composed of healthy foods that may be fortified such as ready-to-eat cereal.

Teens who skip meals often snack in response to hunger instead of eating a meal. Most teens (92% of males, 91% of females)

consume at least one snack per day, and the majority of teens who report snacking consume two or more snacks per day (USDA, ARS, 2016c). Snack foods consumed by teens are often high in added fats, sweeteners, and sodium. Soft drinks and other sugar-sweetened beverages are consumed commonly, accounting for a substantial proportion of daily caloric intake and representing an important source of caffeine consumption (see *Focus On: Caffeine and Substance Use by Adolescents*). Daily average energy intake from sugar-sweetened beverages is 232 calories among teen boys and 162 calories among teen girls, representing 9.3% and 9.7% of total daily calories respectively (Rosinger et al, 2017). Frequent snacking may promote higher total energy intake and a higher proportion of energy provided by added and total sugars (Larson and Story, 2013). However, national data indicate that snacks also make positive contributions to intake of key nutrients. For example, 2013–2014 NHANES data for male and female adolescents indicate that foods and beverages consumed at snack occasions provide 16% to 17% of folate intake, 21% to 25% of vitamin C intake, 20% of vitamin D intake, 23% to 25% of calcium intake, and 16% to 19% of iron intake (USDA, ARS, 2016d). Because snacks are prevalent and often consumed in place of meals, teens should be encouraged to make healthy choices when choosing these snack foods and beverages. **Box 17.2** provides ideas for healthy snacks or meal alternatives for teens.

Fast Foods and Convenience Foods

Convenience foods include foods and beverages from vending machines, canteens, school stores, fast-food restaurants, and convenience stores. As adolescents spend considerable amounts of time in and around schools, convenience foods available at school and in the surrounding neighborhood are likely to influence their eating patterns. National data indicate vending machines are available in 33% of middle schools and 66% of high schools (Centers for Disease Control and Prevention, 2015). About one quarter of all

BOX 17.2 Adolescent-Friendly Healthy Snacks

Unsweetened, low-fat yogurt layered with berries and granola
 Oatmeal made with milk and sliced fruit
 Whole grain crackers with cheese and fruit
 Sliced apples dipped in peanut butter
 Whole-wheat bagel or english muffin half topped with cream cheese, peanut butter or almond butter
 Air-popped popcorn
 Whole-wheat pita wedges topped with 1 to 2 tablespoons of hummus
 Baked tortilla chips with bean dip or salsa
 Baked potato topped with salsa or broccoli and melted cheese
 Graham crackers and peanut or almond butter
 Frozen yogurt or 100% juice bars with no added sugar
 Trail mix (dried fruit with nuts and seeds)
 Baby carrots with hummus
 Whole grain, low sugar granola bars
 Mini rice cakes or popcorn cakes with hummus
 Whole-wheat tortilla wraps with turkey, cheese, lettuce, and tomato

middle schools and 29% of high schools have a school store where students can purchase food or beverages (Centers for Disease Control and Prevention, 2015). In addition, middle schools and high schools often have a fast-food restaurant or convenience store within walking distance. Fast-food restaurants and convenience stores are socially acceptable places for teens to eat, spend time with their friends, and even work.

FOCUS ON

Caffeine and Substance Use by Adolescents

Three out of four adolescents consume caffeine on a given day, mostly from soft drinks, tea, and coffee (Branum et al, 2014). Although average caffeine intake among adolescents does not exceed the recommended daily limit of 100 mg, energy drinks are becoming increasingly popular, and the amount of caffeine in these drinks is not regulated by the Food and Drug Administration (FDA) (Branum et al, 2014; Seifert et al, 2011). The FDA has imposed a limit on caffeine of 71 mg per 12-ounce serving for soft drinks, whereas energy drinks have been found to contain nonnutritive stimulants (e.g., caffeine and guarana) in amounts that range from 2.5 to 171 mg per ounce (Terry-McElrath et al, 2014). Of further concern, at least one study has found that energy drink users are more likely than their peers to report alcohol, cigarette, and illicit drug use.

The relationship between energy drink consumption and substance abuse was explored using a 2010–2011 survey. This survey data were collected from a nationally representative sample of 21,995 secondary school students (grades 8, 10, and 12) who were participating in the Monitoring the Future study (Terry-McElrath et al, 2014). Students self-reported how many energy drinks they consumed on an average day. Substance use data were also self-reported, including frequency of alcohol, cigarette, marijuana, and amphetamine use in the past 30 days. Energy drink consumption was related to greater use of each substance for students in all grades. This research suggests that certain groups of adolescents may be particularly likely to consume energy drinks and to be substance users, and nutrition educators should inform parents and adolescents about the masking effects of caffeine in energy drinks on alcohol- and other substance-related impairments.

Highly processed convenience foods tend to be low in vitamins, minerals, and fiber, but high in calories, added fat, sweeteners, and sodium. National data suggest that many teens consume one or more items from a fast-food restaurant or the convenient snack options at school on a given day (Poti et al, 2014). Few adolescents are willing to stop purchasing such convenience foods because the low price, easy

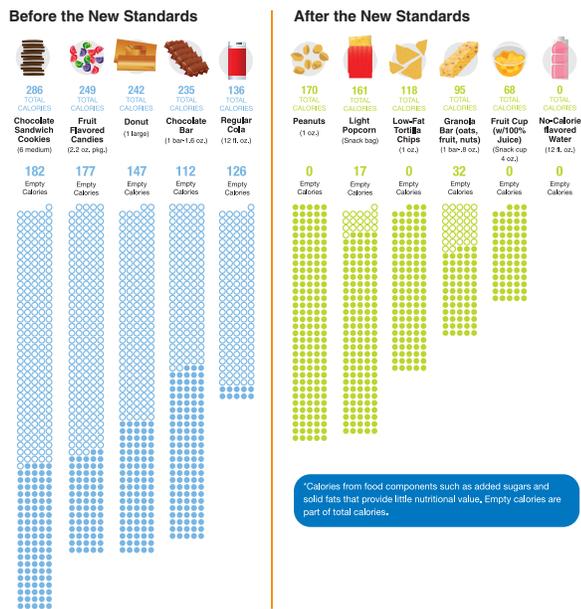

access, and taste appeal to them. Instead of asking young people to not eat these foods, health professionals should counsel them on how to make healthy choices and work with schools to implement the USDA nutrition standards for convenience foods sold in schools (Fig. 17.4; Hayes et al, 2018). Counseling adolescents with concrete guidelines that are easy to remember, such as choosing snacks or vending and

SMART SNACKS IN SCHOOL

The Healthy, Hunger-Free Kids Act of 2010 requires USDA to establish nutrition standards for all foods sold in schools—beyond the federally-supported meals programs. This new rule carefully balances science-based nutrition guidelines with practical and flexible solutions to promote healthier eating on campus. The rule draws on recommendations from the Institute of Medicine, existing voluntary standards already implemented by thousands of schools around the country, and healthy food and beverage offerings already available in the marketplace.

• Equals 1 calorie ○ Shows empty calories*

USDA is an equal opportunity provider and employer.

Fig. 17.4 Smart Snacks in School: U.S. Department of Agriculture nutrition standards for convenience foods sold in schools. Available at: <https://www.fns.usda.gov/school-meals/tools-schools-focusing-smart-snacks>.

fast-food options with fewer than 5 g of fat per serving and no more than a few grams of added sugar, can be particularly effective. Adolescents also can be encouraged to check labels to determine whether foods are made from whole grains or are high in added sweeteners or sodium.

Family Meals

The frequency with which adolescents eat meals with their families decreases with age (Child Trends, 2013). Nearly half of 12- to 14-year-olds eat meals with their families at least 6 days per week compared with just more than one third of 15- to 17-year-olds. Adolescents who eat meals with their families have been found to have better academic performance, to be less likely to engage in risky behaviors such as illicit drug use, and to be less likely to have school problems compared with peers who do not frequently engage in family meals (Goldfarb et al, 2015).

Developing healthful eating patterns at family meals during adolescence may improve the likelihood that individuals will choose to consume nutritious foods in adulthood and may protect them from the future development of overweight (Berge et al, 2015). Family meals not only allow for more communication between teens and their parents but also provide an ideal environment during which parents can model healthy food and beverage choices and attitudes toward eating. Teens who eat at home more frequently have been found to consume fewer soft drinks and more calcium-rich foods, fruit, and vegetables (Larson et al, 2013) (see *Focus On: Family Meals and Nutritional Benefits for Teens*).

FOCUS ON

Family Meals and Nutritional Benefits for Teens

When teens regularly share dinners with their families, they are more likely to have diets of higher nutritional quality, and some evidence suggests the practice may protect them against the future development of overweight in young adulthood (Berge et al, 2015). However, different schedules and difficulty finding time to eat together are common barriers to sharing the evening meal. One study examined whether there are similar benefits associated with eating breakfast together (Larson et al, 2013). Students at 20 public middle schools and high schools in the Minneapolis-St. Paul metropolitan area of Minnesota were surveyed about their dietary practices and how often they have a family meal at breakfast and at dinner. Approximately 71% of students at these schools qualified for free or reduced-price school meals and 81% represented a racial/ethnic background other than non-Hispanic white. Among these students, family breakfast meals occurred on average less often than family dinners (1.5 breakfast meals versus 4.1 dinner meals per week) and less than 10% of students ate together daily with “all or most” of their family at breakfast. However, participation in more frequent family breakfast meals was linked to several markers of better diet quality (e.g., more fruits, whole grains, and fiber) as well as lower risk for overweight. These associations were found while accounting for family dinner frequency as well as structural and organizational characteristics of families and thus suggest that although it is not always possible to eat dinner together, coming together for other meals such as breakfast can provide benefits. Health professionals should encourage families to eat together at breakfast as well as at dinner, and to provide supports for addressing challenges such as lack of time, food security, and limited food preparation skills.

Media and Advertising

The advertising of food and beverages is a multi-billion dollar business. In 2016 a total of more than \$13.5 billion was spent by food, beverage, and restaurant companies on advertising their products (Harris et al, 2017). These food-related companies promote their products using a number of different techniques (e.g., contests, product placements, sponsorships, celebrity endorsements, viral marketing) and multiple forms of media; however, television is a dominant advertising medium. Of the \$13.5 billion spent on advertising by food-related companies, \$10 billion was spent on television advertising (Harris et al, 2017).

The high television advertising expenditures translate to the daily average of 10 to 11 food-related ads being viewed by youth. Despite recent declines in the amount of time youth spend watching television, an average of more than 2 hours per day are spent with television and the number of food-related ads appearing per hour of television programming was found to increase between 2007 and 2016. An analysis of television advertising found that just 56 of the more than 20,300 food-related companies were responsible for 85% of food-related ads viewed by youth; these companies include several that participate in the self-regulatory programs known as the Children’s Food and Beverage Advertising Initiative (CFBAI) and Children’s Confection Advertising Initiative (CCAI) but also a large number of companies that do not limit their child-directed advertising to healthier dietary choices. Although the CFBAI and CCAI companies were further found to have kept their pledges from 2007 to 2016 by reducing ads for less healthy products on children’s television channels and media primarily directed to children under age 12 years, these improvements had limited benefits for adolescent viewers. During this period, adolescent exposure to ads for candy, sugary drinks, snack food, and fast-food brands was conversely found to increase. Most food advertisements viewed by adolescents are for products high in fat, sugar, or sodium, and fast-food restaurant advertisements are the most

frequently viewed (Powell et al, 2010). Research shows that food advertising increases young people's immediate and future food choices and food brand preferences and it is not until late adolescence that a young person's ability to cope with advertising will surface (Lapierre et al, 2017). Along with ongoing efforts to limit young people's exposure to advertising for unhealthy products, media literacy education can and should be taught to teens to assist them in determining the accuracy and validity of media and advertising messages.

Dieting and Body Image

Body image concerns are common during adolescence. Many adolescents describe themselves as being overweight despite being at a healthy BMI, signifying a disturbance in their body image. Poor body image can lead to weight control issues and dieting. The Youth Risk Behavior Surveillance System data from 2017 show that 47.1% of U.S. high school students were attempting to lose weight. The prevalence of dieting was higher among female (59.9%) than male (34.0%) students. Hispanic females had the highest prevalence of dieting at 65.6%, followed by white females (58.6%), black females (55.3%), Hispanic males (45.7%), white males (30.6%), and black males (28.9%) (Kann et al, 2018).

Eating nutrient-dense foods (e.g., fruits and vegetables, lean meats and fish, low fat or nonfat dairy, legumes, nuts) to limit calories and getting regular exercise can be viewed as healthy weight loss behaviors when used in moderation and can be a starting point for nutrition education and counseling to improve eating behaviors. However, not all dieting behaviors have the potential to improve health. High-risk dieting practices are used by many adolescents and carry with them the risk of poor nutritional status and increased risk for **disordered eating** (see Chapter 21). The most recent available national survey data on disordered eating behaviors indicate that fasting, or refraining from eating for more than 24 hours, was practiced by 17% of female and 7% of male U.S. high school students in the past month as a means of dieting (Eaton et al, 2012). Furthermore, 6% of females and 4% of males had used diet pills to lose weight; the prevalence of this behavior was highest among Hispanic students and increased with age. The use of purging methods, including vomiting and laxative or diuretic use, was reported by 6% of females and 3% of males. White and Hispanic students were more likely to report purging behaviors than African American students. In providing adolescents with advice around healthy weight loss behaviors, it is prudent to also screen for the use of any high-risk dieting practices so that appropriate counseling regarding the harms of such practices can be provided.

NUTRITION SCREENING, ASSESSMENT, AND COUNSELING

The American Academy of Pediatrics recommends that adolescents have an annual health screening to address priority issues, including physical growth and development, social and academic competence, emotional well-being, risk reduction (e.g., for substance use, sexually transmitted infections), and violence and injury prevention (Hagan et al, 2017). The supervision of physical growth and development should involve an assessment of nutrition risk and the provision of anticipatory guidance. Nutrition screening should include the assessment of height, weight, and BMI to determine weight status; evaluation for the presence of iron deficiency anemia (females only); review of oral health (e.g., regular dental visits, intake of high-sugar foods); and assessment of physical fitness and media use, including time spent engaged with social media (Anderson and Jiang, 2018). Anticipatory guidance should further address healthy eating behaviors and building a positive body image.

Weight, height, and BMI should be plotted using the Centers for Disease Control and Prevention (CDC) National Center for Health Statistics BMI tables to determine appropriateness of weight for height (see Appendix 3). A BMI below the fifth percentile may signal the presence of chronic or metabolic disease, growth failure, or an eating disorder. A BMI at or above the 85th percentile but below the 95th percentile may indicate that an adolescent is overweight, whereas a BMI at or above the 95th percentile may indicate the presence of obesity. For some young people, a high BMI value reflects high lean body mass rather than high levels of body fat; therefore, it can be valuable to conduct further direct assessment of body fat when done in a sensitive manner and used to inform counseling that is focused on health behaviors (Hagan et al, 2017) (for additional information, see Chapter 5).

When nutrition screening indicates the presence of nutritional risk, a full assessment should be conducted. Nutrition assessment should include a complete evaluation of food intake through a 24-hour recall, dietary records, or brief food frequency questionnaire (see Chapter 4). The adequacy of energy, fiber, macronutrients, and micronutrients should be determined, as well as excessive intake of any dietary components such as sodium or sweeteners. Nutritional assessments also should include an evaluation of the nutritional environment, including parental, peer, school, cultural, and personal lifestyle factors. The attitude of the adolescent toward food and nutrition is important; helping the adolescent overcome perceived barriers to eating well through methods such as motivational interviewing is an essential component of nutrition counseling.

Teens who live in food-insecure households, temporary housing, or shelters, or who have run away from home are at especially high nutritional risk, as are adolescents who use alcohol and street drugs. It is important that health professionals working with high-risk teens develop partnerships with community-based food assistance programs to ensure that youth have access to a steady, nutritious food supply. Homeless teens, as well as those living in temporary shelters, benefit from nutrition counseling focusing on lightweight, low-cost, prepackaged foods that do not require refrigeration or cooking facilities. Dried fruit, nuts, granola bars, cereal bars, tuna in pouches, and meat jerky are foods that should be available for runaway or homeless teens.

Education and counseling should be tailored to meet any specific nutrition diagnoses identified during the assessment. An adolescent with a diagnosis of type 2 diabetes who experiences rapid weight gain requires a different type and intensity of counseling than a teen who has been diagnosed with iron deficiency anemia. Knowledge, attitude, motivation, and behavior must be addressed when guiding adolescents toward acquiring healthful food habits. For a plan to succeed the adolescent needs to be interested in making change; therefore an assessment of a teenager's desire to change is essential. Encouraging the desire to change usually requires attention, creativity, patience, and significant rapport building (see Chapter 13).

Information can be provided in various settings ranging from the classroom to the hospital (Fig. 17.5). It is valuable for clinicians to understand the change process and how to communicate it meaningfully so they can provide personalized and more effective counseling. Parents may be included in the process and are encouraged to be supportive. Recommended eating plans based on recommended energy intakes for adolescents are shown in Table 17.7.

SPECIAL TOPICS

Vegetarian Dietary Patterns

As adolescents mature, they begin to develop autonomous social, moral, and ethical values. These values may lead to vegetarian eating

Fig. 17.5 Adolescents who help prepare nutritious meals become engaged in the healthy eating process.

practices because of concerns about animal welfare, the environment, or personal health. Concerns about body weight also motivate some adolescents to adopt a vegetarian diet because it is a socially acceptable way to reduce dietary fat. Some research has suggested that adolescents who consume vegetarian diets are less likely to be overweight or obese than their omnivorous peers (Schürmann et al, 2017). Well-planned vegetarian diets that include a variety of legumes, nuts, seeds, fruits and vegetables, and whole grains can provide adequate nutrients for adolescents (Melina et al, 2016); however, there is a need for additional research on the benefits and possible risks of vegetarian diets for young people under the age of 18 years, especially if they are overly restrictive.

Vegetarian diets that become increasingly more restrictive should be viewed with caution, because this may signal the development of disordered eating, with the vegetarian diet used as a means to hide a restriction of food intake (Melina et al, 2016). This increased risk for unhealthy weight control behaviors seems to persist even after the vegetarian eating style is discontinued, suggesting that although the

issues are related, vegetarian diets likely do not cause disordered eating and instead may serve as a symptom.

Vegetarian adolescents often have optimal intakes of iron, vitamin A, and fiber and low intakes of dietary cholesterol. Vegetarian diets are consistent with the Dietary Guidelines for Americans and can meet the DRIs for all nutrients. A sample eating plan to assist vegetarian adolescents in achieving adequate energy and nutrient intakes is listed in Table 17.8.

Vegan diets, which do not include animal products of any kind, do not provide natural sources of vitamin B₁₂ and may be deficient in calcium, vitamin D, zinc, iron, and long-chain omega-3 fatty acids (Melina et al, 2016). Therefore vegan adolescents need to choose foods naturally high in or fortified with these nutrients. A daily multivitamin-mineral supplement is essential for vegans. Instructing adolescents and their caregivers on the planning of a well-balanced vegetarian diet and use of fortified foods can prevent potential nutrient deficiencies.

Skin Health

Skin health is impacted by the appearance of acne, which most often peaks during adolescence and affects 80% to 90% of U.S. adolescents.

Effective treatment for the condition is important because acne can significantly affect quality of life and in some cases lead to social withdrawal, anxiety, or depression. There is some research suggesting the potential value of incorporating medical nutrition therapy in the treatment of acne. For example, a recent study among 250 young adults (ages 18 to 25) in New York City found evidence that dietary factors may influence or aggravate acne development by comparing the self-reported usual dietary patterns of participants who reported no or mild acne to those with moderate to severe acne (Burriss et al, 2014). Young adults with moderate to severe acne reported higher glycemic index diets, including more added sugars, total sugars, milk servings, saturated fat, and trans fatty acids and fewer servings of fish. The majority of all participants (58%) additionally reported the perception that diet aggravates or influences their acne.

The evidence from this study combined with other epidemiologic, observational, and experimental research does not demonstrate that diet causes acne but indicates it may aggravate or influence the condition to some degree (Burriss et al, 2013). It is possible that medical nutrition therapy as an adjunct to dermatology therapy may be beneficial for some young people with acne. However, a number of questions

remain that must be addressed by additional research before the efficacy and clinical relevance of diet therapy can be established and evidence-based guidelines developed to guide dietitian nutritionists in practice.

Currently, the most reasonable approach to practice is to approach each young person with acne on an individual basis to determine whether dietary counseling may be beneficial. The evidence base most consistently supports guiding individuals with acne toward a healthful, low-glycemic load diet that is low in saturated fat and high in whole grains, fruit, and vegetables. An additional dietary intervention that may similarly offer multiple health benefits is to recommend increasing consumption of omega-3 fatty acids (see Appendix 26). As long as intake of calcium and vitamin D are sufficient, it may further be beneficial to recommend a diet lower in dairy but as yet the quantity of milk necessary to exacerbate acne has not been established.

Promoting Healthy Weight-Related Attitudes and Behaviors

An estimated 10% to 20% of teens engage in disordered eating behaviors, such as binge-purge behavior, compensatory exercise, laxative and diuretic abuse, and binge eating (Neumark-Sztainer et al, 2012). These behaviors do not occur with enough regularity or frequency to be diagnosed as an eating disorder, but they may have significant health implications for adolescents. Symptoms that may signal the presence of unhealthy weight-related attitudes and disordered eating behaviors include recurring gastrointestinal complaints, amenorrhea, or unexplained weight loss. Females at an overweight BMI have been found to be twice as likely to engage in disordered eating behaviors. In order to identify and intervene on these risky behaviors, it is valuable to conduct screening for disordered eating. In particular, it is important for screening questions to address body dissatisfaction, fear of weight gain, frequency of dieting and fasting, use of laxatives and diuretics, use of diet pills, fear of certain foods (e.g., foods containing fat or sugar), vomiting, bingeing, and compensatory exercise.

Adolescents are particularly vulnerable to the complications of eating disorders. The effect of malnutrition on linear growth, brain development, and bone acquisition can be persistent and irreversible. It is important for the achievement of a strong recovery that symptoms of an eating disorder are recognized by others early in the course of illness and that health professionals are involved in implementing an effective care plan so that symptoms can be quickly reduced (Vall and Wade, 2015) (see Chapter 21).

Promoting a Healthy Weight Status

Adolescent weight status is typically evaluated based on BMI (weight/height² [kg/m²]) as shown in Appendix 3. Maintaining behaviors that promote a healthy weight status in adolescence is important for overall health and well-being during this period of development as well as for future adult health. Weight status is influenced by a complex set of factors, including genetics, metabolic efficiency, PAL, dietary intake, medical and behavioral health conditions, medication use, and environmental and psychosocial factors (see Chapter 20). Inadequate weight gain and underweight are concerns for some adolescents with special health care needs, but the most prevalent concern among young people this age is excess weight gain.

Among 12- to 15-year-olds and 16- to 19-year-olds in the United States, the prevalence of being at an overweight BMI, higher than the 85th percentile, is respectively 38.7% and 41.5%. The prevalence of being at an obese BMI, at or above the 95th percentile, is approximately 20.5% among both age groups; the prevalence of severe obesity (120% of the 95th percentile) is estimated to be 7% to 10%

among youth (Skinner et al, 2018). For some adolescents, a high BMI reflects high lean body mass rather than potentially unhealthy levels of body fat (Hagan et al, 2017). However, adolescents who are at an overweight BMI are more likely to have metabolic abnormalities such as elevated blood glucose, triglycerides, cholesterol, and liver enzymes. Laboratory testing and additional screening are therefore recommended for adolescents at a high BMI to assess for the presence of chronic disease risk factors and presence of diabetes and liver disease (Hagan et al, 2017). If risk factors are noted, it is recommended that aspartate aminotransferase (AST) and alanine aminotransferase (ALT) measurements be completed to assess liver function and screen for nonalcoholic steatohepatitis (see Chapter 28). It is recommended that a fasting glucose level be drawn on any overweight adolescent with two or more risk factors for CVD or with a family history of diabetes. For adolescents at an obese BMI, it is recommended that microalbumin/creatinine ratio also be assessed. Additional assessments for conditions such as sleep apnea, orthopedic disorders, polycystic ovary disease, and hormonal abnormalities should be performed based on presenting symptoms.

Current guidelines for adolescent overweight and obesity suggest a staged care, multicomponent treatment process (Box 17.3) based on a teen's BMI, age, motivation, and the presence of comorbid conditions (Hagan et al, 2017; Henry et al, 2018). Four stages are recommended, with progress through the stages based on age, biologic development, level of motivation, weight status, and success with previous stages of treatment (Hoelscher et al, 2013). Advancing to the next stage of treatment may be recommended if insufficient progress is made to improve weight status or resolve comorbid conditions after 3 to 6 months. There is evidence that counseling to promote healthy weight status is most effective when it includes group pediatric weight management sessions and family involvement (Henry et al, 2018). Regardless of the approach taken, it is critical that the focus of counseling is on making healthy lifestyle and dietary choices. Adolescents at a higher weight status need to be supported by their family and not subjected to shaming comments about their weight from health professionals, caregivers, or peers.

Bariatric surgery has been used as a treatment for producing weight loss, but concern has been expressed regarding its use in adolescents (Ryder et al, 2018). Recommendations for bariatric surgery suggest that it may be justified only by the presence of severe obesity (Kelly et al, 2013). While long-term outcome data show that bariatric surgery may lead to improvements in cardiometabolic health, difficulty in complying with dietary restrictions after surgery often leads to complications (Inge et al, 2017). Complications of bariatric surgery include dumping syndrome after high carbohydrate intake, voluntary excessive food intake, and B vitamin deficiencies caused by poor compliance with vitamin-mineral supplementation (see Chapter 20).

In summary, overweight and obesity in adolescence have short- and long-term health consequences. Adolescents who are at an overweight BMI and particularly those who experience rapid weight gain or a BMI that represents severe obesity are at higher risk for hyperlipidemia, hypertension, insulin resistance, and type 2 diabetes compared with normal weight peers (Ryder et al, 2018). Not all adolescents at higher BMIs experience metabolic abnormalities during this stage of development; however, epidemiologic studies of obesity and disease risk demonstrate that an obese BMI is associated with greater risk of premature mortality and morbidity. Premature mortality and morbidity are most often related to the presence of diabetes, hypertension, coronary heart disease, stroke, asthma, and polycystic ovary syndrome among individuals who were overweight or obese during adolescence (Reilly and Kelly, 2011).

BOX 17.3 Staged Care Treatment for Overweight and Obesity

Four treatment stages are recommended, with progress through the stages based on the adolescent's age, biologic development, level of motivation, weight status, and success with previous stages of treatment. Advancing to the next stage of treatment may be recommended if insufficient progress is made to improve weight status or resolve comorbid conditions after 3 to 6 months.

Stage 1 is appropriate for adolescents at an overweight body mass index and with no comorbid conditions and/or sexual maturity rating (SMR) of 4 or less. This stage of care consists of general nutrition and physical activity advice and can be provided by a single health care provider, including physicians, nurses, and dietitians who have training in pediatric weight management. Weight loss should be monitored monthly by the provider and not exceed 1 to 2 pounds per week. Achieve 1 hour of moderate-to-vigorous physical activity each day. Limit daily screen time to no more than 2 hours.

Guidelines for Stage 1

- Remove television and other forms of screen media from the bedroom.
- Consume five fruit and vegetable servings per day, but limit intake of juice.
- Limit eating occasions away from home with the exception of school meals.
- Participate in family meals on most days of the week.
- Consume at least three meals per day rather than frequently snacking.
- Eat mindfully, only when hungry, and only until satiated.
- Reduce consumption of most energy-dense foods and beverages and eliminate consumption of sugar-sweetened beverages.
- Select appropriate portion sizes when eating at home and away from home.

Stage 2 includes the same concepts as stage 1, but it provides more structure. This stage of obesity treatment can be provided by a single health care provider with training in motivational counseling. However, referrals for additional services such as physical therapy or counseling may be necessary for some adolescents. Stage 2 treatment is considered successful if weight maintenance or weight loss of up to 2 pounds per week is achieved. Assessment of progress should be monitored monthly.

Guidelines for Stage 2

- Monitor food and beverage intake through daily food and exercise journals or record books.
- Set goals for food and physical activity behavior changes and monitor progress toward goals.

- Limit time spent with screen media to no more than 60 minutes per day.
- Follow a structured meal plan with scheduled meal and snack times.
- Plan and monitor physical activity to ensure 60 minutes of moderate-to-vigorous activity is achieved each day.
- Reinforce successful lifestyle changes through the use of age-appropriate, nonfood rewards such as tickets to a local event or museum, jewelry, clothing, or music.

Stage 3 is more structured than stage 2. Youth with a BMI at or above the 99th percentile for age and gender may start treatment in stage 3. Treatment services are provided by a multidisciplinary team that includes a physician or pediatric nurse practitioner, a counselor (psychologist or social worker), a registered dietitian nutritionist, and an exercise physiologist or physical therapist. Stage 3 treatment is considered successful when BMI no longer exceeds the 85th percentile for age and gender; however, weight loss should be monitored to not exceed 2 pounds per week. If no improvement is seen after 3 to 6 months, or if comorbid conditions worsen, it is recommended that treatment advance to stage 4.

Guidelines for Stage 3

- The treatment program provides at least 50 hours and ideally more than 70 hours of intervention within 2 to 6 months.
- A family component and an adolescent-only component are offered.
- A highly structured meal plan is developed and monitored.
- A highly structured physical activity plan is developed and monitored.
- A formal behavior modification program is instituted by a counselor, with parental involvement as appropriate.

Stage 4 treatment is a tertiary care service and is reserved for severely obese adolescents or those who have a BMI at or above the 95th percentile for age and gender and who have significant comorbidities that require concerted intervention. This treatment stage is available only in clinical settings that employ a full range of health professionals who are trained specifically in the behavioral and medical management of pediatric obesity.

Guidelines for Stage 4

- Intensive dietary regimens, such as meal replacement, protein-sparing modified fasts, and oral medication.
- Bariatric surgery may be used.

Adapted from Spear B et al: Recommendations for treatment of child and adolescent overweight and obesity, *Pediatrics* 120:S254, 2007 and U.S. Preventative Services Task Force; Barton M: Screening for Obesity in Children and Adolescents: U.S. Preventive Services Task Force Recommendation Statement, *Pediatrics* 125:361, 2010.

Promoting Cardiovascular Health

Whereas a healthy diet during adolescence helps to prevent CVD in adulthood, the presence of hyperlipidemia and hypertension are important risk factors. Hyperlipidemia and hypertension are apparent in adolescence and have been shown to be predictive of CVD risk in later life. Components of a health screening assessment aimed at the identification and prevention of risk for CVD and other chronic diseases are listed in [Table 17.9](#). [Table 17.10](#) lists the classification criteria for the diagnosis of hyperlipidemia among youth. National data suggest that one in five adolescents 12 to 19 years old has elevated blood lipid levels ([CDC, 2010](#)). The prevalence of hyperlipidemia among adolescents varies according to BMI from 14% among adolescents at a BMI, 85th percentile to 22% among adolescents at an overweight BMI and 43% among adolescents at an obese BMI. The prevalence of low, high-density lipoprotein (HDL) cholesterol and high triglyceride levels appeared to increase with age. Adolescent males were almost three times more likely to have low HDL cholesterol levels compared with females

at any age. These youth are considered candidates for therapeutic lifestyle counseling with emphasis on nutrition and physical activity intervention.

The National Heart, Lung, and Blood Institute (NHLBI) has recommended that all youth with elevated blood lipids be referred to a registered dietitian or nutritionist for medical nutrition therapy. The dietary recommendations for youth up to 21 years of age with elevated low-density lipoprotein (LDL) cholesterol are listed in [Box 17.4](#), and those for elevated triglycerides and non-HDL cholesterol are listed in [Box 17.5](#).

National screening criteria for blood pressure levels among adolescents are available through the National Heart Lung and Blood Institute through the NIH. Adolescents 13 years of age and older who have consistent systolic readings of 130-139 mm Hg or diastolic readings of 80-89 mm Hg meet the diagnostic criteria for hypertension.

Dietary counseling and weight management are integral components of hypertension treatment. The Dietary Approaches to Stop

TABLE 17.9 Suggested Health Screening Schedule for Health Promotion and Chronic Disease Prevention

Risk Factor	Ages 12-17 Years	Ages 18-21 Years
Family history of premature cardiovascular disease	<ul style="list-style-type: none"> Update previous family history at each visit. Provide dietary counseling and referral based on family history as necessary. 	<ul style="list-style-type: none"> Assess changes in family history at least annually. Provide dietary counseling and referral based on family history as necessary.
Eating behaviors and patterns	<ul style="list-style-type: none"> Assess diet using appropriate methods. Provide education and counseling as needed. 	<ul style="list-style-type: none"> Review eating behaviors and provide education to improve dietary intake and nutritional status.
Growth and weight status	<ul style="list-style-type: none"> Weigh and measure teen at each visit. Plot height, weight, and BMI. Review with adolescent and parent(s). If adolescent is overweight, provide step 1 counseling to adolescent and parent(s) and schedule follow-up visit. If adolescent is obese, provide step 2 counseling and refer to a comprehensive weight management program. 	<ul style="list-style-type: none"> Weigh and measure client at each visit. Calculate BMI based on height and weight measurements. If overweight or obese, thoroughly assess diet and physical activity patterns and provide counseling as appropriate. If overweight or obese, refer to primary health provider for full health assessment.
Blood lipids	<ul style="list-style-type: none"> Refer adolescent with family history of premature heart disease, family history of dyslipidemia, or those who are overweight/obese to primary care provider and request a blood lipid panel. Review blood lipid levels with adolescent and parent(s). Provide nutrition counseling as appropriate. If adolescent is overweight, provide dietary counseling in accordance with step 1. If adolescent is obese, provide dietary counseling in accordance with step 2 and refer to comprehensive weight management program. The addition of plant sterols or stanols at no more than 2 g/day can be recommended for teens with familial hyperlipidemia. If dietary management is not effective, refer to primary care provider for physical examination and management of dyslipidemia by medication as needed. 	<ul style="list-style-type: none"> Refer adolescent with family history of premature heart disease, family history of dyslipidemia, or those who are overweight/obese to primary care provider and request a blood lipid panel. Review blood lipid levels with adolescent and parent(s). Provide nutrition counseling as appropriate. If client is overweight or obese, provide dietary counseling as appropriate and refer to weight management program. Department of Health and Human Services (USDHHS), National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI): *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents*. Summary report, NIH Publication No 12-7486A, October 2012.

BOX 17.4 Dietary Recommendations for Elevated Low-Density Lipoprotein Cholesterol in Adolescents

- Limit total fat intake to no more than 25% to 30% of calories.
- Limit saturated fat intake to no more than 7% of calories.
- Dietary cholesterol intake should not exceed 200 mg/day.
- Plant sterol esters and/or stanol esters can replace usual fat intake up to 2 g/day for children with familial hypercholesterolemia.
- Up to 12 g of psyllium fiber can be added to the diet each day as cereal enriched with psyllium.
- At least 1 hour of moderate to vigorous exercise should be obtained daily.
- Sedentary and/or screen time should be limited to less than 2 hours each day.

Adapted from U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute: *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents*. Summary report, NIH Publication No 12-7486A, October 2012.

Hypertension (DASH) eating pattern has been shown to be effective in reducing blood pressure in many individuals (see Chapter 32 and Appendix 17). In addition to following the DASH diet, adolescents with elevated blood pressure should be counseled to reduce sodium intake to less than 2000 mg/day and to achieve and maintain a healthy body weight.

The NHLBI has developed the CHILD 1 (Cardiovascular Health Integrated Lifestyle Diet) diet and nutrition guidelines, which integrate dietary approaches to prevent hypertension and hyperlipidemia, and promote a healthy weight (Table 17.11). These guidelines include the

BOX 17.5 Dietary Recommendations for Adolescents with Elevated Triglyceride or Non-High-Density Lipoprotein Cholesterol Levels

- Limit total fat intake to no more than 25% to 30% of calories.
- Limit saturated fat intake to no more than 7% of calories.
- Reduce intake of added and natural sugars in the diet.
- Replace simple carbohydrates with complex carbohydrate and whole grains.
- Avoid sugar-sweetened beverages.
- Increase the intake of fish high in omega-3 fatty acids.

Adapted from U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute: *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents*. Summary report, NIH Publication No 12-7486A, October 2012.

TABLE 17.11 Cardiovascular Health Integrated Lifestyle Diet (CHILD 1) Recommendations, Ages 11 to 21 Years

Primarily select fat-free unflavored milk, water, and unsweetened tea as beverage choices.
Limit or avoid sugar-sweetened beverages.
Try to consume a range of 25% to 30% of daily energy needs from total fatty acids.
Limit saturated fatty acids to 8% to 10% of daily energy needs.
Keep monounsaturated and polyunsaturated fatty acids to no more than 20% of daily energy intake.
Avoid trans fatty acids.
Limit dietary cholesterol to 300 mg/day.
Choose foods high in dietary fiber often to include a goal of 14 g fiber per 1000 kcal.
Choose naturally sweetened juices (no added sugar) and limit intake to 4 to 6 oz/day.
Limit sodium intake.
Try to eat breakfast daily.
Try to eat meals together with other family members at the same table.
Limit fast food meals.
Use the Dietary Approaches to Stop Hypertension eating plan as a guide to plan meals.
Aim to keep average energy intake close to estimated energy requirements with adjustment for growth and physical activity as needed.

Adapted from U.S. Department of Health and Human Services (USDHHS), National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI): *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents*. Summary report, NIH Publication No 12-7486A, October 2012.

DASH dietary guidelines as well as recommendations for upper limits for total and saturated fatty acids and dietary cholesterol intake. The CHILD 1 guidelines recommend avoiding sweetened beverages, limiting juice intake, and increasing fiber intake to a level of 14 g/1000 kcal.

Metabolic syndrome is considered to be a clustering of risk factors that, taken together, signal a need to intensify the depth and breadth of prevention measures that are recommended. It is estimated that 3.3% of all U.S. adolescents have metabolic syndrome; the rate is much

higher among adolescents at an obese BMI, among whom it is estimated to be 29.2% (Friend et al, 2013).

Preventing and Screening for Diabetes

The exact prevalence of diabetes among adolescents is not known, but it is estimated that approximately 193,000 people under the age of 20 have diabetes (CDC, 2017). Findings from the SEARCH for Diabetes in Youth Study suggest that the incidence of type 1 and type 2 diabetes is 21.7 cases and 12.5 cases respectively per 100,000 people younger than 20 years (Mayer-Davis et al, 2017). Ethnic and racial minority youth are at increased risk for both type 1 and type 2 diabetes compared with their non-Hispanic white counterparts.

The growing incidence of type 2 diabetes among adolescents is of particular public health concern. Between 2002 and 2012, the incidence of type 2 diabetes increased by 7.1% (Mayer-Davis et al, 2017). Type 2 diabetes is more common in those with a family history of diabetes and in those who have significant and rapid weight gain or obesity. Recommendations for type 2 diabetes screening, including assessment for physical signs such as acanthosis nigricans (dark, velvety patches of skin in body folds and creases), are listed in Box 17.6. The prevention of type 2 diabetes includes following the CHILD 1 dietary guidelines and additional physical activity at a level to reduce body weight (U.S. Department of Health and Human Services [USDHHS], National Institutes of Health [NIH], NHLBI, 2012).

Promoting Physical Activity

Participation in adequate physical activity is critical to the prevention of diabetes as well as the promotion of cardiovascular health, a healthy weight, high quality sleep, academic achievement, and overall well-being (National Center for Chronic Disease Prevention and Health Promotion, 2014; Physical Activity Guidelines Advisory Committee, 2018). National recommendations for physical activity are for adolescents to be active at least 60 minutes each day, including participation in vigorous activity at least 3 days each week (USDHHS, 2018). In addition, it is recommended that muscle-strengthening (e.g., working with resistance bands, lifting weights, yoga) and bone-strengthening activities (e.g., running, jumping rope, basketball) be included in the 60 minutes of physical activity at least three times a week. The Move Your Way campaign through the Office of Disease Prevention and Health Promotion was developed along with these national recommendations and

may be a useful source of educational materials. In order to achieve these recommendations for being active and getting adequate sleep, the American Academy of Pediatrics recommends that adolescents and their parents develop limits for media use (e.g., designated media-free times, consistent limits on time spent using media and types of media) as part of a Family Media Use Plan (Council on Communications and Media, 2016). Many young people do not meet minimum recommendations for physical activity and a high proportion spend excessive amounts of time engaged with screen media. Overall, slightly less than half of U.S. high school students report being physically active for at least 60 minutes per day on 5 days or more per week; males are more active than females with 57% versus 37% meeting recommendations. Media use is also high on school days among high school students, with 43.0% reporting that they played video or computer games or used a computer for 3 or more hours per day and 20.7% reporting they watched television 3 or more hours per day.

Adolescent athletes have unique nutrient needs. Adequate fluid intake to prevent dehydration is especially critical for young athletes. Young adolescents are at higher risk for dehydration because they produce more heat during exercise but have less ability to transfer heat from the muscles to the skin. They also sweat less, which decreases their capacity to dissipate heat through the evaporation of the sweat.

Athletes who participate in sports that use competitive weight categories or emphasize body weight are at elevated risk for the development of disordered eating behaviors. A concern among female athletes is the female athlete triad relationship, a constellation of low body weight and inadequate body fat levels, amenorrhea, and osteoporosis (see Chapter 22). The female athlete triad may lead to premature bone loss, decreased bone density, increased risk of stress fractures, and infertility (De Souza et al, 2017). Nutrition assessment and education for teenage athletes should focus on obtaining adequate energy, macronutrients, and micronutrients to meet the needs for growth and development and to maintain a healthy body weight. The use of anabolic agents (such as steroids or insulin) and other ergogenic supplements should also be included in nutrition screening. National survey data show that 2.9% of U.S. high school students have taken steroids without a prescription at least once in their life, with a higher proportion of males reporting steroid use than females (3.3% vs. 2.4%) (Kann et al, 2018). Furthermore, several studies have found that athletes are more likely than nonathletes to use performance-enhancing substances (LaBotz and Griesemer, 2016).

Meeting Nutritional Needs During Pregnancy

Although birth rates among females 15 to 19 years have declined over the past few decades and reached a low of 20.3 births per 1000 adolescents in 2015, adolescent pregnancy remains a significant public health issue (Martin et al, 2018). Adolescent females who become pregnant are at particularly high risk for nutritional deficiencies because of elevated nutrient needs. Pregnant adolescents with a **gynecologic age** (the number of years between the onset of menses and current age) of less than 4 and those who are undernourished at the time of conception have the greatest nutritional needs. As with adult women, pregnant adolescents require additional folic acid, iron, zinc, and other micronutrients to support fetal growth (see Chapter 14). Calcium and vitamin D are also important nutrients in pregnancy, because both are necessary for growth and development of the adolescent mother and fetus (Young et al, 2012). Pregnant adolescents need a full nutrition assessment early in pregnancy to determine any nutrient deficiencies and to promote adequate weight gain. Weight gain recommendations for pregnancy are listed in Table 14.11 in Chapter 14. Referral to appropriate food assistance programs such as the Special Supplemental Nutrition Program for Women, Infants and Children is an important part of prenatal nutrition education.

BOX 17.6 Recommendations for Screening Adolescents for Type 2 Diabetes Mellitus

Youth who are at an overweight or obese body mass index and exhibit two of the following risk factors are at high risk:

- First- or second-degree relative with a history of type 2 diabetes
- Member of a racial/ethnic group considered at higher risk (American Indian, African American, Latino, Asian American/Pacific Islander)
- Dyslipidemia
- Hypertension
- Acanthosis nigricans
- Polycystic ovary syndrome

Screening should begin at age 10 or the onset of puberty, whichever occurs first. Screening should occur every 2 years.

Adapted from U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute: *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents. Summary report*, NIH Publication No 12-7486A, October 2012.

CLINICAL CASE STUDY

Cherise is an 18-year-old white female and high school senior who saw a nurse at the school-based clinic. While taking her medical history, the school nurse noted that Cherise had frequent headaches and fatigue. Cherise's blood pressure reading fell into the 92nd percentile. The school nurse referred her to a local community clinic for a more thorough evaluation.

A physician's assistant (PA) at the community clinic took a social history and performed a physical examination on Cherise. A sexual maturity rating (SMR) stage of 5 was noted. The PA noted that Cherise's BMI had increased over the past year from the 85th to the 95th percentile for her age and gender. Her blood pressure registered at the 94th percentile. The family history revealed a strong family history of cardiovascular disease, diabetes, and renal disease. Cherise thought her father may be taking medication for his cholesterol and blood pressure, but she reported no health issues for her mother. No signs of acanthosis nigricans were noted on the physical examination.

Laboratory results show that Cherise had elevated total, non-HDL, and LDL cholesterol levels along with a marginally low HDL level. The liver enzyme and blood glucose values were at the upper end of normal. A referral was made for Cherise to see a registered dietitian nutritionist (RDN) for nutrition and exercise counseling.

The outpatient RDN reviewed Cherise's medical history, confirmed her family history of cardiovascular disease, and measured her height and weight. Cherise's BMI value plotted at the 95th percentile. The RDN completed a 24-hour dietary recall with Cherise, beginning with the last thing she had eaten that day and working backward to facilitate a complete and accurate recall. The RDN also inquired about usual dietary patterns and physical activity as well as the presence of any food allergies/intolerances and avoidances.

Cherise reported that she usually skipped breakfast because she didn't have time to eat in the morning, but she often buys a caramel macchiato from the school store at 7:15 AM. The first food Cherise ate most days was usually a snack from the vending machine at 10:30 AM, which consisted of a granola bar or a bag of chips and a juice drink. Occasionally she would purchase a la carte lunches of tacos or a burger, but generally she skipped lunch. Cherise was out of school at 2 PM each day, at which time she went to work as a clothing sales clerk at the local mall. She had a half-hour break in the late afternoon or early evening, when she would go to the food court for dinner. Her evening meal usually consisted of one to two slices of pepperoni pizza, two tacos, or one to two pieces of fried chicken with a soft drink. About half of the time she also ordered fries or nachos. When Cherise returned home from work at 10:15 PM, she usually had a snack of ice cream, tortilla chips, spicy cheese puffs, or microwave popcorn while doing her homework. A large glass of juice or lemonade usually accompanied her snack. On weekends, Cherise worked as many hours at the mall as she could, often meeting friends for pizza or fast food on her nights off. Her physical activity consisted of walking between the house and bus stop in the morning and evening, walking around school between classes, and being on her feet in the evenings at her sales job.

The RDN counseled Cherise regarding dietary changes and physical activity. A follow-up visit was scheduled 4 weeks in the future.

Cherise did not return to see the RDN for her follow-up appointment and did not keep her follow-up appointments with the PA. Five months later, she returned to see the PA at which time her health status was reassessed. Cherise's

blood pressure was still at the 94th percentile and her BMI now at the 96th percentile. When counseled about her dietary habits and physical activity, Cherise reported that she had tried to follow the recommendations of the RDN but found it hard because of time constraints. She reported that she wanted to lose weight and thought she could do this because she would graduate in a few weeks and would have more time to devote to exercise and preparing food at home. The PA suggested she see the RDN again for more dietary and physical activity counseling.

The RDN reviewed the previous dietary recommendations with Cherise and suggested she attend the clinic's 12-week weight management program. Cherise attended the first five sessions of the program, then stopped. She had lost 12 pounds during the five sessions. Several months later Cherise was once again seen by the PA. Her blood pressure continued to be elevated and her BMI was plotted at the 94th percentile. When questioned about the weight loss program, Cherise reported that her mother had changed jobs and lost her health insurance benefits, so she could no longer participate in the program. The RDN connected Cherise with the local YMCA, which offered a weight management program for adults on a sliding fee scale. Five months later Cherise's BMI was assessed at 26.8 and a weight loss of 19 pounds from previous levels was noted.

Nutrition Diagnostic Statements

- Excessive energy intake (NI-1.3) related to inconsistent meal patterns and dietary history including mostly low fiber and energy-dense convenience foods as evidenced by a BMI at the 95th percentile
- Excessive fat intake (NI-5.6.2) related to a preference for convenience foods, including pizza, fried snacks, and ice cream as evidenced by elevated total and LDL cholesterol
- Inadequate physical activity (NB-2.1) related to a busy work and school schedule as evidenced by patient reported not having enough time to participate in regular physical activity
- Limited adherence to nutrition-related recommendations (NB-1.6) related to socioeconomic barriers and busy work and school schedule as evidenced by BMI up 1 percentile at follow-up visit

Nutrition Care Questions

1. How would you classify Cherise's blood pressure based on the reading at the school nurse's office?
2. How would you classify Cherise's weight based on the readings at the first visit at the community clinic? Is there any additional information you would want to know about her weight history to make your assessment?
3. Based on her family health history, what laboratory tests would you order to be consistent with the National Heart, Lung, and Blood Institute (NHLBI) recommendations?
4. What type of nutrition recommendations would be ideal for Cherise based on her blood pressure, weight gain history, and laboratory results?
5. What specific strategies would be beneficial for the RDN to recommend to Cherise regarding improving her dietary intake?
6. What strategies would you recommend for Cherise to change her level of physical activity?

This chapter emphasizes the background and tools for encouraging adults to set nutrition-related lifestyle goals that promote positive health and reduce risk factors. Other chapters of this text provide a focus on the present and potential role of medical nutrition therapy (MNT) in the prevention and intervention for major chronic diseases and conditions that affect food and nutrition choices in the adult years, such as cardiovascular disease (CVD), diabetes, cancer, weight gain, and osteoporosis. Added to these are health-related conditions such as arthritis, Alzheimer's disease, renal disease, and inflammatory-related conditions, which research indicates have potential links to lifestyle and food and nutrition choices. The role of inflammation in chronic disease is becoming increasingly evident (see Chapter 7).

The adult years are a time for nutrition and dietetics professionals to be leaders and team members helping adults achieve and maintain positive health. The goals for Healthy People 2020 provide the framework (Centers for Disease Control and Prevention [CDC], 2017a). The evidence is convincing that decisions for a healthy lifestyle must be made early in life for health promotion and disease prevention (Academy of Nutrition and Dietetics [AND], 2013b).

SETTING THE STAGE: NUTRITION IN THE ADULT YEARS

The focus of this chapter is on nutrition and food-related behaviors for the years after adolescence but before one is deemed an “older adult,” often defined as age 65 based on traditional retirement age, although this definition is in a period of change. Admittedly this is a wide range of ages, and, like all population groups, the adult years are heterogeneous. The description of what constitutes being an “older adult” is in constant flux as people change their retirement age, as life expectancy projections are adjusted, and as medical science and lifestyle alterations extend life spans and opportunities for an optimum quality of life. A life expectancy of 80 and above is a reality backed up by CDC statistics with life expectancy in 2017 at 78.8 (CDC, 2018c). Evidence continues to indicate that the adult years set the framework for quality

of life as well as life expectancy. Nutrition and food-related behaviors are key factors, and the earlier prevention becomes the goal, the better the outcome (AND, 2013b).

The dietary reference intakes (DRIs) (see inside cover) provide an overview of the nutrient recommendations for age groups under the DRI umbrella. Staying current on changes in DRI is a critical part of the nutrition and dietetics professional's tools because changes are made as research is validated. Nutrient needs in the adult life cycle are similar but, as in all life stages, are affected by gender, state of health, genetics, medications, and lifestyle choices such as eating behaviors, smoking, and physical activity level. These are markers, determined through assessment, that a nutrition and health professional can use to determine this population's needs. Other markers are less evident and include the adult's perceptions of quality of life and motivation in the areas of nutrition and health (National Institutes of Health [NIH], 2018d).

When the objectives are prevention and behavior change, such markers become critical. Research continues to indicate that positive changes at any age and lifestyle behaviors can make a difference in total health and life expectancy. Making these changes early in life, rather than later, and maintaining them throughout the adult years should be goals. Genetics always has been a consideration in assessment of nutrition status and life potential, but the evolving science of **nutritional genomics** has become an important marker in nutrition and dietetics practice (see Chapter 6).

SETTING THE STAGE: MESSAGES

A first step for nutrition and dietetics professionals is to recognize that many adults are prime targets for nutrition and health information that offers positive guidance that is understandable and implementable. However, this translates into growing evidence that adults can also be targets for misinformation and guidance based on promises and quick-fixes rather than evidence-based MNT. Rebekah Nagler, PhD, studied the potential role of consumer reaction to what

appeared to be contradictory nutrition information or guidance. According to Nagler, confusion and backlash may make people more likely to ignore not only the contradictory information but also the widely accepted nutritional advice such as eating more fruits and vegetables. Nagler also noted that those with the greatest exposure to contradictory information expressed the most confusion with nutrition (Nagler, 2014).

As with any group, adults must be approached with strategies and guidance that fit their health and education needs as well as their capability to implement them. There needs to be an understanding that research is dynamic and ongoing. This should be firmly fixed in the minds of the messenger (the nutrition professional) and the receiver (the patient or client). It is the role of the nutrition professional to verify messaging, separating current evidence-based messages from those based on preliminary or single studies. What is reported as news or guidance to the consumer may appear to be contradictory to current practice when in fact the basis is preliminary research rather than evidence based.

The challenge to nutrition and dietetics professionals is staying current on research and guidelines while acknowledging the potential motivations of their audience or clients and their sources of information. In a technologically savvy world with instant access to nutrition and health advice by self-proclaimed as well as credentialed professionals, this becomes even more of a challenge.

Surveys support the idea that adults are seeking nutrition information and using it to make positive lifestyle changes but are finding that making these changes is a challenge. Time, lack of willpower, conflicting messages, and identifying the efficacy of the messages are cited as barriers (International Food Information Council [IFIC], 2017). The 2017 IFIC Foundation Food and Health Survey identified barriers and noted that consumer confusion is a key concern. Consumers expressed doubt about their choices and noted that they relied on their social network for advice. However, they also noted limited trust in the advice from friends and family. Trust was high for health professionals including RDNs. Interest in adopting and maintaining healthy eating behaviors and confidence for food safety was higher in the baby boomer generation and older adults than in younger adults (IFIC, 2017). As with any age grouping, knowing more about a person's food- and nutrition-related behaviors and beliefs is a critical part of determining how to reach that person with a message.

Another helpful tool for reaching adults is to review the influences of behavior and knowledge on nutrition and health. A review of the health and nutrition information in the media reinforces the idea that nutrition and health information is popular. However, consumers are selective about their personal concerns and their source of information. The IFIC Foundation Food and Health Surveys in 2013, 2015, 2017, and 2018 noted strong interest in trying to lose weight. However, in the 2017 study it was reported that the interest in weight loss benefits from adjusting food intake fall dramatically with age. For those ages 18 to 34, 40% of the respondents reported an interest. At ages 18 to 34 there was a slight drop to 38%, with 23% reported at ages 50 to 64 and 28% at ages 65 to 80 (IFIC, 2017). Changes reported include lowering the amounts of food eaten, eating more fruits and vegetables, drinking more water or low- or no-calorie beverages, including more whole grains, reducing the choice of foods higher in sugar or added sugars, and consuming smaller portions. All these changes are in line with guidance that is suggested in the Dietary Guidelines for Americans (DGA).

The interest in nutrition and in food continues to be evident in the adult years. Popular literature demonstrates a growing interest in cooking, cookbooks, supermarket RDNs, grocery store and farm-to-table events, and other food-related activities (IFIC, 2018). This is

Fig. 18.1 Cooking at home can be the best way to eat balanced and nutritious meals but can also be the most challenging during the adult years due to busy schedules.

surprising because despite all this interest in cooking, Americans continue to cook less and eat fewer meals at home. Cooking at home is a challenge in the adult years due to busy schedules (Fig. 18.1).

Messages regarding the potential benefits and risks of certain foods and nutrients are being heard by consumers. These include messages on the negative effect of saturated fat, trans fatty acids, and sodium. Food companies are changing products to reflect a more health-promoting choice, and restaurants are following this lead. Proposed changes in labeling laws for both food and restaurants have added pressure as the amounts of calories, sodium, and other key nutrients become more identifiable to the consumer. A study on energy and sodium contents of menu items in U.S. chain restaurants concluded that when industry marketing indicated healthier options, it was balanced by simultaneous less-healthy changes in menu choices. For example, as lower-calorie options were offered, the appetizer menu added more fried foods to dip in high-sodium sauces with the featured drinks. It was concluded that there was no meaningful change in energy and sodium content in main entrées in a 1-year (2010–2011) time period (Wu and Sturm, 2014). As the new requirements for restaurant labeling of menu items are fully implemented, it will be interesting to see if this results in both food establishments offering healthier options and customers making healthier choices.

The nutrition and dietetics professional can be a positive influence in advocating and educating for meaningful and real changes in the food supply with a focus on prevention. However, there must be a consumer-driven effort to support these changes. To be a leader, or at least a player, the nutrition and dietetics professional must be aware of community resources and influences, available food sources, and changing food behaviors. Although this chapter focuses on adults, it's important to remember that children are affected by their adult role models, which increases the potential benefits from a focus on prevention.

INFORMATION SOURCES

Where consumers get their information is a factor to consider. The source and the appeal of the message affect how realistic and meaningful information is to the consumer. However, the scientific value and the application of evidence-based information vary. To the adult consumer, the promise of specific benefit is more important than the standard “it’s good for you” message, and the scientific validity of the message may not be the determining point. The 2017 IFIC study pointed to this belief (IFIC, 2017).

Sources of information continue to change. Traditional print sources decline as digital and electronic sources increase. Use of phones for digital applications, or “apps,” is a growing trend and so is creating, marketing, and evaluating apps. The AND and its affiliates have resources available to identify valid sources. Publications are available to assist in evaluating and selecting digital tools. One such book is *Bits & Bytes: A Guide to Digitally Tracking Your Food, Fitness, and Health*, coauthored by Meagan F. Moyer, MPH, RDN, LD, and the AND (Bits and Bytes, 2016). AND Dietetic Practice Group newsletters and postings frequently include reviews. An ongoing column, *CLICK*, is in the magazine *Food & Nutrition* (published by the AND) (AND CLICK, 2018). The Internet and related links are major information sources thus creating another challenge to the professional seeking to provide evidence-supported information.

Regarding believable and credible human sources of nutrition information, health professionals, including registered dietitians, doctors, and nurses, continue to be rated as the most credible (IFIC, 2017). However, when consumers were asked about the factors that affect their willingness to believe new food and health information, others in their environment, including family and friends, were named as potential influencers.

Surveys have shown an increase in the number of consumers familiar with MyPlate and in those who use food labels, shelf information, and other tools (IFIC, 2017, 2018). Popular literature indicates a growing segment of the population interested in food, cooking, cookbooks, celebrity chefs, and so on, and labels them “foodies.” The Nutrition Facts panel and other label information (see Chapter 10) influence nutrition and food decisions, but there may be gaps in the interpretation. The growing lists of ingredients, unknown terminology, changing ingredients, and even the format can make nutrition labels less useful. Changes in the format and content of labels as well as front-of-package systems have been discussed for at least 10 years and are a work in progress. Changes in portion size, the Nutrition Facts panel, and the front-of-package/label claims will be in place by 2020 (U.S. Department of Health and Human Services [USDHHS], 2018b; U.S. Department of Agriculture [USDA], 2018b, 2018c).

Studies indicate that consumers will use labels and would welcome a reliable front-of-package system (Wu and Sturm, 2014). Although the movement for more labeling on menus has been met with mixed reactions, regulations will require labeling by 2020. All these efforts are additional pieces of what is a developing puzzle that involves actions at the state and regional level as well as from federal sources. A continuing theme is the need for an overall consumer-related valid message based on current, understandable evidence-based tools. Also critical to the effort is credentialed food, nutrition, and health professionals who can guide consumers to sources they can easily use to validate information.

Nutrition Information and Education for Adults

Mainstream adults in reasonable health frequently are ignored as a unique segment of the population who can benefit from nutrition assessment and education. Preventive strategies are likely to be targeted

to address the formative years of prenatal, infancy, childhood, adolescence, and young adulthood. Older adults are another group likely to be the focus of health intervention strategies and quality-of-life messages as this is a growing age group. The population group in the middle of the continuum, the adult aged 25 to approximately 65, is likely to be segmented in reference to a potential or existing disease state, a life event, or a lifestyle choice. For example, adults are targeted as having or being at risk for diabetes or heart disease, in need of a medication, being pregnant, or being an athlete.

The adult who is not pregnant, an athlete, or “sick,” but who seeks guidance on normal nutrition or prevention of disease, may be directed toward diets for chronic disease or weight loss. Such information may be a good fit when the information is based on science, but it can miss the mark on overall prevention goals. Fortunately, the guidance provided by such groups as the American Heart Association (AHA), the AND, the American Diabetes Association (ADA), and the American Cancer Society (ACS) tend to mirror the 2015–2020 DGA. These guidelines will continue to change with the updating of the DGA (USDHHS, 2018a). The overall focus on diet with evolving guidelines is to emphasize quality of food choices, including a message of the role of “healthy fats” (NIH, 2018c). Another change that affects how the DGA will be implemented both by consumers and food producers is the elimination of trans fats as ingredients (Food and Drug Administration [FDA], 2018a).

Several guidelines and reports are aimed at heart-healthy guidance. Heart disease remains the number one disease-related cause of death in adult men and women. The AHA released prevention guidelines in 2006 with a focus on improving overall health and achieving improved cardiovascular health of all Americans by 20% by 2020 (Lloyd-Jones et al, 2010). In November 2013 the AHA, along with the American College of Cardiology (ACC) and the National Heart, Lung, and Blood Institute (NHLBI), released four guidelines based on evidence-based reviews sponsored by NHLBI (see Chapter 32) (Harold and Jessup, 2013). The ACC/AHA recommends a diet high in vegetables, fruits, whole grains, low-fat poultry, fish, non-tropical vegetable oils, nuts, and low-fat dairy, and low in sweets, sugar-sweetened beverages, and red meat (see Chapter 32). The Dietary Approaches to Stop Hypertension (DASH) diet pattern or USDA food pattern (MyPlate) is recommended to achieve this diet. The 2015–2020 DGA is consistent with the ACC/AHA emphasizing increasing the intake of vegetables and fruit to meet the MyPlate guidance of half the plate. A 2015 study by the Produce for Better Health Foundation (PBH) noted that fruit and vegetable consumption has declined 7% over 5 years (from 2009 to 2014). Adults ages 18 to 44 (along with children of all ages) were cited as a population group showing this decrease (PBH, 2015). Nutrition messages related to consumption of fat, choices of fat sources, and choices of vegetables and fruits frame the guidance provided by the AHA, AND, ADA, and ACS as well as meet guidance provided by the DGA.

Guidelines for diabetes prevention continue to be related to healthy lifestyle guidelines of the DGA (see Chapter 29). A 2014 study indicated that research will continue to explore obesity and overweight. In a Danish study the link to being obese or overweight was a factor but there was a time difference noted. Maintaining an overweight or obese status for multiple years increased the risk more than the presence of elevated body mass index (BMI) or weight. This led to the conclusion that focusing on small weight reduction for the total population may be more beneficial than concentrating on weight loss targeted to high-risk individuals (Vistisen et al, 2014).

Health education and public health programs, along with improved research and care, have contributed to changes in morbidity and mortality of the adult population. U.S. adults are on a path to

positive change, moving from knowledge to action (CDC, 2013, 2018a, 2018b, 2018c). Nutrition assessment is a critical component of MNT and guidance for prevention. The nutrition and dietetics professional should either lead or be a part of lifestyle management teams. These professionals can link MNT to food and economic and social choices, and they can frame the guidance to be useful and achievable. Nutrition education, basic cooking ability, communication, and assessment skills add other dimensions to the goal of moving adults to action. Adults in the awareness and action stages are likely to be looking for answers, often short-term fixes or reversals of a health problem rather than more realistic long-term behavior changes. For example, adults may want to know where carbohydrates fit into the total diet and whether there are “better carbs,” the message on “good” or any fat now that trans fats have been almost banned, a “healthy” or “unhealthy” food or diet, whether to buy organically grown or locally grown foods, or what to do about sodium. These are issues best addressed by skilled nutrition and dietetics professionals who can provide valid current information that answers short-term questions but builds on long-term solutions.

Guidance based on science generally addresses total diet and lifestyle rather than single nutrients or foods. The concepts of *healthful eating*, *nutrient density*, and *nutritious foods* are debated by food and nutrition professionals as science and technology move forward. Unfortunately, food and nutrition debates and new research findings, often meant to clarify the evidence, are fodder for media coverage, adding to the confusion and perception of mixed messages. A search for information on choosing foods for health can result in evidence-based information such as the DGA, as well as questionable guidance based on single studies or product promotion. The combination of marketing and electronic media makes it easier to mix science with speculation and outright untruths. Adults with an interest in improving the nutritional quality of their diet may end up with unreliable advice pointing to quick-fix solutions.

The Wellness Years and Food Security

The adult years span a broad range chronologically and are complicated by physiologic, developmental, and social factors. Along with their genetic and social history, adults have accumulated the results of behaviors and risks from environmental factors. These factors shape the heterogeneity of the adult years. Nonetheless, the adult years are an ideal time for positive health promotion and disease prevention messages. In the transitions from early to middle adulthood, health and wellness may take on a new importance. This may be the result of a life event or education (an epiphany) that triggers awareness that being well and staying well are important. Examples include learning the results of a screening for blood pressure, cholesterol, or diabetes; facing the reality of death; facing the health crisis of a peer or family member; or realizing that clothes do not fit as well as they should. Regardless of the reason, the concept of wellness takes on a new meaning, and these events are teachable moments.

The Wellness Councils of America (WELCOA) describes **wellness** as a process that involves being aware of better health and actively working toward that goal (WELCOA, 2018). With this mindset, a state of wellness can exist at any age and can start at any point in a person's life course. Wellness is more than physical health and well-being. A state of well-being includes mental and spiritual health and encompasses the ability of a person to move through Maslow's Hierarchy of Needs (Maslow, 1970).

The ability to address nutrition needs requires **food security** (i.e., access to a safe, acceptable, and adequate source of food). Part of the issue of food security is quantity and part is quality. According to USDA data, in 2016, 87.7% of U.S. households were food secure,

slightly higher than in 2012. Of the remaining population, 12.3% of households were reported as food insecure (USDA, 2016).

The current economic climate has put added emphasis on food security or access and potential population inequalities. The highest levels of food insecurity are reported to be in African American, Native American, and Hispanic households (USDA, 2016).

The issues of quantity, quality, and acceptability are a part of the food security discussion. It is often more expensive to eat healthy foods than less healthy, high-calorie foods. However, limited skills in the areas of wise food purchasing and food preparation coupled with limited food access and equipment resources further complicate a person's ability to follow advice for a healthy lifestyle. This emphasizes the need for adult consumer education in basic food skills. The Supplemental Nutrition Assistance Program (SNAP), formerly known as food stamps, aims to alleviate food insecurity and eligibility, for participation is based on income level. The program includes some money for nutrition education (USDA, 2018b). SNAP, like other food and nutrition assistance programs, is being reviewed and altered not only to adjust access but also to increase the nutrition quality and types of food offered. The fact that SNAP is a program that serves the working poor as well as those who are unemployed often is overlooked. Feeding America is a website to visit for more information on food insecurity (Feeding America, 2014, 2018). Food insecurity frames the need for guidance from nutrition and dietetics professionals on food access, acceptability, and use.

Quality of Life and Work-Life Balance

Perceptions of personal health (mental and physical) relate to views on wellness and perceptions of quality of life. **Health-related quality of life (HRQOL)** is a concept used to measure the effects of current health conditions on a person's everyday life. To capture this and create a tool for professionals, the CDC measures population HRQOL perceptions, including the perception of “feeling healthy.” Using HRQOL, one can learn about how adults relate their health to their daily performance. On average, Americans report feeling “unhealthy” approximately 6 days a month and “healthy” or “full of energy” approximately 19 days a month; adults with the lowest income levels and more chronic diseases report more “unhealthy” days (CDC, 2016b, 2016c).

To promote quality of life, adults are being urged to set a goal of “work-life” balance. This is not a new concept and fits into the need for stress reduction and relaxation as a part of a healthy lifestyle. However, the idea of balancing work time with leisure also can be a reason adults use for not exercising, not cooking, eating on the run, ignoring nutrition guidelines, or skipping meals. Leisure time can be interpreted as screen time, inactivity while watching activity, or social interaction, all of which are sedentary and may be accompanied by eating and drinking. Regardless of the reasons and the interpretations, the idea of work-life balance is a message that is receiving social media attention and an issue that often is related to multitasking and assuming multiple roles (Fig. 18.2). In the concept of wellness or prevention, there is a mental health link as well as a potential block to leading a health-promoting lifestyle, not only for adults but also for their associates, family members, and others in their sphere of influence. The pros and cons and the potential health benefits of work-life balance is a topic for worksites and for dietetic and nutrition professionals (CDC, 2017a).

The adult years offer unique opportunities to evaluate health status, build on positive factors, and change the negative factors that affect quality of life. Because adults are teachers, coaches, parents, caregivers, and worksite leaders, targeting the wellness-related attitudes and behaviors of adults potentially can have a multiplier effect. A positive wellness focus may influence the health of the adult and anyone who is in their sphere of influence.

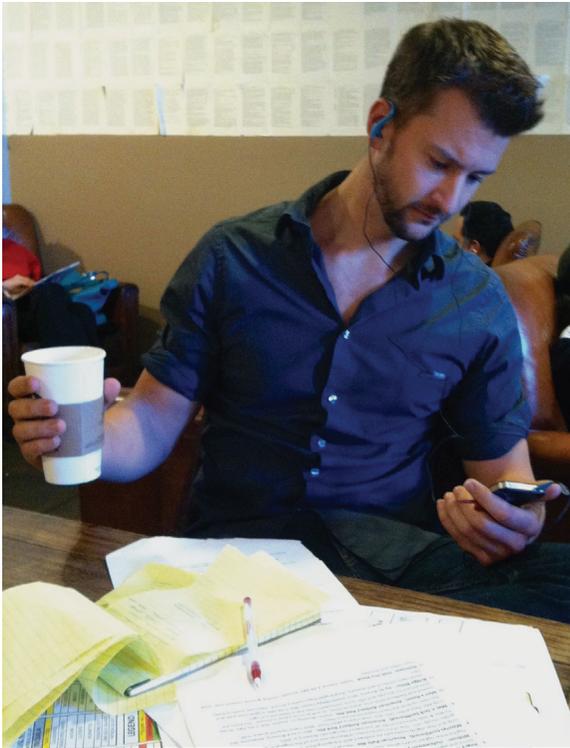

Fig. 18.2 Eating quickly without attention, when stressed or when multitasking, often results in poor nutritional intake in the adult years.

LIFESTYLE AND HEALTH RISK FACTORS

Lifestyle choices, including activity, lay the framework for health and wellness. The health of people living in the United States has continued to improve in part because of education that has led to lifestyle changes. Life expectancy has continued to increase (projected at 78.7 years), and the morbidity and mortality rates from heart disease, cancer, and stroke have dropped (CDC, 2016a, 2018c). Overall life expectancy for the African American population is 3.8 years less than that of the Caucasian population. This disparity is attributed to higher death rates from heart disease, cancer, homicide, diabetes, and perinatal conditions (CDC, 2013). These statistics point the way for increased emphasis on prevention and intervention initiatives in minority populations.

Even when the emphasis is on wellness and prevention, there is a strong link to risk factors that influence morbidity and mortality. In the United States the leading causes of death and debilitation among adults include (1) heart disease, (2) cancer, (3) chronic lower respiratory diseases, (4) cerebrovascular disease, (5) accidents (unintentional injuries), (6) Alzheimer's disease, (7) diabetes, and (8) nephritis, nephrotic syndrome, and nephrosis. Chronic diseases, including heart disease, stroke, cancer, and diabetes, are among the most costly and preventable of all health problems and account for one third of the years of potential life lost before age 65 and for 75% of the nation's medical care costs. These health issues have direct links to diet and lifestyle, but they are also affected by complex social determinants and environmental factors (Box 18.1).

The information quoted is for all adults, but when adjusting for age, the leading causes of death for young adults 18 to 44 are related to preventable causes, with suicide and homicide in the top three causes for adults under 34 years of age. Accidents or unintentional

BOX 18.1 A Focus on Health Disparities and Nutrition

Differences in health between populations have been observed by researchers and clinicians for a long time. Historically, those differences have been most stark when comparing the general population to racial and ethnic minorities. In 1899 American sociologist and author W. E. B. Du Bois wrote in his book *The Philadelphia Negro* about the higher death rates, prevalence of disease, and generally poorer health of urban African Americans (Williams, 2010). But what at the time was viewed by many as the result of biological and immutable differences between races, Du Bois argued and modern researchers now know is in fact the product of a complex mix of social, behavioral, environmental, and genetic contributors to health disparities, and not a fixed characteristic of any one group or race.

Health disparities are differences in the burden of disease or worse health outcomes in a group compared with the general population. Disparities can be found in the overall rate of disease incidence, prevalence, morbidity, mortality, or survival rates. According to the National Institutes of Health, groups observed to have these differences are designated health disparity populations and include racial and ethnic minorities, populations of low socioeconomic status, sexual and gender minorities, and rural or medically underserved persons (NIMHD, 2019).

The determinants of health that factor into health disparities cover many more aspects than just biology. Social determinants of health (see Chapter 8) including socioeconomic factors, psychological influences, social support, discrimination, and a variety of related components are critically important to understanding disparities. These determinants span the behavioral, physical, or built environment, and sociocultural and health care domains, and have impacts on the individual, interpersonal, community, and societal levels (NIMHD, 2017).

Nutrition is a key component in understanding and, in many cases, addressing health disparities. In many diseases in which disparities persist across groups, including hypertension, type 2 diabetes, kidney disease, and obesity, medical nutrition therapy (MNT) is critical to effective intervention. However, additional nutrition-focused research needs to be done in order to determine the most effective methods for addressing disparities in affected communities. In order to address the nonbiological aspects of disparities, simple diet-based strategies alone are not enough. Individual and community values, health literacy, and sustainability are determining factors in the long-term success of the ability of professionals to improve health disparities.

injuries play a different role in younger adults. Accidents are the fifth leading cause of death and debilitation among all adults but moves up to first place for adults under 44, with emphasis on ages 25 to 44 (CDC, 2016a, 2018b, 2018c). Presumably the other leading causes of death, involving chronic diseases and those more diet related, can be important prevention teaching points at younger ages. Add to the list osteoporosis and new links to such health issues as Alzheimer's disease or arthritis as health problems that affect health care costs and

loss of quality of life and that have a potential lifestyle and nutrition link (CDC, 2018a).

Overweight and obesity are either precursors to or complications in all of these diseases. The prevalence of overweight, as measured by a BMI of 25 or more, has increased at all ages but appears to be holding steady and even showing slight decline. It is important when looking at the overall health of adults to consider elevated BMI as a major risk factor but to move to the next phase of total assessment to identify the health profile. Hypertension, hyperlipidemia, and elevated blood glucose often are seen together with or without obesity, known as the **metabolic syndrome** (see Chapter 29). Increasing numbers of obese and overweight adults have been linked to an increase in the number of cases of metabolic syndrome. There is a genetic link to this syndrome but lifestyle is a major issue. Evidence suggests that it is possible to delay or control the risk factors associated with metabolic syndrome with lifestyle changes, including health-promoting diet and exercise patterns, with the help of health professionals (NIH, 2018c; CDC, 2018a, 2016b).

Obesity and overweight directly link with calorie imbalance. An estimated less than half of U.S. adults participate in regular physical activity, with one fourth reporting no activity. Many health risks in the adult years, including coronary artery disease, certain types of cancer, hypertension, type 2 diabetes, depression, anxiety, and osteoporosis have a relationship with lack of participation in regular physical activity and poor eating behaviors. One cannot achieve positive health without a combination of physical activity and food choices that fit personal needs for energy balance and nutrition.

On the other end of the weight spectrum is chronic underweight, frequently accompanied by undernutrition. Anorexia nervosa is the extreme condition, found in both genders across the age span. An unhealthy weight or unhealthy concern about body weight not only affects overall health but in women also can affect fertility and the ability to conceive.

HEALTH DISPARITIES AND GLOBAL HEALTH

Eliminating disparities that increase the health risks for affected populations is a major goal of effective health policy. **Health disparities** (see Box 18.1) related to inadequate access to safe and affordable food are often based on race, ethnicity, gender, education, income level, and geographic location. Inadequate access to care is a disparity that has a major effect on a person's wellness. Chronic diseases and obesity have been shown to be more of a burden to racial minorities and women (CDC, 2016b, 2018a). There is a higher incidence of heart disease, diabetes, and obesity or overweight in low-income, African American, and Hispanic populations (CDC, 2018a). These same population groups have limited access to preventive care, nutrition education, and guidance (USDHHS, 2018a, 2018b). Research and public policy aimed at addressing the social determinants and structural discrimination that contribute to these health disparities is imperative to improving health for all.

World Health

The problems associated with chronic diseases are similar in other countries (World Health Organization [WHO], 2017). Also cited are infectious diseases such as human immunodeficiency virus, tuberculosis, and tropical diseases as barriers to global achievement of positive health status. Eight United Nations Millennium Development Goals seek to reduce the number of people who suffer from hunger and to increase access to safe water and sanitation. However, obesity has been cited as being of epidemic proportions globally, with

at least 2.8 million people dying each year as a result of being overweight or obese.

WHO: Key Facts (WHO, 2018)

- Worldwide, obesity has tripled since 1975.
- In 2016, more than 1.9 billion adults 18 years and older were overweight. Of these, 650 million were obese.
- 39% of adults aged 18 years and over were overweight and 13% were obese.
- Most of the world's population live in countries where overweight or obesity kill more people than underweight.
- 41 million children under the age of 5 were overweight or obese in 2016.
- Over 340 million children and adolescents aged 5-19 were overweight or obese in 2016.

This condition, once associated with higher-income countries, is now listed by WHO as prevalent in low- and middle-income countries. The growing international problem of obesity is a point for consideration and involvement.

Access to a safe and affordable food supply goes beyond the borders of the United States. The quality and quantity of food and lifestyle factors are concerns that require more than provision of food. A newer and growing emphasis on food lifestyles is identifying "food deserts." CDC defines **food deserts** as areas that lack access to affordable fruits, vegetables, whole grains, low-fat dairy, and other foods that make up the full range of a healthy diet (CDC, 2017b). USDA expands the definition with a focus on limited access to supermarkets, supercenters, and other sources of affordable and healthy foods, noting food deserts can occur in rural or urban settings. Knowing the potential of access to healthy foods, knowing the limitations, and working to expand this access is a critical part of assisting adults and families in meeting nutrition goals. The USDA Food Access Research Atlas and Economic Research Services Outlook are starting points for nutrition and dietetic professionals (USDA, 2016, 2018a).

NUTRITIONAL FACTORS AFFECTING ADULT WOMEN AND MEN

Women's Health

The reproductive years constitute a significant stage of a woman's life. Many issues that affect the health of women are related to the monthly hormonal shifts associated with menses. Osteoporosis, heart disease, and some cancers are disease states that are affected by specific hormones. Pregnancy and breastfeeding have an effect on a woman's health (see Chapter 14). Breastfeeding helps control weight, lower the risk for diabetes, and improves bone health. Therefore encouraging women to breastfeed is a potential prevention strategy for the future health of the mother and infant.

Shifts of estrogen and progesterone hormones trigger the female reproductive cycle and affect health. Associated with menses is a complex set of physical and psychological symptoms known as **premenstrual syndrome (PMS)**. Reported symptoms vary but are described as general discomfort, anxiety, depression, fatigue, breast pain, and cramping. Such symptoms are reported to occur approximately 1 week to 10 days before the onset of menses and increase in severity into menses. Currently, there is no single cause or intervention identified for PMS. Hormone imbalance, neurotransmitter synthesis defects, and low levels of certain nutrients (i.e., vitamin B₆ and calcium) have been implicated (NIH, Office of Dietary Supplements [ODS], 2018c, 2018d, 2018f). A diet high in sodium and refined carbohydrates has been

implicated, but the evidence is not complete enough to make recommendations (NIH, ODS, 2018d). A greater emphasis on a plant-based diet of whole grains, fruits, vegetables, lean or low-fat protein sources, and low-fat dairy or soy beverages is a reasonable intervention and may cause relief in some women. Exercise and relaxation techniques have been reported as lessening the symptoms.

When menses end, either because of age or surgical removal of reproductive organs, women have unique health and nutrition concerns. Perimenopause and menopause generally begin in the late 40s. However, genetics, general health, and the age that menses began can alter the timing of this marker. Typically, estrogen production decreases around age 50, when endogenous estrogen circulation decreases approximately 60%. The effects include a cessation of menses and the loss of the healthful benefits of estrogen. Even after the ovaries cease production, a weaker form of estrogen continues to be produced by the adrenal glands, and some is stored in adipose tissue.

As estrogen decreases, symptoms associated with menopause may occur. The onset of menopause and the reported side effects vary. Some women experience a gradual decline in the frequency and duration of menses, whereas others experience an abrupt cessation. The symptoms most often reported include low energy levels and vasomotor symptoms (hot flashes). Bone, heart, and brain health are affected. The decrease in circulating estrogen limits the body's ability to remodel bones, resulting in a decrease of bone mass. Lower levels of circulating estrogen also affect blood lipid levels, increasing total cholesterol and low-density lipoprotein (LDL) cholesterol levels and decreasing high-density lipoprotein (HDL) levels. Brain function, particularly memory, also is affected but the memory loss associated with menopause is often temporary.

Managing menopause promotes emphasis on plant-based foods for the benefits of **phytoestrogens**, soluble fiber, and other components. Having sufficient calcium, vitamin D, vitamin K, and magnesium, and using the DRI as the guideline are important for protecting bone health. Although soy (isoflavones) continues to be rumored by the popular press as a way to control hot flashes, current research is not definitive (NIH, NCCIH, 2016). A study of American women published in *Menopause* found that only women who are able to produce the soy metabolite equol get relief from hot flashes by eating soy (Newton et al, 2015). Of 357 study participants 34% were equol producers. The authors warned that a readily available test for the metabolite must be developed, and more randomized studies are needed to be able to make any recommendations that soy be a treatment for hot flashes.

Heart disease, cancer, and stroke continue to be the leading causes of death in women (CDC, 2017b). Again, although genetics are a factor, lifestyle is a major predictor and complicating factor.

Weight is a risk factor for heart disease and some cancers. Weight gain is an issue for women, with a 35% prevalence of obesity in American women aged 20 to 74 years compared with 33% in the same aged men. One half of non-Hispanic African American women and two fifths of Hispanic women are obese, compared with one third of non-Hispanic white women (CDC, 2016b, 2018b). Physical activity with aerobic endeavors and resistance and weight-bearing exercise is protective for bone, cardiovascular, and emotional health. The key nutrition message is one of balanced food intake with nutrient-dense foods that are low in fat. However, once again personal assessment and tailoring to meet individual needs are a critical part of success in weight loss and maintenance.

Men's Health

The leading causes of death among American men include heart disease, prostate and lung cancers, and unintentional injuries. For the adult man, a diet that supports reducing the risk for heart disease is

especially important because men develop heart disease at a younger age than women. Regular exercise and activity are important. Along with contributing to cardiovascular health, weight-bearing exercise has a positive effect on bone health.

Another issue in adult men is iron intake. Unless adult men are diagnosed with iron deficiency anemia and require additional iron, they should not seek additional iron from multivitamin or mineral supplements, enriched sports drinks, or energy bars. Excessive iron intake is problematic because it is an oxidant in the body; men and postmenopausal women do not have menstruation, pregnancy, or lactation to get rid of excess iron.

Like women, today's male population also is affected by obesity and the risk factors that come with excess weight such as diabetes, heart disease, and orthopedic problems. The ACS reports that one in seven men will have prostate cancer in his lifetime but only one in 36 will die of this disease. Obesity may play a role in these cancers. Some studies indicate that foods high in lycopene, an antioxidant found in tomatoes and other fruits and vegetables, may provide a protective role in lowering the risk factors for developing prostate cancer. Although this is still being studied, it is an emerging area for nutrition and diet in lowering risk factors and an area for dietetic and nutrition professionals to continue to explore. Such factors as how the food high in lycopene is prepared may have an effect on the usefulness of the lycopene (ACS, 2018).

INTERVENTIONS, NUTRITION, AND PREVENTION

Adults are in the ideal life cycle phase for health promotion and disease prevention nutrition advice because of the combination of life experience and influence. This group has the potential to shape personal lifestyle choices and influence others. The tools are in place, including the DGA, MyPlate, and the Nutrition Facts panel on food labels (see Chapter 10).

The vegetarian diet or a more plant-based diet and the Mediterranean diet have become popular with health and nutrition professionals and the public. The motivation is both personal health and health of the planet and support the recommendations of the DGA.

Implementation of positive choices and moving people along the continuum of a healthy lifestyle are other issues. Studies indicate consumers are aware of the concerns associated with lifestyle and diet but have a limited interest in making sustainable changes (IFIC, 2017, 2018). Consumers are aware of the implied promises for good health that come with messages from the media, friends, and health professionals; however, they are unlikely to move from awareness to action without motivation stronger than a message or promise. One perception of consumers is that eating healthful foods means giving up foods they like or having to eat foods that do not have the taste they prefer. A total diet approach of making gradual changes to food and lifestyle choices may help. The Small Steps: Big Rewards program is an example of such an approach with a goal of preventing type 2 diabetes (NIH, National Diabetes Education Program, 2018b).

The steps to prevention and health promotion, even when small, are personal responsibilities that cannot be legislated. Americans have many choices: what and where they eat, where they receive their information, and what they include or exclude from their lifestyle. Adults value choice and food selection as a right, even if it leads to poor health, chronic disease, or death. Some messages are directed at reaching adults where they live and work. For the working adult population, much of the day is tied to a worksite. There are increasing efforts in the private and public sectors to promote positive work site nutrition-related behaviors and programs.

FOOD TRENDS AND PATTERNS

Where one eats, who prepares it, and how much is consumed are patterns of behavior and choice. There is no stereotypical “adult” lifestyle. Adults may be single or partnered, with or without children, and working outside the home or at home. The sit-down family meals at home have given way to eating on the run, take-out, and drive-through. Too little time for planning or preparation and limited cooking skills can lead to reliance on processed foods, speed-scratch cooking (combining processed with fresh ingredients), or more food prepared out of the home. Today’s economic climate and changing dietary recommendations present new challenges. The nutrient-dense approach is essential because energy needs decrease as age increases. Reaching men and women with an understandable and relevant message, especially heads of households or gatekeepers, is critical.

The **consumer price index (CPI)** estimates that Americans spend more than half of their food dollars away from home. This is an amount that continues to increase and that fluctuates by month. The CPI for food measures the average change over time in the prices paid by urban consumers, using a representative market basket of consumer goods and services. The Economic Research Service (ERS) of the USDA follows these expenditures and manages the data set. This is a valuable resource for monitoring expenditures and planning for meaningful interventions (USDA, 2018a).

Changing food patterns and the use of more processed and purchased foods can result in an increase in dietary sodium, fat, and sweeteners and a decrease in use of basic foods such as fruits, vegetables, and whole grains. Portion sizes (either the amount presented, or the amount eaten) replace serving sizes (what is recommended as a serving by the DGA or other source), as others determine what is considered a “meal” or “snack.” Portions have continued to increase in size in the United States.

Dietary changes have affected nutrition and already are reflected in the current concerns for weight and nutrient imbalances. The 2015 DGA and MyPlate (see Chapter 10) can be viewed as attempts to put more emphasis on basic foods that are nutrient dense rather than calorie dense and on total amounts of foods per day rather than numbers of servings. The most current information is reflected in the information used to shape the 2015 DGA but stay tuned as the 2020 DGA will change (Health.Gov, 2018).

Adult diets are likely to be higher in total fat than the 30% of total calories recommended in the 2015 DGA and include a predominance of carbohydrates as added sugar and refined grains. Fruit and vegetable guidelines are not being met, although increases are being noted. Although chicken and fish servings have increased, animal sources outweigh plant-based protein sources. Health guidelines continue to move in the direction of increasing plant-based foods. Key nutrients that may be in short supply are calcium, magnesium, and potassium; the antioxidants vitamins A, C, and E; and vitamin D (USDHHS, 2018a). Accessing information building to the 2015 DGA (Scientific Report of the 2015 DGA Advisory Committee) will give a clearer picture (Health.Gov, 2018).

NUTRITIONAL SUPPLEMENTATION

A position of the AND (formerly the American Dietetic Association) is that the best nutritional strategy for promoting optimal health and reducing the risk of chronic disease is to choose a variety of nutrient-rich foods. Additional nutrients from fortified foods and supplements help people meet their nutritional needs as specified by science-based nutrition standards such as the DRI (AND, 2009a). In making this statement, the AND puts food first but leaves the door open for those

with specific nutrient needs, identified through assessment by a dietetic or health professional, to be nutritionally supplemented.

Traditionally, one thinks of vitamins and minerals, fiber, and protein as nutrient supplements, generally in a pill, capsule, or liquid form. The DRIs are the standards used with most adults. However, food fortification is another form of nutrient supplementation. The level of fortified foods (such as energy bars, sports drinks, smoothies, or ingredients for fortification) in the marketplace puts another layer of potential nutrient sources in the mix with traditional supplements. Less traditional supplements such as herbals and other natural dietary “enhancers” are added to the array of supplements available to consumers. Information continues to build on the safety of some of the ingredients used to fortify or supplement. Examples include the 2014 report on the safety of caffeine added to foods and supplements and the ongoing updates from the NIH, ODS, and National Center for Complementary and Integrative Health (IOM, 2014; NIH, 2016; NIH, NCCIH, 2018a).

Either because of choice, access, or health-related issues, Americans may not meet the dietary recommendations for promoting optimal health. Several segments of the adult population fall into high-risk groups who are unlikely to meet their nutrient needs because of life stage (e.g., pregnancy), alcohol or drug dependency, food insecurity, chronic illness, recovery from illness, or choosing a nutritionally restrictive diet or lifestyle. Other persons with special needs include those with food allergies or intolerances that eliminate major food groups, persons using prescription drugs or therapies that change the way the body uses nutrients, those with disabilities that limit their ability to enjoy a varied diet, and those who are just unable or unwilling because of time or energy to prepare or consume a nutritionally adequate diet. These adults potentially need a nutritional supplement (AND, 2009a, 2013b).

FUNCTIONAL FOODS

Articles and news reports have attributed many benefits to what are known as **functional foods**. In the 1980s the Japanese government created a class of foods they labeled as functional, meaning that they had health benefits beyond nutrition. Here in the United States the FDA has not yet defined functional foods, but the AND defines them as “whole foods along with fortified, enriched, or enhanced foods that have a potentially beneficial effect on health when consumed as part of a varied diet on a regular basis at effective levels based on significant standards of evidence.” Adults interested in attaining and maintaining wellness are frequently interested in altering dietary patterns or choosing these foods for added health benefits. The desire for fewer calories and multiple health benefits, especially when children are in the home, is driving the growth in the U.S. functional foods market. Sloan describes this drive for real-food solutions, for “healthy” foods as a reminder to consumers of the long-term value of staying healthy (Sloan, 2012). Eight out of ten Americans are making an effort to eat healthfully, and 42% are concerned about the nutrient content of the foods they buy. One result is an increase in sales of functional foods and beverages. Sloan notes that young adults, ages 18 to 24, are the top users of functional foods and beverages. This increase in sales of these foods and beverages is related to the search for healthier foods from familiar staples with better health profiles as well as options for individual nutrients (Sloan, 2012).

In a 2013 position paper on functional foods, the AND notes all food is functional at some level, but there is growing evidence of components in food beyond traditional nutrients (AND, 2013a). Examples of large classes of functional foods are conventional foods, such as whole grains, fruits, vegetables, and nuts, as well as modified foods like

sports drinks, bars, yogurt, cereal, and orange juice. These are examples of foods believed to have benefits beyond their usual nutrient value (AND, 2013a; IFIC, 2018). Functional foods can include whole foods as well as those that are fortified, enriched, or enhanced by the addition of food components or nutrients.

Providing this information to the segment of the adult population looking for ways to enhance health not only gains the adults' attention but also takes nutrition guidance to a higher level. Research continues to provide information on dietary patterns and components of foods that may have added benefits for health. Helping to lower blood cholesterol or control blood glucose, serving as an antioxidant or scavenger against harmful components, promoting a healthy gastrointestinal tract, or stimulating activity of detoxification

enzyme systems in the liver are examples of benefits being reported and researched for validity.

Phytochemicals or **phytonutrients** (from the Greek word *phyto*, meaning “plant”) are biologically active and naturally occurring chemical components in plant foods. In plants, phytochemicals act as natural defense systems for their host and offer protection against microbial invasions or infections. They also provide color, aroma, and flavor, with more than 2000 plant pigments identified. These include flavonoids, anthocyanins, and carotenoids. Functional foods have become a favorite topic of the consumer press, which often exaggerate the benefit of the food (see *Focus On: Chocolate: A Functional Food?*). As part of human consumption, phytonutrients can have antioxidant, detoxification, and antiinflammatory functions in the body.

FOCUS ON

Chocolate: A Functional Food?

Chocolate can be considered a healthy food, as long as it is eaten in moderation. White chocolate is generally the cocoa butter portion with added sugar and flavorings and does not possess the same health benefits as milk or dark chocolate. Some facts about chocolate are the following:

- Chocolate is a plant food, made from beans harvested from a cocoa tree. Once the beans are removed from a pod, they are fermented, dried, roasted, and then ground. This produces a liquid, which is pressed to separate the cocoa butter from the solids. The end result is a cake that is then ground to make cocoa powder.
- Cocoa butter contains saturated fat, but research indicates the effect on blood cholesterol is neutral and may even be positive. However, it is a calorie source.
- Chocolate is a source of flavonoids, naturally occurring compounds that serve as antioxidants. Known as polyphenols, these are the same antioxidants found in tea, red wine, and some fruits and vegetables. These compounds give chocolate its rich color as well as potential health benefits. Dark chocolate has the most flavonoids.
- It is believed flavonoids help the body repair damage to cells and may even provide a protective shield.

- Chocolate is also a source of plant sterols, B vitamins, magnesium, and potassium, all with potential heart-health benefits.
- Chocolate can potentially improve mood because cocoa is believed to have a positive effect on boosting endorphin and serotonin levels in the brain.
- There are some potential negatives along with the potential of an allergic reaction:
 - Cocoa is a source of oxalates. For some this can be a trigger for certain types of kidney stones.
 - Caffeine is present in chocolate with dark chocolate taking the lead and milk chocolate at about one third the amount of the dark chocolate. This is a stimulant with varying effects based on your health and the amount consumed.
 - Dark chocolate is a source of tyramine, also present in red wine, and some fermented and aged foods. Still under investigation but worth noting is the potential for triggering migraine headaches.
 - Chocolate is often in foods with excessive calories. Added sugar and fat in popular chocolate desserts, candies, and beverages bring to light the ongoing theme. Keep the portions real for your personal needs.

Soy is another example of a food with value beyond quality protein but like others, research is still being collected and evaluated. The potential health benefits of soy products or components of soy include the potential of reducing the risk for heart disease and certain types of cancer and reducing vasomotor symptoms (hot flashes) in menopausal females. Note that soy itself, as a plant, has no cholesterol and is a source of **isoflavones**, a **phytoestrogen** or plant estrogen. In 1999 the FDA approved a food label claim for soy, addressing its potential role in reducing the risk of heart disease. This was reevaluated in 2013 when FDA Model guidelines noted the following:

1. 25 grams of soy protein a day, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease.
2. Diets low in saturated fat and cholesterol that include 25 g of soy protein a day may reduce the risk of heart disease (FDA, 2018c).

The ACS concludes that cancer survivors may safely consume up to three servings daily (ACS, 2014; McCullough, 2012). Soy continues to be considered a quality protein with potential of added health benefits (NIH, NCCIH, 2016).

One cannot address dietary guidance without considering the issues of functional components and functional foods. Rather than isolating and promoting food components, current thinking supports the

emphasis on food as a package and as a first source for nutrients and potential enhancers. In the big picture it is the person's health status, lifestyle choices, and genetics that form the potential for wellness, but dietary enhancement is a tool that gains attention and helps the person move forward on the wellness continuum.

ADULT HEALTH NEXT STEPS

The objectives for this chapter are to introduce direction for the well adult. This is a segment of the population who already may be a candidate for MNT, but the intent is to focus on resources for prevention and wellness. A 2013 position of the AND, *The Role of Nutrition in Health Promotion and Chronic Disease Prevention*, was a rallying point. In this position the statement was made that primary prevention is the most affordable method to prevent chronic disease (AND, 2013b). Prevention strategies include MNT because the line between being “healthy” and being “well” relates to control, maintenance, and, for the adult, taking personal responsibility for setting a path as early as possible in the life cycle. However, an important strategy is selecting nutrient-dense foods, a point made in the 2015 DGA and emphasized in a 2016 practice paper of the AND (AND, 2016).

CLINICAL CASE STUDY

Aileen is a 28-year-old African American woman who lives in a suburb of Chicago with her husband and 12-year-old daughter. She is 5 ft, 10 in tall and currently weighs 165 pounds. In the past 2 years she has gained 10 pounds. At a recent neighborhood health fair at the YMCA, Aileen's blood glucose and blood pressure screening results were higher than they had been a year ago but were still in a good range. She has a family history of heart disease and diabetes and recognizes that her weight gain is an issue. Both she and her husband work full time and blending their schedules with that of their daughter is hectic. They have one car needed by her husband for work. Aileen travels mostly by bus and does all the cooking and shopping. They have a kitchen with a range, oven, microwave, and refrigerator/freezer. She describes her food shopping habits as chaotic and last minute, often stopping at the local convenience store since the distance to the nearest supermarket is 5 miles by car. They eat out (fast food or take-out) for most lunches and at least two dinners a week. They have no regular activity or exercise. As a family, they have the minimum health insurance with a large copayment; thus they do not have an ongoing health care routine.

Aileen made an appointment with a locally based health care source. She asked for dietary counseling and was asked to bring a 1-day food recall for the registered dietitian. She reported the following: breakfast: egg and sausage on a bagel, coffee; midmorning: low-fat snack bar from vending machine with coffee; lunch: double burger with cheese on a bun and large fries, ketchup, and extra pickles, diet soda; dinner: frozen dinner that included chicken, rice, and corn. She had an iceberg lettuce salad with diet ranch dressing "to add something green." Beverage was a diet soda. During the evening she had a dish of chocolate ice cream and sweet tea. She reports that in her coffee she likes two packets of sugar and some nondairy creamer.

Nutrition Diagnostic Statements

- Altered nutrition related laboratory values related to busy schedule, reduced access to a supermarket, consumption of high sodium and high glycemic convenience foods and recent weight gain as evidenced by elevated blood glucose and blood pressure.
- Physical inactivity related to time constraints and busy schedule as evidenced by report of no regular exercise in daily routine.

Nutrition Care Questions

1. What social, lifestyle, and nutrition triggers are likely to be identified by the dietitian?
2. What foods should Aileen consider including in her diet to build a prevention-related meal plan?
3. Plan a meal pattern and two sample meals that illustrate your recommendations, including at least one at-home and away-from-home breakfast, lunch, and dinner.

Nutrition in Aging

Janice L. Raymond, MS, RDN, CSG

Lindsey Callihan, MS, RDN, CSG

KEY TERMS

achlorhydria	gerontology	palliative care
activities of daily living (ADLs)	glaucoma	polypharmacy
age-related macular degeneration (AMD)	home- and community-based services (HCBS) waivers	pressure injury
Blue Zones	hospice care	presbyopia
cataract	hyposmia	quality of life
constipation	instrumental activities of daily living (IADLs)	Resident Assessment Instrument (RAI)
culture change in long-term care	long-term services and supports (LSS)	sarcopenia
Dining Practice Standards	Mini Nutrition Assessment (MNA)	sarcopenic obesity
dysgeusia	Minimum Data Set (MDS)	sedentary death syndrome (SeDS)
dysphagia	National Pressure Ulcer Advisory Panel (NPUAP)	senescence
food first		skilled nursing facility (SNF)
functionality		xerostomia
geriatrics		

THE OLDER POPULATION

In 2017 there were an estimated 962 million people age 60 or older in the world. This is 13% of the global population. Europe has the greatest percentage population age 60 and older at 25%. The number of older persons worldwide is projected to be 1.4 billion in 2030 and could rise to 3.1 billion in 2100 ([United Nations World Population Aging Report, 2017](#)). Population aging, now a global phenomenon, is no longer limited to developed, higher-income countries.

Today, one in seven Americans is age 65 or older. They are living longer, healthier, and more functionally fit lives than ever before. [Fig. 19.1](#) shows older adults involved in physical activities. Those born today can expect to live an average of 80 years. Women who reach age 65 can expect to live an additional 20.4 years, and men, 17.8 years. By the year 2050 the population older than age 65 will grow from approximately 44 million to 84 million, increasing from 14% to 21% of the population. The fastest-growing segment is those older than age 85, currently 6 million and increasing to 18 million in 2050. Members of minority groups also will increase from 21% to more than 39% of the older population ([Colby and Ortman, 2014](#); [Ortman et al, 2014](#)) ([Figs. 19.2 and 19.3](#)).

The year 2030 marks an important demographic turning point in U.S. history according to the U.S. Census Bureau's 2017 National

Population Projections. By 2030, all baby boomers will be older than age 65. This will expand the size of the older population so that one in every five residents will be retirement age.

A few years ago no state had more people older than age 65 than those younger than 18. Growth in the older-than-65 population will equal 3.5 times the U.S. growth as a whole. This demographic shift has enormous social, economic, and political implications ([Ortman et al, 2014](#)).

Women live longer than men. The older-than-65 female/male ratio is 129:100; it increases to 200:100 among those older than age 85. More than 71% of older men are married, whereas only 45% of older women are married ([Ortman et al, 2014](#)). Almost half (45%) of women over age 75 live alone; thus more men die married and most women die unmarried.

Classification

Everyone knows people older than themselves, but those considered “old” depends a lot on one’s own age. Today gray hair color, wrinkles, retirement, or age 65 no longer defines old. Yet qualifying as an “older adult” is based on the minimum eligibility age of 65 in many federal programs. The U.S. Census Bureau uses a stratified system to define this generation-spanning age group; those aged 65 to 74 are the young old; 75 to 84, old; and 85 or older, oldest old. Some consider today’s new old to be those in their 90s. The more than 100,000 centenarians alive today are no longer considered unique, and many of them still live independently (see *Focus On: Centenarians . . . Life in the Blue Zone*).

GERONTOLOGY, GERIATRICS, AND THE SPECTRUM OF AGING

Gerontology is the study of normal aging, including factors in biology, psychology, and sociology. **Geriatrics** is the study of the chronic diseases frequently associated with aging, including diagnosis and treatment. Although medical nutrition therapy commonly has been practiced in hospitals and long-term care facilities, nutrition services have moved out of hospitals and into homes and communities where the focus is on health promotion, risk reduction, and disease prevention.

NUTRITION IN HEALTH PROMOTION AND DISEASE PREVENTION

In aging adults, nutrition care is not limited to disease management or medical nutrition therapy but has broadened to have a stronger

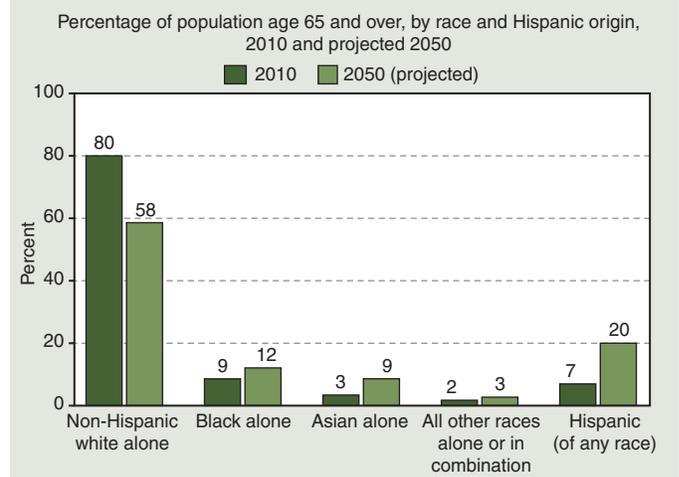

Fig. 19.3 Population age 65 and over, by race and Hispanic origin, 2010 and projected 2050. Note: The term non-Hispanic white alone is used to refer to people who reported being white and no other race and who are not Hispanic. The term black alone is used to refer to people who reported being black or African American and no other race, and the term Asian alone is used to refer to people who reported only Asian as their race. The use of single-race populations in this chart does not imply that this is the preferred method of presenting or analyzing data. The U.S. Census Bureau uses a variety of approaches. The race group "All other races alone or in combination" includes American Indian and Alaska Native alone; Native Hawaiian and other Pacific Islander alone; and all people who reported two or more races. Reference population: These data refer to the resident population. (U.S. Census Bureau: 2010 Census Summary File 1; Table 4. <http://www.census.gov/prod/cen2010/doc/sf1.pdf>, 2011.)

focus on healthy lifestyles and disease prevention. Without increased emphasis on better diets and more physical activity at all ages, health care expenditures will rise exorbitantly as the population ages. It is never too late to emphasize nutrition for health promotion and disease prevention. Older Americans, more than any other age group, want health and nutrition information and are willing to make changes to maintain their independence and quality of life. They often need help in improving self-care behaviors and they want to know how to eat healthier, exercise safely, and stay motivated.

Nutrition may include three types of preventive services. In primary prevention, the emphasis is on nutrition in health promotion and disease prevention. Pairing healthy eating with physical activity is equally important.

Secondary prevention involves risk reduction and slowing the progression of chronic nutrition-related diseases to maintain functionality and quality of life. Functionality as related to strength and mobility is perceived as a positive way to discuss fitness versus disability and dependence.

In tertiary prevention, care/case management and discharge planning often involve chewing and appetite problems, modified diets, and functional limitations. Complex cases often are influenced by nutrition issues that must be addressed; care managers can benefit from consulting with dietitians. In some circumstances dietitians are the case managers.

THEORIES ON AGING

Gerontologists study aging and have diverse theories about why the body ages. No single theory can fully explain the complex processes of aging (Park and Festini, 2017). A good theory integrates knowledge

FOCUS ON

Centenarians . . . Life in the Blue Zone

Centenarians are a growing segment of older adults in the United States and in other developed nations, including Japan. The worldwide estimate of centenarians is 450,000. The U.S. Census Bureau estimated for 2009 there were about 65,000 centenarians and that there will be more than 1 million by 2050. As with the aging population as a whole, women represent 85% of the long lived. A new group of individuals older than age 110, supercentenarians, have sufficient numbers to merit dedicated research.

What is known about extremely long-lived individuals? Centenarians generally have delays in functional decline. They also tend to either never develop a chronic disease or develop one late in life. Much has been written about longevity in the southern Japanese of Okinawa. The ongoing Okinawa Centenarian Study suggests that low caloric intake may produce fewer destructive free radicals. This intake plus an active lifestyle, natural ability to combat the stresses of life, and a genetic predisposition favor a healthy, functional, longer life.

The National Institute on Aging has identified communities around the world where people are living longer and living measurably better. They called these areas, where people reach the age of 100 at rates 10 times greater than in the United States, the **Blue Zones**. One such community is Okinawa. Others include the Nicoya Peninsula in Costa Rica, Ikaria in Greece, and Sardinia in Italy. Only one Blue Zone exists in the United States, the Loma Linda community in California. Residents of Loma Linda boast the longest life spans in America, living on average a decade longer than other Americans. These Blue Zone groups have been found to have common characteristics related to food: very little animal protein and four to six servings of fruits, vegetables, legumes, and nuts. However, eating wisely is only part of what seems to be a prescription for long life. The people of these communities don't smoke and make regular low-intensity exercise part of their daily routine (e.g., gardening, walking). They are people who can articulate their purpose in life, are spiritually fulfilled, and have strong social networks.

In the New England Centenarian Study, independent function to at least age 90 was identified as a predominant feature of those who live to 100 or more. Other important factors are that few centenarians are obese, they rarely smoke, and while alcohol is part of the traditional diet in all but the Loma Linda group, it is consumed in moderation or not at all. At least 50% of centenarians have first-degree relatives or grandparents who also achieved very old age, and many have exceptionally old siblings (Buettner and Skemp, 2016).

and tells how and why phenomena are related. Broadly, theories can be grouped into two categories: predetermined (genetic) and accumulated damage. A loss of efficiency comes about as some cells wear out, die, or are not replaced. Identification of the mechanisms that affect aging could lead to interventions that slow or alter aging. Most likely several theories explain the heterogeneity in older populations (Table 19.1).

PHYSIOLOGIC CHANGES

Aging is a normal biologic process. However, it involves some decline in physiologic function. Organs change with age. The rates of change differ among individuals and within organ systems. It is important to distinguish between normal changes of aging and changes caused by chronic diseases like heart disease, diabetes, and arthritis.

The human growth period draws to a close at about age 30, when senescence begins. **Senescence** is the organic process of growing older and displaying the effects of increased age. Disease and impaired

TABLE 19.1 Predetermination and Accumulated Damage Theories on Aging

Theory	Description
Predetermination: Built-in mechanism determines when aging begins and time of death	
Pacemaker theory	“Biologic clock” is set at birth, runs for a specified time, winds down with aging, and ends at death.
Genetic theory	Life span is determined by heredity.
Rate of living theory	Each living creature has a finite amount of a “vital substance,” and, when it is exhausted, the result is aging and death.
Oxygen metabolism theory	Animals with the highest metabolisms are likely to have the shortest life spans.
Immune system theory	Cells undergo a finite number of cell divisions that eventually cause deregulation of immune function, excessive inflammation, aging, and death.
Accumulated damage: Systemic breakdown over time	
Crosslink/glycosylation theory	With time, proteins, DNA and other structural molecules in the body make inappropriate attachments, or crosslinks, to each other, leading to decreased mobility, elasticity, and cell permeability.
Wear-and-tear theory	Years of damage to cells, tissues, and organs eventually take their toll, wearing them out and ultimately causing death.
Free radical theory	Accumulated, random damage caused by oxygen radicals slowly causes cells, tissues, and organs to stop functioning.
Somatic mutation theory	Genetic mutations caused by oxidizing radiation and other factors accumulate with age, causing cells to deteriorate and malfunction.
Telomere length	Telomeres protect and cap linear chromosome ends. Short telomeres have been associated with many age-related conditions.

DNA; Deoxyribonucleic acid.

function are not inevitable parts of aging. Nevertheless, certain systemic changes occur as part of growing older. These changes result in varying degrees of efficiency and functional decline. Factors such as genetics, illnesses, socioeconomic, and lifestyle determine how aging progresses for each person. Indeed, one's outward expression of age may or may not reflect one's chronologic age, and ageist stereotypes should be eliminated. The oldest woman to have finished a marathon was Gladys Burrill in 2012 who was 93—and she didn't start running marathons until her mid-80s. Jaring Timmerman began competitive swimming at 79 and broke records in 2014 at age 104.

Body Composition

Body composition changes with aging. Fat mass, visceral fat, and intermuscular fat increase, whereas lean muscle mass decreases (Santanasto et al, 2017). **Sarcopenia** is defined as age-related loss of skeletal muscle function and muscle mass. It is known to increase risk for falls and decrease quality of life. International clinical guidelines on the diagnosis and management of sarcopenia were recently published

(Dent et al, 2018). Included is a measurement tool that would standardize diagnosis of sarcopenia, something that has thus far not been agreed on. Also included is a recommendation for rapid screening using gait speed. Treatment recommendations for sarcopenia include the prescription of resistance-based physical activity, and a conditional recommendation for protein supplementation/a protein-rich diet. The proposed term “skeletal muscle function deficit” best describes the variety of muscular conditions that contribute to clinically meaningful mobility impairment (Correa-de-Araujo and Hadley, 2014). All losses are important because of the close connection between muscle mass and strength. By the fourth decade of life, evidence of sarcopenia is detectable, and the process accelerates after approximately age 75. Prevention strategies deserve emphasis because of the strong relationships of sarcopenia to functional decline, disability, hospitalization, institutionalization, and mortality (Litchford, 2014).

Sarcopenic obesity is the loss of lean muscle mass in older persons with excess adipose tissue. Together the excess weight and decreased muscle mass exponentially compound to further decrease physical activity, which in turn accelerates sarcopenia. An extremely sedentary lifestyle in obese persons is a major detractor from quality of life.

Sedentary lifestyle choices can lead to **sedentary death syndrome (SeDS)**, a phrase coined by the President’s Council on Sports, Fitness, and Nutrition. It describes the life-threatening health problems caused by a sedentary lifestyle. Sedentary lifestyle can be defined as a level of inactivity below the threshold of the beneficial health effects of regular physical activity or, more simply, burning fewer than 200 calories in physical activity per day.

Although no amount of physical activity can stop the biological aging process, there is evidence that exercise can minimize the physiologic effects of a sedentary lifestyle and increase the time a person remains active by limiting the development and progression of chronic disease. There is emerging evidence that suggests both psychological and cognitive benefits from regular exercise in older adults. According to the American College of Sports Medicine, the exercise prescription for older adults should include aerobic exercise, muscle strengthening exercise, and flexibility exercise. The Centers for Disease Control and Prevention (CDC) quantifies the amount of exercise older adults need and the National Institute on Aging (NIA) has a guide for physical activity (CDC, 2013; NIA, 2010).

A summary of the World Health Organization (WHO) recommendations for exercise for people age 65 years and older (Taylor, 2014) are as follows:

1. At least 150 min of moderate-intensity aerobic activity per week, or at least 75 min of vigorous-intensity aerobic activity or an equivalent combination.
2. Aerobic activity should be performed in bouts of at least 10 min duration.
3. For additional health benefits, undertake up to 300 min of moderate-intensity or 150 min of vigorous-intensity aerobic activity or an equivalent combination per week.
4. People with poor mobility should do balance exercises to prevent falls on 3 or more days.
5. Muscle-strengthening activities should be done on 2 or more days.
6. If older adults are unable to do the recommended amounts of physical activity due to health conditions, they should be as physically active as they are able.

Taste and Smell

Sensory losses affect people to varying degrees, at varying rates, and at different ages. Genetics, environment, and lifestyle are part of the decline in sensory competence. Age-related alterations to the sense of taste, smell, and touch can lead to poor appetite, limited food choices, and lower nutrient intake. Some **dysgeusia** (altered taste),

loss of taste, or **hyposmia** (decreased sense of smell) are attributable to aging. Thinning of epithelium and decline in the regeneration of olfactory receptor cells leads to dysfunction (Schiffman, 2009). Medications may play as big a role as aging in this population. Other causes include conditions such as Bell’s palsy, head injury, diabetes, liver or kidney disease, hypertension, neurologic conditions including Alzheimer’s disease and Parkinson’s disease, and zinc or niacin deficiency. Untreated mouth sores, tooth decay, poor dental or nasal hygiene, and cigarette smoking also can decrease these senses.

Because taste and smell sensation thresholds are higher, older adults may be tempted to overseason foods, especially to add more salt, which may have a negative effect in many older adults. Because taste and smell stimulate metabolic changes such as salivary, gastric acid, and pancreatic secretions and increases in plasma levels of insulin, decreased sensory stimulation may impair these metabolic processes as well.

Hearing and Eyesight

While hearing loss is not the only condition that impedes a caregiver’s ability to communicate with their patients, there is no question that the communication barriers it imposes are among the most impactful. For millions of older Americans, many of whom are among the oldest-old, hearing loss strips away the opportunity for clinicians and caregivers to share information simply by speaking. As hearing worsens, the exchange and flow of information slows to a trickle, and conversation and discussion simply stop. The consequences are known to be broadly negative for patients and caregivers alike.

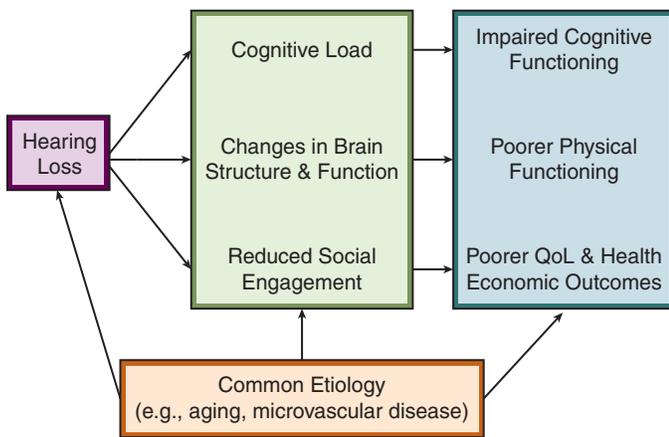

The WHO (March 2018) has estimated that 360 million people worldwide have hearing loss that is moderate or higher in severity (what the WHO refers to as “disabling” hearing loss). In the United States, an estimated 40 million people (Lin et al, 2011) have bilateral hearing loss that is severe enough to constantly inhibit conversation. Hearing loss is exceedingly more prevalent among the elderly. There is widespread consensus the prevalence will increase as the population ages. The most common cause is the aging process. So-called age-related loss affects both ears equally, increases in severity over time, and is not preventable. Other causes include loud noise (noise-induced hearing loss), drug-induced loss (there are a number of ototoxic medications), hearing loss that has hereditary roots, and loss that is disease and illness-related (National Institute on Deafness and Other Communicative Disorders, National Institutes of Health, 2013a).

Levels of severity. Hearing loss is typically defined using one of four levels of severity. Individuals with mild loss have difficulty hearing normal conversation, especially in environments with background noise. As the hearing loss progresses to the moderate level, speech-sounds are increasingly difficult to hear with any clarity. In the absence of hearing aids, words have to be spoken in a raised voice at a close distance to be heard. For those with severe hearing loss, speech becomes largely unintelligible and even the most sophisticated hearing aids grow ineffective. Those who have profound loss are functionally deaf and rely mainly on sign language and lip reading to converse with others. As a condition that typically worsens with age, the higher levels of loss are more prevalent among those who have reached their 70s or 80s.

Impact. There is substantial evidence that higher levels of hearing loss have a broadly detrimental impact on the individual’s physical and cognitive functioning, psychological health, self-esteem, and overall satisfaction with their quality of life. Recent research has shown an association between hearing loss and a decline in both cognitive and physical functioning. A study at Johns Hopkins University (Chien and Lin, 2012) found that older adults with hearing loss experience a rate of decline in thinking and in memory that is 30% to 40% faster than among those with normal hearing. Other studies have shown that hearing loss is associated with dementia, physical decline, and an

increased frequency of falls. Studies reporting on the alienating effects of hearing loss have found that it is a source of loneliness, isolation, depression, anxiety, and paranoia, and that it leads to marked decrease in satisfaction with family life. Hearing loss causes the individual to feel embarrassed, upset, lonely, and withdrawn; and they may appear confused, uncaring, and difficult. Studies have shown that hearing loss causes feelings of dependence, frustration, and guilt, that it induces behaviors that include bluffing and being demanding, and that it often results in decreased self-esteem (Ciorba, 2012).

Hearing loss by gender. Researchers at Johns Hopkins have reported that the prevalence of hearing loss is significantly higher among males. However, while the prevalence among males is especially pronounced in the younger age groups, it diminishes as age increases. In all, males account for 70% of those with hearing loss between the ages of 30 and 69, but only 51% among those in their 70s, and only 38% among those over the age of 80.

Treatment. Apart from surgical implants in the most severe cases, hearing aids are the only form of treatment. But while the technology has advanced significantly in recent years, adoption and use remains extremely low.

Box 19.1 illustrates how speech is distorted by hearing loss, in this case the loss that occurs (and worsens) as we age (Presbycusis).

Hearing loss can be difficult to spot. It is easy to imagine that a patient’s hearing loss is easy to identify and detect. As it turns out, that is often not the case. It is not uncommon, for instance, for patients to hide their hearing loss by engaging in a number of “bluffing” behaviors that can give caregivers a false sense of having communicated effectively.

If a patient has hearing loss, the caregiver’s “speaking behaviors” can help. When working with an elderly patient population, the chances are very high of encountering patients with varying levels of hearing loss. One of the findings of the National Council on Disability was that most clinicians and caregivers do not have a practical understanding of how to communicate effectively with patients who have hearing loss, and they often do not appreciate the medical necessity of employing appropriate methods of communication to ensure the effectiveness of their care.

In all cases, it is important to keep in mind that correct speaking behaviors should be employed regardless of whether the patient is using a hearing aid or an assistive listening device.

KEY SPEAKING BEHAVIORS

- Stand in front of the patient and as near to them as possible.
- Make sure the patient can see your mouth as you talk.
- Speak clearly, slowly, and “mouth” your words more than you would with patients who have normal hearing.
- Speak up and ask the patient if a different volume level would be helpful (in some cases talking louder not only doesn’t help, but can make matters worse).
- Look directly at the patient (don’t look down, at a computer screen, etc.).
- Choose your words more carefully (esoteric words will be harder for the patient to understand).
- Be patient—you may be asked to repeat yourself (you may be asked to do so repeatedly).

While it is tempting to yell to be heard, it is usually not a good idea. Yelling can be irritating and raises concerns about patient privacy and often does not make speech any easier to understand. If speech sounds garbled, yelling only makes the garbled speech louder, not clearer.

For some patients, the only recourse will be to write messages down for them to read. Whiteboards are used most often and although this is a cumbersome process requiring patience, it is often the only solution.

Age-related macular degeneration (AMD) is a disease of the retina that affects central vision and can lead to blindness in older people. AMD is the leading cause of legal blindness in Americans age 65 and older. It affects more than 1.75 million individuals in the United States. It is expected to increase to more than 5 million by 2050 (American Optometric Association [AOA], 2014). Smoking, race (it is more common in Caucasians), and family history are known risk factors (Chew et al, 2014; National Eye Institute, 2014). As the population ages, AMD is becoming a more significant public health problem. AMD occurs when the macula, the center part of the retina, degrades. The result is central vision loss. The macular pigment is composed of two chemicals, lutein and zeaxanthin. A diet rich in fruits and vegetables may help delay or prevent the development of AMD. Micronutrition supplementation often is used in the treatment of AMD (Aslam et al, 2014; Korobelnik, 2017).

Presbyopia is a loss of elasticity in the crystalline lens that causes an inability to focus clearly at close distances and results in the need for reading glasses. This becomes apparent around the fourth decade of

BOX 19.1 Missing Sounds by Hearing Loss Severity

Level of Hearing Loss	Spoken Sentence	Missing Sounds
Normal Hearing	I am your dietitian and I will be helping you manage your congestive heart failure with small, manageable dietary changes.	
Mild	I am your dietitian and I will be helping you manage your congestive heart failure with small, manageable dietary changes.	K, f, s, th
Moderate	I am your dietitian and I will be helping you manage your congestive heart failure with small, manageable dietary changes.	Above plus ch, p, h, g, sh
Severe	my u d e t t n d w e e n y u m n e y u c n e t v e t u e w m, m n e e d e t y n e	Above plus i, o, a, r, b, l, v

life (AOA, 2014). As it worsens, poor vision interferes with shopping, cooking, and eating.

Glaucoma is damage to the optic nerve resulting from high pressure in the eye. It is the second most common cause of vision loss, affecting approximately 3 million Americans. Hypertension, diabetes, and cardiovascular disease (CVD) increase the risk of glaucoma.

A **cataract** is a clouding of the lens of the eye. Approximately half of Americans 65 and older have some degree of clouding of the lens. The most common treatment is surgery; the clouded lens is removed and replaced with a permanent prosthetic lens. A diet high in beta carotene, selenium, lutein, omega-3 fat, and vitamins C and E may delay cataract development (AOA, 2014). Studies show that a high sodium intake may increase risk of cataract development. Ultraviolet (UV) radiation exposure is related directly to 5% of worldwide cataracts. When the UV index is 3 and above, protective sunglasses are recommended.

Immunocompetence

Age-related alterations in the immune system include both cellular and serologic changes that cause dysfunction in the response to foreign and self-antigens. Immune response is slower and less efficient. The mechanisms of age-related changes in immune function are not fully understood but likely depend on genetics, environmental factors, and lifestyle choices (Keenan, 2018). Maintaining good nutritional status promotes good immune function.

Oral

Diet and nutrition can be compromised by poor oral health (see Chapter 24). Tooth loss, use of dentures, and **xerostomia** (dry mouth) can lead to difficulties in chewing and swallowing. Decreases in taste sensation and saliva production make eating less pleasurable and more difficult. Oral diseases and conditions are common among people who grew up without the benefit of community water fluoridation and other fluoride products. However, the percentage of Americans age 65 and older who are missing all of their natural teeth (edentulous) is falling. Missing, loose, or decayed teeth or poor-fitting, painful dentures are common problems that make it difficult to eat some foods. People with these mouth problems often prefer soft, easily chewed foods and avoid some nutritionally dense options such as whole grains, fresh fruits and vegetables, and meats.

The nutrition-related consequences of **polypharmacy**, taking five or more medications or over-the-counter drugs daily, are significant. More than 400 commonly used medications can cause dry mouth. Preparing foods that are moisture-rich such as hearty soups and stews, adding sauces, and pureeing and chopping foods can make meals easier to eat. In addition, those with poor oral health may benefit from fortified foods with increased nutrient density (see *Focus On: Food First!*).

Gastrointestinal

Some gastrointestinal (GI) changes are considered to be normal consequences of aging though some changes can be attributed to other clinical causes and should be evaluated (Box 19.2). GI changes can negatively affect a person's nutrient intake, starting in the mouth. As a normal consequence of aging, taste and smell changes occur in the older adult including decreased ability to taste salt, bitter, sweet, and sour. Additionally, changes in salivation due to natural aging or medication side effects can further alter taste sensations and cause challenges for older adults.

Age- and disease-related changes in swallow function, including reduction of oral and esophageal muscle mass and connective tissue elasticity, can cause delay in the swallow processes of older adults. Increased oropharyngeal phase of swallowing (see Chapter 39),

BOX 19.2 Gastrointestinal (GI) Changes with Aging

Head: Decreased velocity of neuronal conduction to GI tract, decreased hunger sensations

Nose/Mouth: Decreased taste, smell, changes in dentition, decreased saliva

Neck: Increased oropharyngeal phase, delayed opening of esophageal sphincter, decreased peristaltic pressure in esophagus

Stomach: Increased and more rapid satiety, reduced peristalsis and gastric contractile force increase in gastric pH

Intestines: Decreased absorption of carbohydrate, protein, triglyceride, folate, B₁₂, D, calcium; increased absorption of vitamins A and C, cholesterol

Lower intestines: Decreased rectal wall elasticity, decreased colonic motility, constipation

delayed opening of the esophageal sphincter, and decreased peristaltic pressure in the esophagus can all contribute to challenges in functional swallow, which may threaten adequate nutrition and make one more susceptible to choking or aspiration. **Dysphagia**, a dysfunction in swallowing, commonly is associated with neurologic diseases and dementia. It increases the risk for aspiration pneumonia, an infection caused by food or fluids entering the lungs (see Chapter 33). Thickened liquids and texture-modified foods can help people with dysphagia eat safely (see Appendix 20).

Gastric changes also can occur. Early satiety due to age-related changes in the stomach in combination with impaired gastric mucosal function leads to an inability to resist damage and can result in ulcers, cancer, and infections. Gastritis causes inflammation and pain, delayed gastric emptying, and discomfort. These affect the bioavailability of nutrients such as calcium, B₁₂, and zinc and increase the risk of developing a chronic deficiency disease.

Achlorhydria is the insufficient production of stomach acid. Sufficient stomach acid and intrinsic factor are required for the absorption of vitamin B₁₂. Although substantial amounts are stored in the liver, B₁₂ deficiency does occur. Symptoms can often be misdiagnosed because they mimic Alzheimer's disease or other chronic conditions and include extreme fatigue, dementia, confusion, and tingling and weakness in the arms and legs (see Chapter 39). It has become common practice to use calcium carbonate antacids as a way to supplement calcium intake, though this is contraindicated in the elderly who are already at risk for inadequate gastric acid.

Constipation is defined as having fewer bowel movements than usual, having difficulty or excessive straining at stool, painful bowel movements, hard stool, or incomplete emptying of the bowel. It is one of the most common disorders in the U.S. population, and its prevalence increases with age. Primary causes include insufficient fluids, lack of physical activity, and low intake of dietary fiber. Studies have also shown that distinct physiologic changes affecting colonic motility occur in older people. They include myenteric dysfunction, increased collagen deposits in the left colon, reduced inhibitory nerve input to the colon's muscle layer, and increased binding of plasma endorphins to intestinal receptors (see Chapter 27).

Diminished anal sphincter pressure or degeneration of the internal anal sphincter and loss of rectal wall elasticity are age-related changes. Constipation also is caused by some medications commonly used in older people such as narcotics and antidepressants that actually slow intestinal transit. Diuretics can cause decreased stool moisture, another contributing factor in constipation.

The incidence of diverticulosis increases with age. Half of the population older than age 60 develop it, but only 20% of them have clinical manifestations. The most common problems with diverticular disease are lower abdominal pain and diarrhea (see Chapter 27).

Each of these changes in the GI could have substantial impact on the overall nutrition of the older adult as limitations in ability to consume adequate food quantity coupled with decreased nutrient absorption can result in undernutrition.

Cardiovascular

CVD, including heart disease and stroke, is the leading cause of death in all genders in all racial and ethnic groups and is not necessarily a disease of aging. CVD age-related changes are extremely variable and are affected by environmental influences such as smoking, exercise, and diet. Changes can include decreased arterial wall compliance, decreased maximum heart rate, decreased responsiveness to beta-adrenergic stimuli, increased left ventricle muscle mass, and slowed ventricular relaxation. Often the end result of hypertension and artery disease is chronic heart failure. One in nine hospital admissions in the United States include the diagnosis of heart failure. A low-sodium diet and fluid restriction are commonly prescribed for this condition. These diet restrictions in conjunction with other side effects of heart failure often lead to decreased nutrient consumption. See Chapter 32 for discussion of the multifaceted approach required to manage CVD in older adults.

Renal

Age-related changes in renal function vary tremendously. Some older adults experience little change, whereas others can have devastating, life-threatening change. On average glomerular filtration rate, measured in creatinine clearance rates, declines by approximately 8 to 10 mL/min/1.73m² per decade after age 30 to 35. The resulting increase in serum creatinine concentrations should be considered when determining medication dosages. The progressive decline in renal function can lead to an inability to excrete concentrated or dilute urine, a delayed response to sodium deprivation or a sodium load, and delayed response to an acid load. Renal function is also affected by dehydration, diuretic use, and medications, especially antibiotics (see Chapter 34).

Neurologic

There can be significant age-related declines in neurologic processes. Cognition, steadiness, reaction time, coordination, gait, sensations, and **activities of daily living (ADLs)** (toileting, bathing, eating, dressing) often decline with age, but the velocity of the decline varies greatly from one individual to another and is dependent on disease as much as on aging. On average, the brain loses 5% to 10% of its weight between the ages of 20 and 90, but most, if not all, neurons are functional until death unless a specific pathologic condition is present (Galvin and Sadowsky, 2012).

It is important to make the distinction between normal, age-related decline and impairment from conditions such as dementia, a disease process (Galvin and Sadowsky, 2012). Memory difficulties do not necessarily indicate dementia, Alzheimer's disease, Parkinson's disease, or any mental disorder (see Chapters 39 and 40). Many changes in memory can be attributed to environmental factors, including stress, chemical exposure, and inadequate food and fluid, rather than to physiologic processes. Urinary tract infections are associated with changes in cognition that mimic dementia but are reversible with treatment (Beveridge et al, 2011). However, even mild cognitive impairment may affect eating, chewing, and swallowing, thus increasing the risk of malnutrition (Lopes da Silva et al, 2014). The greatest risk factor for developing dementia is in fact advanced age.

Pressure Injuries

Pressure injuries, formerly called pressure sores and before that, bedsores or decubitus ulcers, develop from continuous pressure that impedes capillary blood flow to skin and underlying tissue. Several factors contribute to the formation of pressure injuries, but impaired mobility, poor circulation, obesity, and urinary incontinence are key.

Older adults with neurologic problems, those heavily sedated, and those with dementia are often unable to shift positions to alleviate pressure. Paralysis, incontinence, sensory losses, and rigidity can contribute to the problem. Notably malnutrition and undernutrition (inadequate energy intake) set the stage for its development and can delay wound healing. The escalating chronic nature of pressure injury in nonambulatory or sedentary individuals requires vigilant attention to nutrition.

The National Pressure Injury Advisory Panel (NPIAP), formerly National Pressure Ulcer Advisory Panel (NPUAP), is an independent not-for-profit professional organization dedicated to the prevention and management of pressure injuries. The NPIAP Board of Directors is composed of leading multidisciplinary experts who share a commitment to the prevention and management of pressure injuries.

The mission of the National Pressure Injury Advisory Panel (NPIAP) is to provide interprofessional leadership to improve patient outcomes in pressure injury prevention and management through education, public policy and research. NPIAP provides vital publications for medical, nursing and nutrition professionals working in all healthcare settings.

The 2019 *International Clinical Practice Guideline for the Prevention and Treatment of Pressure Injuries (CPG)* presents recommendations and summarizes the supporting evidence for pressure injury prevention and treatment. The new edition was developed as a four-year collaboration between the National Pressure Injury Advisory Panel (NPIAP), the European Pressure Ulcer Advisory Panel (EPUAP) and the Pan Pacific Pressure Injury Alliance (PPPIA). It provides a detailed analysis and discussion of available research, critical evaluation of the assumptions and knowledge in the field, recommendations for clinical practice, important implementation considerations, a description of the methodology used to develop the guideline, and acknowledgment of the many experts formally involved in the development process. The guideline may be purchased at www.guidelinesales.com.

Several classification systems describe pressure injuries. The six stages of injury, based on the depth of the sore and level of tissue involvement, are described in Table 19.2. As wound nutrition tends to equal whole-body nutrition, coordinated efforts of a multidisciplinary treatment team are important. The benefits of specific levels of energy (30-35 kcal/kg) and protein (1.25-1.5 g/kg) for prevention of pressure injuries in patients at risk of malnutrition recommended in the previous guidelines are now considered inconclusive. The 2019 guidelines focus on individualized assessment by the RDN rather than standardized prescriptions. However the recommendation above for calories and protein remain for individuals with existing pressure injuries. Additionally, a high calorie, high protein supplement is recommended for those with a pressure injury who are malnourished and unable to meet their needs through diet alone. Recommendations for a protein supplement high in arginine, zinc and antioxidants was included for stage II, III and IV pressure injuries (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel and Pan Pacific Pressure Injury Alliance, 2019).

QUALITY OF LIFE

Quality of life is a general sense of happiness and satisfaction with one's life and environment. Health-related quality of life is the personal sense of physical and mental health and the ability to react to factors in the physical and social environments. To assess health-related quality of life, common measures and scales, either general or disease-specific, can be used. Because older age often is associated with health problems and decrease in functionality, quality-of-life issues become relevant.

Depression

Psychological changes often manifest as depression, and its extent can vary widely from person to person. Among older persons depression

TABLE 19.2 Pressure Injury Stages**Deep Tissue Injury**

Deep Tissue Pressure Injury: Persistent nonblanchable deep red, maroon, or purple discoloration

Intact or nonintact skin with localized area of persistent nonblanchable deep red, maroon, or purple discoloration or epidermal separation revealing a dark wound bed or blood-filled blister. Pain and temperature change often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structures are visible, this indicates a full thickness pressure injury (unstageable, stage 3 or stage 4). Do not use Deep Tissue Pressure Injury (DTPI) to describe vascular, traumatic, neuropathic, or dermatologic conditions.

Stage 1

Stage 1 Pressure Injury: Nonblanchable erythema of intact skin

Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury, heralding sign of risk.

Stage 2

Stage 2 Pressure Injury: Partial-thickness skin loss with exposed dermis

Partial-thickness loss of skin with exposed dermis. The wound bed is viable, pink or red, moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture associated skin damage (MASD) including incontinence associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive related skin injury (MARS), or traumatic wounds (skin tears, burns, abrasions).

Stage 3

Stage 3 Pressure Injury: Full-thickness skin loss

Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. Slough and/or eschar may be visible. The depth of tissue damage varies by anatomic location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and/or bone are not exposed. If slough or eschar obscures the extent of tissue loss, this is an unstageable pressure injury.

Stage 4

Stage 4 Pressure Injury: Full-thickness skin and tissue loss

Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining, and/or tunneling often occur. Depth varies by anatomic location. If slough or eschar obscures the extent of tissue loss this is an unstageable pressure injury.

Unstageable

Unstageable Pressure Injury: Obscured full-thickness skin and tissue loss

Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a stage 3 or stage 4 pressure injury will be revealed. Stable eschar (i.e., dry, adherent, intact without erythema, or fluctuance) on the heel or ischemic limb should not be softened or removed.

National Pressure Ulcer Advisory Panel (NPUAP) announces a change in terminology from pressure ulcer to pressure injury and updates the stages of pressure injury. April 2016.

often is caused by other conditions such as heart disease, stroke, diabetes, cancer, grief, or stress. Depression in older people frequently is undiagnosed or misdiagnosed because symptoms are confused with other medical illnesses. Untreated depression can have serious side effects for older adults. It diminishes the pleasures of living, including eating; it can exacerbate other medical conditions; and it can compromise immune function. Depression is associated with decreased appetite, weight loss, and fatigue. Nutritional care plays an important role in addressing this condition (see Chapter 40). Providing nutrient- and calorie-dense foods, additional beverages, texture-modified foods, and favorite foods at times when people are most likely to eat the greatest quantity can be very effective. In that comorbidities lead to polypharmacy and concern regarding drug-drug interactions, providers may choose to omit antidepressants, which leaves the depression untreated.

Given the untoward consequences of unintentional weight loss with aging and the lack of Food and Drug Administration–approved

medications for appetite stimulation in older adults, food and nutritional interventions along with the treatment of underlying conditions that contribute to weight loss, such as poor dentition, deserve greater attention. One antidepressant, mirtazapine (Remeron), has helped increase appetite and weight gain in depressed elderly patients. With appropriate monitoring for side effects, mirtazapine may be a drug of choice for older persons experiencing weight loss and depression (Rudolph, 2009) and could potentially decrease gastroparesis, nausea, and vomiting (Malamood et al, 2017).

Food and nutrition contribute to one's physiologic, psychological, and social quality of life (Raymond, 2019). A measure of nutrition-related quality of life has been proposed to document quality-of-life outcomes for individuals receiving medical nutrition therapy. Effective strategies to improve eating and thereby improve nursing home residents' quality of life are well established but could be more widely implemented (Bernstein and Munoz, 2012) (see *New Directions: Culture Change*).

NEW DIRECTIONS

Culture Change

Culture Change in Long-Term Care

The Pioneer Network was formed in 1997 by a small group of prominent professionals (including dietitians) working in long-term care to advocate for person-directed care. This group called for a radical change in the culture of aging so that when our grandparents, parents—and ultimately we—go to a nursing home or other community-based setting, it is to thrive, not to decline. This movement, away from institutional provider-driven models to more humane consumer-driven models that embrace flexibility and self-determination, has come to be known as the *culture change movement*. The belief is that the quality of life and living for older Americans is rooted in a supportive community and cemented by relationships that respect each individual regardless of age, medical condition, or limitations.

The mission of the Pioneer Network is to:

- Create communication, networking, and learning opportunities
- Build and support relationships and community
- Identify and promote transformations in practice, services, public policy, and research
- Develop and provide access to resources and leadership

Values and Principles

- Know each person.
- Each person can and does make a difference.
- Relationship is the fundamental building block of a transformed culture.
- Respond to spirit, as well as mind and body.
- Risk-taking is a normal part of life.
- Put person before task.
- All elders are entitled to self-determination wherever they live.
- Community is the antidote to institutionalization.
- Do unto others as you would have them do unto you.
- Promote the growth and development of all.
- Shape and use the potential of the environment in all its aspects: physical, organizational, psycho/social/spiritual.
- Practice self-examination, searching for new creativity and opportunities for doing better.
- Recognize that culture change and transformation are not destinations but a journey, always a work in progress.

Functionality

Functionality and functional status are terms used to describe physical abilities and limitations in, for example, ambulation. **Functionality**, the ability to perform self-care, self-maintenance, and physical activities, correlates with independence and quality of life. Disability rates among older adults are declining, but the actual number considered disabled is increasing as the size of the aging population grows. Limitations in ADLs (toileting, bathing, eating, dressing) and **instrumental activities of daily living (IADLs)** such as managing money, shopping, telephone use, travel and transportation, house-keeping, preparing meals, taking medications correctly, and other individual self-performance skills needed in everyday life, are used to monitor physical function (*Federal Interagency Forum on Aging-Related Statistics, 2012*).

Many nutrition-related diseases affect functional status in older individuals. Inadequate nutrient intake may hasten loss of muscle mass and strength, which can have a negative effect on performing ADLs. Among the older adults who have one or more nutrition-related chronic diseases, impaired physical function may cause greater disability, with increased morbidity, nursing home admissions, or death.

Frailty and Failure to Thrive

The four syndromes known to be predictive of adverse outcomes in older adults that are prevalent in patients with frailty or “geriatric failure to thrive” include impaired physical functioning, malnutrition, depression, and cognitive impairment. Symptoms include weight loss, decreased appetite, poor nutrition, dehydration, inactivity, and impaired immune function. Interventions should be directed at easily remediable contributors in the hope of improving overall functional status. Optimal management requires a multidisciplinary, multifaceted approach. Occupational therapists and speech therapists are essential to comprehensive care management. Nutrition interventions, especially those rectifying protein-energy malnutrition, are essential but often difficult to implement in an older person who is disinterested in eating. Because overall diet quality has been shown to be associated inversely with prevalent and future frailty status in a large cohort of community-living older men, more attention to the total dietary intakes when advancing age is critical (*Galvin and Sadowsky, 2012*). Liberalization of overly restrictive diet prescriptions is often key to improving calorie intake and dietary quality (*Raymond, 2019*). It is important to recognize when failure to thrive is actually normal end of life. Spiritual support is an important component of the care.

Weight Maintenance

Obesity

The prevalence of obesity in all ages has increased during the past 25 years in the United States; older adults are no exception. Obesity rates are greater among those ages 65 to 74 than among those age 75 and older. Obesity is a major cause of preventable disease and premature death. Both are linked to increased risk of coronary heart disease, type 2 diabetes, endometrial, colon, postmenopausal breast, and other cancers, asthma and other respiratory problems, osteoarthritis, and disability. Obesity causes a progressive decline in physical function, which may lead to increased frailty. Overweight and obesity can lead to a decline in IADLs.

Weight loss therapy that maintains muscle and bone mass is recommended for obese older adults because it improves physical function and quality of life and reduces the multiple medical complications associated with obesity. Weight maintenance, not weight loss, should be the goal in the very old because extra weight is actually a benefit. Normal BMI standards are not appropriate for the very old since they have not been validated in this population.

Weight loss of no more than 10% of total body weight over 6 months should be the initial goal in those who are appropriate for weight intervention. Mild calorie restriction and increased activity should be encouraged (see Chapter 20).

Having a higher body weight after age 70 may be health protective. A study reviewed data from two long-term studies and found that adults who were overweight averaged a 13% lower risk of death from any cause over 10 years, compared with those who were in the optimal BMI range (*Flicker et al, 2010*). Those who were underweight were 76% more likely to die, although the obese had the same mortality risk as those of within the optimal BMI range. The researchers concluded that the body mass index (BMI) thresholds for overweight and obese may be overly restrictive for older adults. Notably, the researchers also found that being sedentary increased the risk of death in men by 28%; in women, the risk was doubled.

Underweight and Malnutrition

The actual prevalence of underweight among older adults is low; women older than age 65 are three times as likely as their male

counterparts to be underweight (Winter et al, 2014). However, many older adults are at risk for undernutrition and malnutrition (Federal Interagency Forum on Aging-Related Statistics, 2012). Among those hospitalized, 40% to 60% are malnourished or at risk for malnutrition, 40% to 85% of nursing home residents have malnutrition, and 20% to 60% of home care patients are malnourished. Many community-residing older persons consume fewer than 1000 kcal/day, an amount not adequate to maintain good nutrition. Some causes of undernutrition include medications, depression, decreased sense of taste or smell, poor oral health, chronic diseases, dysphagia, and other physical problems that make eating difficult. Social causes may include living alone, inadequate income, lack of transportation, and limitations in shopping for and preparing food.

Health care professionals frequently overlook protein-energy malnutrition (PEM). The physiologic changes of aging, as well as changes in living conditions and income, contribute to the problem. Symptoms of PEM often are attributed to other conditions, leading to misdiagnosis. Some common symptoms are confusion, fatigue, and weakness. Older adults with low incomes, who have difficulty chewing and swallowing meat, who smoke, or who engage in little or no physical activity are at increased risk of developing PEM.

Strategies to decrease PEM include increased caloric and protein intake. Strategies to improve intake in a long-term care community should be individualized based on the specific situation. Nutrition risk screening is an important first step (see Chapter 4).

In community settings older adults should be encouraged to eat energy-dense and high-protein foods. Federal food and nutrition services are also available for the many who reside at home (see sections below and *Focus On: Food First!*). Diets should be individualized rather than restricted to offer more choices and honor personal preference (Dorner and Friedrich, 2018). Simple, practical approaches, such as adding gravies and creams, can increase calories and soften foods for easier chewing.

FOCUS ON

Food First!

There are many reasons for practitioners to consider changing from the use of commercially manufactured nutritional supplements to nutrient-dense real food. Although commercial nutritional supplements are convenient to use and provide high calories and high protein, people like to eat food and drink fluids that taste good, provide a variety of flavors, and are familiar to them. Food is more than a can of milk protein with added vitamins and minerals, it is culture, tradition, and part of life celebrations. The smell of food and appearance on a plate is part of the overall eating experience.

Fortified foods at meals and snack time in lieu of commercially prepared supplements can satisfy the most demanding palate because they can be flexible and individualized. Virtually any food can be calorie enhanced; many can be protein enhanced.

Fortified food programs have been known by a variety of names: Every Bite Counts, Nutrition Intervention Program, Enhanced Food Program, Super Foods, or Food Fortification Program. Today, thanks to the Dining Practice Standards published in 2011 and adopted by the Centers for Medicare and Medicaid, **Food First!** is the term of choice for this approach. Traditionally, fortified food programs have focused on adding calories and protein to a couple of foods on the menu each day. For example, cream is added to hot cereal and powdered milk is added to milk (double-strength milk). This approach can lead to lack of variety and food fatigue. A program approach to fortifying food will provide more flexibility and ultimately be more successful.

Digna Cassens, MHA, RDN

Modified from www.flavorfulfortifiedfood.com.

When difficulties meeting nutritional needs arise in the older adult, there may be a question as to the benefits of placing a feeding tube and administering artificial nutrition. Though this can be an option for some older adults with significant swallowing difficulties who are cognitively intact, it is the position of the American Geriatrics Society (2014) that feeding tubes are not recommended for adults with advanced dementia. In older adults with advanced dementia, feeding tubes have been associated with increased agitation, use of chemical and physical restraints, tube-related complications including hospital visits, risk of aspiration, and greater likelihood of new pressure injury development. For those with advanced dementia, it is recommended that close attention be paid to assistance at meals, individual-centered approaches to eating and should include a focus on altering the environment to maximize oral intake for the older adult with advanced dementia.

NUTRITION SCREENING AND ASSESSMENT

Simple and easy-to-use nutrition screening tools have been validated (Skipper et al, 2012). However, the physical and metabolic changes of aging can yield inaccurate results. Examples are anthropometric measurements: height, weight, and BMI. A meta-analysis of BMI and all-cause mortality concluded that being overweight was not associated with an increased risk of mortality in older populations. The mortality risk increased in underweight older people, those with a BMI of less than 23 (Winter et al, 2014).

With aging, fat mass increases and height decreases as a result of vertebral compression. An accurate height measure may be difficult in those unable to stand up straight, the bed bound, those with spinal deformations such as a dowager's hump, and those with osteoporosis. Measuring arm span or knee height may give more accurate measurements (see Appendix 11). BMIs based on questionable heights are inaccurate and result in misdiagnosis of malnutrition. Clinical judgment is needed for accuracy.

The **Mini Nutritional Assessment (MNA)** includes two forms: a screening Short Form (MNA-SF) and the full assessment (Kaiser et al, 2009). The validated MNA-SF is the most widely used screening method to identify malnutrition in noninstitutionalized older adults (see Chapter 4). It includes six questions and a BMI evaluation, or a calf circumference if a BMI is not possible. The MNA-SF is being used as a screening assessment tool in long-term care and is especially useful in the short stay units.

NUTRITION NEEDS

Many older adults have special nutrient requirements because aging affects absorption, utilization, and excretion of nutrients (Bernstein and Munoz, 2012). The dietary reference intakes (DRIs) separate the cohort of people age 50 and older into two groups, ages 50 to 70 and 71 and older. The current U.S. Dietary Guidelines are for adults in general and can be found in Chapter 10. They emphasize intake of whole grains, fruit and vegetables, legumes, nuts, and low-fat dairy and suggest minimizing intake of foods low in solid fats and added sugars, and processed meat. Other studies show that older persons have low intakes of calories, total fat, fiber, calcium, magnesium, zinc, copper, folate, and vitamins B₁₂, C, E, and D. When challenged by decreased appetite, early satiety, and reduced access to food, meeting recommendations can become difficult for the older adult. It is very important to consider these and other factors which inhibits one's ability to meet estimated needs including socioeconomic status, disease state and overall health, ability to chew and swallow, and ability to taste. It is the position of the Academy of Nutrition and Dietetics that

estimated needs for older adults should be met with individualized nutrition care plans based on nutritional status, medical condition, and personal preference and that restrictive diets specific to disease state should be thoroughly evaluated based on risk and benefit to each individual (Table 19.3).

There is no predictive equation specific to older adults. However, the Mifflin-St. Jeor energy equation can be used to assess calorie needs in healthy older or obese adults (see Chapter 2) though it can often overestimate an older individual's needs. A quick energy estimate is provided in the table below. Certain disease states such as end-stage

TABLE 19.3 Nutrient Needs Change with Aging

Nutrient	Changes with Aging	Practical Solutions
Energy	Basal metabolic rate decreases with age because of changes in body composition. Energy needs decrease 3% per decade in adults.	Encourage nutrient-dense foods in amounts appropriate for caloric needs.
Protein 0.8 g/kg minimum	Minimal change with age but research evidence is growing that the current RDA is too low. Researchers are suggesting 1.0–1.2 gm/kg.	Protein intake should not be routinely increased; excess protein could unnecessarily stress aging kidneys.
Carbohydrates 45%–65% total calories Men 30 g fiber Women 21 g fiber	Constipation may be a serious concern for many.	Emphasize complex carbohydrates: legumes, vegetables, whole grains, fruits to provide fiber, essential vitamins, minerals. Increase dietary fiber to improve laxation especially in older adults.
Lipids 20%–35% total calories	Heart disease is a common diagnosis.	Overly severe restriction of dietary fats alters taste, texture, and enjoyment of food; can negatively affect overall diet, weight, and quality of life. Emphasize healthy fats rather than restricting fat.
Vitamins and minerals	Understanding vitamin and mineral requirements, absorption, use, and excretion with aging has increased but much remains unknown.	Encourage nutrient-dense foods in amounts appropriate for caloric needs. Oxidative and inflammatory processes affecting aging reinforce the central role of micronutrients, especially antioxidants.
Vitamin B ₁₂ 2.4 mg	Risk of deficiency increases because of low intakes of vitamin B ₁₂ , and decline in gastric acid, which facilitates B ₁₂ absorption.	Those 50 and older should eat foods fortified with the crystalline form of vitamin B ₁₂ such as in fortified cereals or supplements.
Vitamin D 600-800 IU*	Risk of deficiency increases as synthesis is less efficient; skin responsiveness as well as exposure to sunlight decline; kidneys are less able to convert D ₃ to active hormone form. As many as 30% to 40% of those with hip fractures are vitamin D insufficient.	Supplementation may be necessary and is inexpensive. A supplement is indicated in virtually all institutionalized older adults.
Folate 400 µg	May lower homocysteine levels; possible risk marker for atherothrombosis, Alzheimer's disease, and Parkinson's disease.	Fortification of grain products has improved folate status. When supplementing with folate, must monitor B ₁₂ levels.
Calcium 1200 mg	Dietary requirement may increase because of decreased absorption; only 4% of women and 10% of men age 60 and older meet daily recommendation from food sources alone.	Recommend naturally occurring and fortified foods. Supplementation may be necessary. However, in older women, high intakes may be occurring with supplements.
Potassium 4700 mg	Potassium-rich diet can blunt the effect of sodium on blood pressure.	Recommend meeting potassium recommendation with food, especially fruits and vegetables.
Sodium 1500 mg	Risk of hypernatremia caused by dietary excess and dehydration. Risk of hyponatremia caused by fluid retention.	Newer evidence based on direct health outcomes is inconsistent with the recommendation to lower dietary sodium in the general population, including older adults, to 1500 mg per day. More research is needed. [†]
Zinc Men 11 mg Women 8 mg	Low intake associated with impaired immune function, anorexia, loss of sense of taste, delayed wound healing, and pressure ulcer development.	Encourage food sources: lean meats, oysters, dairy products, beans, peanuts, tree nuts, and seeds, especially pumpkin seeds.
Water	Hydration status can easily be problematic. Dehydration causes decreased fluid intake, decreased kidney function, increased losses caused by increased urine output from medications (laxatives, diuretics). Symptoms: electrolyte imbalance, altered drug effects, headache, constipation, blood pressure change, dizziness, confusion, dry mouth and nose.	Encourage fluid intake of at least 1500 mL/day or 1 mL per calorie consumed. Risk increases because of impaired sense of thirst, fear of incontinence, and dependence on others to get beverages. Dehydration is often unrecognized; it can present as falls, confusion, change in level of consciousness, weakness or change in functional status, or fatigue.

BOX 19.3 Nutrition Needs for Older Adults**Quick Calorie Estimate**

Healthy older adult	18-22 kcal/kg women 20-24 kcal/kg men
Weight gain for underweight or older adult experiencing unintended weight loss	25-40 kcal/kg
Pressure injury	30-35 kcal/kg

Quick Protein Estimate

Healthy older adult	1.0-1.2 g/kg
Dialysis or pressure injury	1.2-1.5 g/kg

Quick Fluid Estimate

Healthy older adult	25-30 kcal/kg or 1 ml/kcal
Congestive heart failure or edema	25 ml/kg
Infection or fluid loss from draining wounds	35 kcal/kg

Adapted from: *Nutrition Care of the Older Adult: A Handbook for Nutrition Throughout the Continuum of Care*, 3rd Ed. Dietetics in Health Care Communities Dietetic Practice Group; Kathleen C. Niedert, RDN, CSG, LD, FADA, Editor-in-Chief; Marla P. Carlson, Editor

renal disease on dialysis, pressure injuries, and congestive heart failure warrant adjustments to estimated needs to ensure adequate calorie, protein, and fluid needs are met. As with any energy estimation, it is important to continue to monitor weight and conduct nutrition-focused physical assessments often to ensure estimates are adequate for each individual (Box 19.3).

MEDICARE BENEFITS

The federal Medicare program covers most of the health care costs of those 65 and older and persons with disabilities. However, this federally funded health insurance program does not cover the cost of residential/institutional long-term care. A portion of payroll taxes and monthly premiums deducted from Social Security payments finance Medicare.

Medicare benefits are provided in four parts. Part A covers inpatient hospital care, some skilled nursing care for specific “skilled services”, hospice care, and some home health care costs for limited periods of time. It is premium free for most citizens. Part B has a monthly premium that helps pay for physicians and physician surrogates, outpatient hospital care, and some other care not covered by Part A (physical and occupational therapy, for example). Part C allows private insurers, including health maintenance organizations (HMOs) and preferred provider organizations (PPOs), to offer health insurance plans to Medicare beneficiaries. These must provide the same benefits the original Medicare plan provides under Parts A and B. Part C HMOs and PPOs also may offer additional benefits, such as dental and vision care. Part D provides prescription drug benefits through private insurance companies.

The **2010 Affordable Care Act** (see Chapter 9) changed Medicare to include an annual wellness visit and a personalized prevention assessment and plan with no copayment or deductible. Prevention services include referrals to education and preventive counseling or community-based interventions to address risk factors. Expansion of medical nutrition therapy reimbursement for registered dietitians/nutritionists was anticipated, however major changes have been made to the original legislation now calling this into question. More universal access to nutrition services has implications for aging healthier and promoting quality of life and independence.

Medicaid, for qualified low-income individuals, finances a variety of long-term care services via multiple mechanisms, including

Medicaid State Plans and **home- and community-based services (HCBS) waivers**, Section 1915 (c). Both provide service to nursing home-appropriate older adults to help prevent or decrease nursing home or institutionalization. States may offer an unlimited variety of services under this waiver. These programs may provide traditional medical services (dental, skilled nursing) and nonmedical services (meal delivery, case management, environmental modifications). States have the discretion to choose the number of older persons served and the services offered.

Program of All-Inclusive Care for the Elderly (PACE) is a comprehensive managed care system for people over 55 who are nursing home eligible and who meet low income criteria. The program is funded through Medicare and Medicaid. Coordinated preventive, primary, acute, and long-term care services allow older adults to remain in their homes for as long as possible (Thomas and Burkemper, 2013). The PACE model is based on the belief that it is better for the well-being of older adults with chronic care needs to be served in the community whenever possible. PACE is multidisciplinary and includes dietitian services. There are more than 100 PACE Programs nationwide.

PACE Programs and HCBS waivers reflect federal commitments to delay or avoid nursing home placement whenever possible. The U.S. Administration on Aging is now under the new umbrella of the U.S. Administration on Community Living. Terms such as “aging in community,” “communitarian alternatives,” “age-friendly living,” “care circles,” and especially “**long-term services and supports**” (LSS) (versus “long-term care”) are indicative of the transformations taking place in the more positive approaches to aging (Bernstein et al, 2012; Rudolph, 2009).

NUTRITION SUPPORT SERVICES**U.S. Department of Health and Human Services Older Americans Act (OAA) Nutrition Program**

The OAA was originally enacted in 1965 and approved for a 3-year reauthorization in 2015 by unanimous vote by the Senate. The OAA Nutrition Program is the largest, most visible federally funded community-based nutrition program for older persons (Lloyd and Wellman, 2015). Primarily a state-run program, it has few federal regulations and considerable variation in state-to-state policies and procedures. Goals of the OAA include supporting seniors’ independence and helping prevent hospitalization and nursing care with funding extending to 56 state agencies, over 200 tribal organizations, and over 20,000 local service providers. Nutrition program funding is distributed based on a formula which considers each state’s population of older adults over age 60. This nutrition program provides congregate and home-delivered meals (usually 5 days per week using Meals on Wheels), nutrition screening, education, and counseling, as well as an array of other supportive and health services. The OAA Nutrition Program, available to all persons age 60 and older regardless of income, successfully targets those in greatest economic and social need, with particular attention to low-income minorities and rural populations. Generally, a higher proportion of older adults who receive OAA services have a higher percent of food insecurity and functional limitations compared with those who do not utilize services (Vieira et al, 2017). Particular attention is paid to those individuals who are members of minority groups, live in rural areas, have low income, have limited English proficiency, and are at risk for institutional care.

More than half of the OAA annual budget supports the nutrition program, which provides about 219 million congregate and home-delivered meals to 2.4 million older adults annually (U.S. Administration on Aging, 2019). According to the ACL and U.S.

Administration on Aging, 91% of participants stated that home-delivered meals have helped them stay in their own homes and more than 60% of participants indicate that home-delivered meals provide one half or more of their total intake for the day. Home-delivered meals have grown to more than 61% of all meals served and almost half of the programs have waiting lists. To receive home-delivered meals, an individual must be assessed to be home bound, frail, or isolated, though the benefits may also extend to caregivers, spouses, and people with disabilities.

At congregate sites, the nutrition program provides access and linkages to other community-based services. It is the primary source of food and nutrients for many program participants and presents opportunities for active social engagement and meaningful volunteer roles. The meals provided are required to be nutritionally dense, supply more than 33% of the recommended dietary allowances (an OAA requirement), and provide 40% to 50% of daily intakes of most nutrients (Lloyd and Wellman, 2015).

The OAA Nutrition Program is closely linked to HCBS through cross-referrals within the Aging Network. Because older adults are being discharged earlier from hospitals and nursing homes, many require a care plan that includes home-delivered meals and other nutrition services (e.g., nutrition screening, assessment, education, counseling, and care planning). Many states are creating programs to provide necessary medical, social, and supportive HCBS, including home-delivered meals, nutrition education, and counseling services. States are being encouraged to help older adults and people with disabilities live in their homes and fully participate in their communities by the ACL. Its role is to build the capacity of the national aging and disability networks to better serve older persons, caregivers, and individuals with disabilities.

U.S. Department of Agriculture (USDA) Food Assistance Programs

For low-income adults, research suggests evidence of lower caloric intake, poorer dietary quality, greater risk of hypoglycemia, lower medication adherence, and difficulty paying bills at the end of the month when finances diminish. Several USDA food and nutrition assistance programs are available to older adults after participants meet certain criteria as all USDA programs are means tested. A recent study suggests that older adults dually enrolled in Medicare and Medicaid services who receive SNAP benefits had reduced hospitalization and emergency department visits compared with those that did not utilize these benefits (Samuel et al, 2018). This could have significant implications on the general health of older adult populations, though the majority of U.S. adults who are eligible for SNAP benefits do not participate. Additional information on USDA food assistance programs can be found in Chapter 9.

Commodity Supplemental Food Program

The Commodity Supplemental Food Program (CSFP) strives to improve the health of low-income Americans by supplementing their diets with nutritious USDA commodity foods. It provides food and administrative funds to states but not all states are enrolled. In states which administer CSFP, services are offered in diverse locations such as public health, nutrition services, or agriculture departments. Eligible populations include adults age 60 and older with incomes less than 130% of the poverty level. Local CSFP agencies determine eligibility, distribute food, and provide nutrition education. The food packages do not provide a complete diet but may be good sources of nutrients frequently lacking in low-income diets and can include dry milk, juice, oats, dry cereal, rice, pasta, peanut butter, dry beans, canned meat/poultry/fish, and canned fruits and vegetables.

Seniors Farmers' Market Nutrition Program

The Seniors Farmers' Market Nutrition Program (SFMNP) is administered by state departments of agriculture, aging and disability services, or federally recognized Native American tribal governments. Not all states operate SFMNP on a statewide basis. SFMNP provides coupons to low-income older individuals to purchase fresh unprepared fruits, vegetables, honey, and herbs at farmers' markets, roadside stands, and community-supported agriculture (CSA) programs. It provides eligible older adults with local, seasonal access to fresh fruits and vegetables as well as nutrition education and information. The SFMNP serves low-income older adults who are generally at least 60 years old and who have incomes not more than 185% of the U.S. poverty guidelines.

Medicaid and Nutrition Services

Older adults who meet certain income criteria may qualify for additional support from Medicaid agencies and Medicaid health plans. Many states use HCBS waivers to support low-income older adults and an increasing number of states are creating LSS to more broadly support older adult communities. Practices supporting the nutrition-related needs of older adults are growing in popularity as states understand the broader implications of addressing these needs. Some Medicaid-based health plans are also increasing their involvement with nutrition professionals, assisting plan members in SNAP enrollment and utilizing assessment data to monitor nutrition-related needs and outcomes (Center for Healthcare Strategies, 2019).

COMMUNITY AND RESIDENTIAL FACILITIES FOR OLDER ADULTS

The report *Long-Term Care Providers and Services Users in the United States, 2015–2016* found that 65,600 paid, regulated long term services providers served over 8.3 million people (Harris-Kojetin et al, 2016). This is in an increase of 7,100 service providers since 2013. Long term care services were provided by 4,600 adult day services, 12,200 home health agencies, 4,300 hospices, 15,600 nursing homes and 28,900 assisted living and similar residential care communities. Each day, there are more than 286,300 enrolled adult day service participants, 1,347,600 skilled nursing facilities (SNFs) residents (for those requiring a higher level of medical care), and 811,500 residential care residents. In 2015, approximately 1,426,000 patients received services from hospices, a 14% increase from 2013.

People move to residential facilities, generally known as assisted living, when they can no longer safely live alone because they have some cognitive impairment requiring supervision or need help with ADLs because of immobility. Care is provided in ways that promote maximum independence and dignity. Assisted living care's annual cost is generally quite a bit less than nursing homes. Residents are encouraged to maintain active social lives with planned activities, exercise classes, religious and social functions, and opportunities to travel outside the facility. These communities are now required in some states to provide therapeutic diets but in those states without such regulation residents have difficulty getting special requirements met for services such as texture modified meals.

Comprehensive state regulations for food and nutrition services in assisted living care is not yet widespread, but there is growing consensus that it should be regulated. Emphasizing that food and nutrition matter at every age, it is essential that support for nutrition and quality of life extend beyond food availability and safety. Dietitian expertise is needed for nutrition assessment and care planning to meet special needs such as type and amounts of macronutrients and micronutrients, texture modifications, and quality of food choices and presentation.

Only about 3% or 1.4 million older adults live in the approximately 15,700 nursing homes (Harris-Kojetin et al, 2019). The percentage of the population that lives in nursing homes increases dramatically with age, especially for those older than age 85. However, the overall percentage has declined since 1990, likely because of healthier aging, the federal cost-containment policy to delay residential placement in nursing homes by providing more aging services in the community, as well as the increased availability and use of hospice. The percentage increases with age, ranging from 1% for persons age 65 to 74 years to 3% for persons age 75 to 84 years and 10% for persons age 85. The cost of nursing home care differs by state with the most expensive reported in Alaska where a semiprivate room is more than \$23,000 per month and the least expensive is Oklahoma at about \$4500 per month (Seniorliving.org).

SNFs are federally regulated by the Centers for Medicare and Medicaid Services; assisted living centers, by each state. More residents are in SNFs for short-stay, post-acute care, thus more comprehensive medical nutrition therapy is now needed. Nutritional care is directed toward identifying and responding to changing physiologic and psychological needs over time that protect against avoidable decline (Box 19.4).

BOX 19.4 Types of Residential Housing

Independent Living Facility (IL or ILF)	Apartment style, condominium, or freestanding home living for independent seniors.
Assisted Living Facility (AL or ALF)	Apartment style housing that offers organized social interaction and support services as needed. Health care services are available by outside providers who visit the facility periodically. Meals are offered and assistance with medication management and some physical assistance with activities of daily living and transportation can be offered.
Skilled Nursing Facility (SNF) Nursing Home	Accredited establishment that offers 24-hour care and access to in-house health care providers and nursing, assistance with activities of daily living, meals and snacks, and organized social activities. Many SNFs also provide rehabilitative services where patients can receive therapy and healthcare services to recover from an injury or illness with the goal of returning to a more independent setting.
Continuous Care Retirement Community (CCRC)	These communities combine all levels of care onto one property and include housing and services for independent, assisted, and skilled living.
Rehabilitation Hospital	Hospital-like setting which provides extended acute care for patients requiring stabilization before transferring to an SNF or more independent setting. These hospitals bridge the gap for patients requiring advanced therapy but who are not appropriate to stay in a general hospital or transfer to a SNF.
Adult Family Home (AFH)	Traditional home in a residential neighborhood which supports needs of its residents by assisting with activities of daily living, meals, and personal care. Most states require licensing and are inspected on a regular basis, though some states do not require licensing of these facilities. Nursing care may be available on site. AFHs typically house between 2 and 9 residents at a time.

The culture change movement in long-term care (LTC) has led to the creation of the **Dining Practice Standards (DPS)**. The DPS were published by the Pioneer Network's Dining Clinical Task Force, a multidisciplinary group of LTC and nutrition experts. These guidelines were agreed to by Centers for Medicare and Medicaid Services (CMS) and over a dozen professional groups, including the Academy of Nutrition and Dietetics (AND). The guidelines provide evidence-based support for resident-centered dining, for liberalized diets, for food first, and for decreased dependence on medical nutritional supplements. CMS has subsequently incorporated the DPS into the survey process.

In 1987 Congress passed reform legislation as part of the Omnibus Reconciliation Act (OBRA) to improve the quality of care in SNFs by strengthening standards that must be met for Medicare/Medicaid reimbursement. Since that time SNFs have been required by CMS to conduct periodic assessments to determine the residents' needs; to provide services that ensure residents maintain the highest practical, physical, mental, and psychological well-being; and to ensure that no harm is inflicted. This is accomplished using the **Minimum Data Set (MDS)**, which is part of the federally mandated process for clinical assessment of residents of LTC facilities licensed under Medicare or Medicaid. Section K of the MDS is specific to nutrition and is generally the responsibility of the dietitian to complete but can be done by nursing staff (Fig. 19.4). This form documents "triggers" that may place a resident at nutrition risk and therefore requires an intervention. This assessment must be done at admission and if there is a significant change in the resident's condition such as weight loss or skin breakdown. Reassessment is required quarterly and annually. The entire process is known as the **Resident Assessment Instrument (RAI)**. It provides the individual assessment of each resident's functional capabilities and helps identify problems and develop a care plan.

High nutrition risk individuals must be identified and assessed monthly by the dietitian. High risk is defined as:

- Significant weight loss defined as 5% of body weight in 1 month or 10% of body weight in 6 months
- Nutrition support (tube feedings or parenteral nutrition)
- Dialysis patients
- Wounds or pressure injuries

Palliative Care and Hospice

During the course of a disease process there are multiple services and approaches that can ease symptoms and focus on keeping one comfortable. **Palliative care** is an approach to care that can be initiated at any point during a person's life or illness and can be provided in conjunction with curative treatment. Palliative care focuses on providing relief from symptoms and alleviating the stress of illness and disease management. Teams of specially trained health professionals work alongside a patient's other providers to give an extra layer of support for achieving the goal of improved quality of life for both the patient and family. Palliative care services can be provided in outpatient or inpatient settings, long term care communities, or at home and may be covered by Medicare, Medicaid, or private insurances. Though the palliative care approach is best to initiate at the diagnosis of a disease, there are many benefits to starting care at any point during the progression of a particular disease.

Hospice care is a service which provides extra support to a terminally ill individual and to the family. Hospice care is covered under Medicaid, Medicare, and most private insurance plans and HMOs. A patient must meet specific criteria to be eligible for hospice care including diagnosis of a terminal illness with an estimate of 6 months or less life expectancy. Once enrolled in services, hospice develops a care plan and care team to meet a patient's individual needs. Hospice teams can include the patient's personal physician, hospice physician, nurses,

home health aides, social workers, clergy, trained volunteer, speech/physical/occupational therapists, and dietitians. The team helps provide relief of pain and symptoms, emotional support to both the patient and family, medical equipment and medications, and bereavement care and counseling to family and friends. Hospice care can be

provided in the home in conjunction with private caregivers or in hospice centers, hospitals, and long-term care communities. For many, this extra level of support can ease the transition, provide comfort, and increase quality of life for the patient and family alike. For more on palliative and hospice care, see Chapter 35.

Section K Swallowing/Nutritional Status	
K0100. Swallowing Disorder	
Signs and symptoms of possible swallowing disorder	
↓ Check all that apply	
<input type="checkbox"/>	A. Loss of liquids/solids from mouth when eating or drinking

Enter Code <input type="text"/>	B. Average fluid intake per day by IV or tube feeding 1. 500 cc/day or less 2. 501 cc/day or more

Fig. 19.4 The Minimum Data Set, Section K version 3.0. (From the Centers for Medicare and Medicaid Services, Baltimore, MD.)

CLINICAL CASE STUDY

MF is an 86-year-old white female resident in a skilled nursing facility with unintentional weight loss. She was admitted 3 months ago from the hospital after a hip fracture. She had been residing in an independent living facility for several years. She reports she has been eating poorly because of difficulty moving around, being generally uncomfortable, and states, "If I am not active, I don't need to eat so much." Intake is less than 50% of regular diet. No problems chewing or swallowing are noted after a speech language pathologist's evaluation. Admission weight was 112 pounds; current weight is 95 pounds. Self-reported height is 5' 3"; Hgb/Hct is normal; total cholesterol is 135; and Mini Nutrition Assessment score is 5. Hip scans show slow fracture healing and no

improvement in bone density; currently she is being supplemented with calcium 1000 mg/day and vitamin D 600 IU/day. Blood pressure is 128/80 with furosemide (Lasix); other medications are lorazepam (Ativan), fentanyl transdermal patch (Duragesic), senna (Senokot-S), docusate (Colace), and mirtazapine (Remeron).

Nutrition Diagnostic Statement

- Unintentional weight loss related to food intake of less than 50% of meals with limited physical activity as evidenced by severe weight loss of 17 lbs/14% of body weight over three months.

Continued

CLINICAL CASE STUDY—cont'd

Nutrition Care Questions

1. Comment on the appropriateness of and use for each medication. Would you suggest any changes or additional medications?
2. What strategies could you use to help improve this resident's food and fluid intake?

3. What suggestions are appropriate to promote fracture healing and increase bone density?
4. Do you suspect that this client is constipated? What would you recommend in terms of food choices to deal with this?

Nutrition for Weight Management

The chapters in this section reflect the evolution of nutritional science, from the identification of nutrient requirements and the practical application of this knowledge to the concepts that relate nutrition to the prevention of chronic and degenerative diseases and to optimization of health and performance.

The relationship between nutrition and dental disease has long been recognized. In more recent decades the possibility of nutrition therapy to prevent and treat bone disease has become an active area of research and we are now aware that the inflammatory process is a factor that nutrition can modulate.

Healthy lifestyles, good nutrition, and physical activity are foundations of health, fitness, and disease prevention. Understanding the role of nutrition in sports and in optimizing performance has led to dietary and exercise practices generally applicable to a rewarding, healthy lifestyle.

Increased access to highly processed and calorically dense foods has led to an overabundant intake of energy for many individuals. Efforts to reduce body weight, widely pursued with varying degrees of enthusiasm and diligence, are often disheartening, making the knowledge presented here so important. Frustration with dieting and stress often lead to eating disorders, which are increasing in frequency and require attention and understanding from the nutrition professional.

Nutrition in Weight Management

Lucinda K. Lysen, RDN, RN, BSN

KEY TERMS

abdominal fat	hyperphagia	night-eating syndrome (NES)
activity thermogenesis (AT)	hyperplasia	nonalcoholic fatty liver disease (NAFLD)
adipocyte	hypertrophy	nonexercise activity thermogenesis (NEAT)
adiposity rebound	hypophagia	nutritional genomics
android fat distribution	incretin	obesity
bariatric surgery	insulin	obesogen
body mass index (BMI)	intermittent fasting (IF)	overweight
brown adipose tissue (BAT)	intra gastric balloon (IGB)	resting metabolic rate (RMR)
carbohydrate-insulin theory of obesity	ketogenic diet	self-help programs
commercial weight loss centers	ketones	sensory-specific satiety
comorbidities	ketosis	set point theory
essential fat	laparoscopic sleeve gastrectomy (LSG)	storage fat
fat mass	lean body mass (LBM)	semivolatile organic compounds (SVOCs)
fat-free mass (FFM)	leptin	telehealth
gastric banding	lipogenesis	underweight
gastric bypass	lipoprotein lipase (LPL)	vagus nerve
ghrelin	meal replacements	very low-calorie diets (VLCDs)
gynoid fat distribution	medically supervised weight loss programs	visceral adipose tissue (VAT)
Health at Every Size; HAES®	metabolic syndrome (MetS)	white adipose tissue (WAT)
hormone-sensitive lipase (HSL)	morbid obesity	yo-yo effect

Body weight is the sum of bone, muscle, organs, body fluids, and adipose tissue. Some or all of these components are subject to normal change as a reflection of growth, reproductive status, variation in physical activity, and the effects of aging. Consistent body weight is orchestrated by neural, hormonal, and chemical mechanisms as well as individual genetic polymorphisms that balance energy intake and expenditure within fairly precise limits. Abnormalities of these complex mechanisms can result in weight fluctuations.

On one end of the weight spectrum is underweight. Although the inability to gain weight can be a primary problem, low body weight is usually secondary to a disease state, an eating disorder, or a psychiatric disorder. In the elderly or in children, unintentional weight loss can be especially detrimental and should be addressed early to prevent malnutrition or other undesirable consequences including poor growth, depressed immune function, hormone imbalance, delayed healing, and loss of bone density. Most crucial is the in utero development of the fetus. Babies deprived of nutrition before birth and who have low birth weight may be primed for accelerated growth after birth when exposed to a nutrient-rich environment (that can sometimes start with excessive intake of infant formula). Furthermore, inadequate passage of nutrients across the placenta and low birth weight eventually can lead to an increased risk of developing obesity and diabetes (Apovian, 2011).

On the other end of the spectrum, and more common, are the conditions of overweight and obesity.

WEIGHT MANAGEMENT AND OBESITY: ITS FOUNDATION IN NUTRITIONAL MEDICINE

The growing amount of attention over the last four decades to the field of weight management and obesity has largely been brought about by the historical findings of a handful of researchers. In the forefront—beginning in the 1970s—was George L. Blackburn, MD, PhD, who, along with Bruce Bistrian, MD, PhD, at Harvard Medical School, and a number of other highly respected colleagues, provided the foundation for what eventually became the field of nutritional medicine. Publications highlighting the inadequate nutrition management of hospitalized patients put this topic and nutritional medicine on the “world map.” Despite the fact that Dr. Blackburn and his group found that many of the hospitalized patients were shockingly malnourished (Blackburn et al, 1977), they also discovered that the patients were often not underweight but instead, were overweight or even obese. This led to Dr. Blackburn’s development of nutritional liquid and solid diets, supplementing patients with protein to encourage loss of body fat while saving muscle and improving nutritional status. The protein-sparing modified fast, which spared protein and

protected organs, became the basis of the very low-carbohydrate diet for weight loss in obese patients (Blackburn, 1973). With obesity reaching epidemic proportions over the years, scientific research expanded, diet and weight loss programs grew dramatically and the specialties of weight management and obesity quickly grew into a billion-dollar industry. Over time, Dr. Blackburn's ongoing landmark studies and cutting edge findings in weight management and obesity brought him recognition around the world, earning him the title “

Father of Obesity” (Table 20.1: The Story of George L. Blackburn, MD, PhD). The growing population of obese individuals and the plethora of evidence that it is associated with chronic disease has motivated intense research on the subject and resulted in obesity as a specialty in nutritional medicine. Obesity meets the criteria to be classified as a “disease,” which has made it reimbursable by insurance companies for medical treatment, and in many cases, for nutritional management by Registered Dietitian Nutritionists.

TABLE 20.1 The Story of George L. Blackburn, MD, PhD

The evolution of the field of obesity and nutritional medicine and the premise on which we practice as nutrition professionals today is largely based upon the countless research and scientific findings and the decades of contributions from the work of George L. Blackburn, MD, PhD.

Dr. Blackburn was born in McPherson, Kansas, and attended the University of Kansas, where he received his baccalaureate degree in chemistry and doctor of medicine degree. After completing his surgical internship and residency at the Fifth Harvard Surgical Service, Boston City Hospital, he attended the Massachusetts Institute of Technology where he received his PhD in nutritional biochemistry. His thesis was entitled “A New Concept and Its Application for Protein-Sparing Therapies During Semistarvation.” This research was the foundation for Dr. Blackburn's milestone studies identifying the high prevalence of protein-calorie malnutrition in general surgical and medical patients. Dr. Blackburn was among the very first to recognize that up to 50% of hospitalized medical and surgical patients suffered from moderate to severe malnutrition. To address these challenges, he pioneered the formulation of intravenous hyperalimentation and introduced some of the first novel disease-specific formulas. It was then, at the New England Deaconess Hospital, Harvard Medical School, that he established the first multidisciplinary nutrition support service in the world, for the safe delivery of total parenteral nutrition. Dr. Blackburn always felt that building bridges and bringing minds together among health care professionals to share knowledge and ideas would lead to the most successful patient outcomes.

Dr. Blackburn, along with Harvard colleague Bruce Bistrian, MD, PhD, was the first to demonstrate that it was possible during weight loss to promote the loss of body fat while preserving lean tissue. The work of Dr. Blackburn's research on amino acid therapy as a means of preserving lean tissue during times of stress

and starvation evolved into his development of the protein-sparing modified fast diet, and the first carefully regimented medically supervised weight loss program of its kind.

Dr. Blackburn was the first surgeon in New England to perform a Roux-en-Y gastric bypass for morbidly obese patients in 1973. He formed a multidisciplinary team to care for his weight loss surgery patients—similar to the nutrition support service. In 2004 and 2009 he organized and chaired the first evidence-based guidelines for weight loss surgery, catalyzing the formation of accreditation bodies and standards for certification of weight loss surgery centers and providers across the United States.

Dr. Blackburn was a founder of the American Society for Parenteral and Enteral Nutrition and served as its second president. He played a key role in the development of the North American Association for the Study of Obesity—now the Obesity Society. He was a member of the Beth Israel Deaconess Medical Center Department of Surgery for 45 years. He established and, for 25 years, directed the Harvard Medical School CME course “Practical Approaches to the Treatment of Obesity”—which is now the Harvard “Blackburn Course in Obesity Medicine.” He authored over 400 original peer-reviewed research publications, nine books, and hundreds of educational documents, guidelines, and reports. Throughout his career, he taught hundreds of medical students, residents, postdoctoral research fellows, registered dietitians, dietetic technicians, nurses, and pharmacists who practice his teachings around the world. In 1992 Dr. Blackburn was nominated for and selected as an honorary member of the American Dietetic Association—now the Academy of Nutrition and Dietetics.

Inseparable from his efforts for over four decades to expand our knowledge in nutrition and metabolism was Dr. Blackburn's identification and unceasing support of the critical role the dietitian plays in patient management. During his lifetime, Dr. Blackburn elevated dietitians as “nutrition experts”. He stressed that the role of the registered dietitian was to assess and monitor nutrition status; provide nutrition counseling, care, and therapy; and is the obvious liaison between medical professionals and health care providers. The central role of the dietitian on Dr. Blackburn's nutrition teams was a model that influenced physicians and administrators and other health care professionals to follow suit, opening doors for dietitians everywhere.

Shortly after Dr. Blackburn's death in 2017, Caroline Apovian, MD, Professor of Medicine and Pediatrics, Boston University School of Medicine, and 2018 president of the Obesity Society, reflected on Dr. Blackburn's tremendous accomplishments during an interview. She said, “George Blackburn was truly the father of nutrition and obesity medicine. His energy and enthusiasm were incredible. He is someone who not only encouraged me to do my best work, but also countless other colleagues and friends. He was a great man whom I and many others will deeply miss.”

Many thanks to Barb Ainsley, DTR, Administrative Associate and former Administrative Assistant to Dr. George Blackburn, Center for the Study of Nutrition Medicine, Feihe Nutrition Lab, Beth Israel New England Deaconess Medical Center, Boston, for her assistance in preparation of this section.

by Barbara Ainsley, DTR and Lucinda K. Lysen, RDN, RN, BSN

BODY WEIGHT COMPONENTS

Body weight often is described in terms of its composition, and different models have been advanced to estimate body fat. Assessment of body composition is discussed in detail in Chapter 5. Traditionally, a two-compartment model divides the body into **fat mass**, the fat from all body sources including the brain, skeleton, intramuscular fat, and adipose tissue, and **fat-free mass (FFM)**, which includes water, protein, and mineral components (Fig. 20.1). The proportions of FFM are relatively constant from person to person.

Although *FFM* often is used interchangeably with the term lean body mass, it is not exactly the same. **Lean body mass (LBM)** includes water, bones, organs and skeletal muscle. LBM is higher in men than in women and represents the largest component of **resting metabolic rate (RMR)**. Minimizing the loss of LBM is desirable during the weight loss process. Water, which makes up 60% to 65% of body weight, is the most variable component of LBM, and the state of hydration can induce fluctuations of several pounds.

Body Fat

Total body fat is the combination of “essential” and “storage” fats, usually expressed as a percentage of total body weight that is associated with optimum health. Muscle and even skeletal mass adjust to some extent to support the burden of excess adipose tissue.

Essential fat, necessary for normal physiologic functioning, is stored in small amounts in the bone marrow, heart, lung, liver, spleen, kidneys, muscles, and the nervous system. In men, approximately 3% of body fat is essential. In women, essential fat is higher (12%) because it includes body fat in the breasts, pelvic regions, and thighs that supports the reproductive process.

Storage fat is the energy reserve, primarily as triglycerides (TGs), in adipose tissue. This fat accumulates under the skin and around the internal organs to protect them from trauma. Most storage fat is “expendable.” The fat stores in adipocytes are capable of extensive variation. This allows for the changing requirements of growth, reproduction, aging, environmental and physiologic circumstances, the availability of food, and the demands of physical activity. Total body fat (essential fat plus storage fat) as a percentage of body weight associated with the average individual is between 18% and 24% for men and 25% and 31% for women. On the other extreme, “elite fit” men are as low as 2% to 5% body fat and women 10% to 13%.

Adipose Tissue Composition

Adipose tissue exerts a profound influence on whole-body homeostasis. Adipose tissue is located primarily under the skin, in the mesenteries

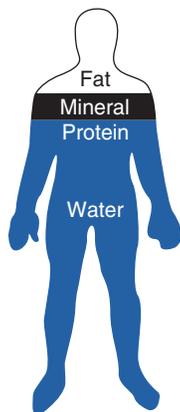

Fig. 20.1 The components of fat-free mass in the body.

and omentum, and behind the peritoneum. This is often referred to as **visceral adipose tissue (VAT)**. Although it is primarily fat, adipose tissue also contains small amounts of protein and water. **White adipose tissue (WAT)** stores energy as a repository for TGs, cushions abdominal organs, and insulates the body to preserve heat. Carotene gives WAT a slight yellow color. Small amounts of **brown adipose tissue (BAT)** can be found in a substantial proportion of adults as well as in infants. Unlike WAT, BAT is made of small droplets and many more iron containing mitochondria, which makes it brown. In adults BAT is activated via cold exposure helping to regulate body temperature, however BAT is not activated in thermoneutral conditions. A general activation of BAT continues to interest drug manufacturers as a potential obesity therapy, but for the present BAT plays only a minor part in human energy metabolism (Tam et al, 2012).

Adipocyte Size and Number

The mature fat cell (**adipocyte**) consists of a large central lipid droplet surrounded by a thin rim of cytoplasm, which contains the nucleus and the mitochondria. These cells can store fat equal to 80% to 95% of their volume. Gains in weight and adipose tissue occur by increasing the number of cells, adding the size of cells as lipid, or a combination of the two.

Hyperplasia (increased number of cells) occurs as a normal growth process during infancy and adolescence. Cell number increases in lean and obese children into adolescence, but the number increases faster in obese children. In teens and adults, increases in fat cell size are more common, but hyperplasia also can occur after the fat content of existing cells has reached capacity.

During normal growth, the greatest percentage of body fat (approximately 25%) is set by 6 months of age. In lean children, fat cell size then decreases; this decrease does not occur in obese children. At the age of 6 years in lean children, **adiposity rebound** occurs, especially in girls, with an increase in body fat. An early adiposity rebound occurring before 5 ½ years old is predictive of a higher level of adiposity at 16 years of age and in adulthood; a period of later rebound is correlated with healthy adult weight (Hughes et al, 2014).

With **hypertrophy** (increased cell size), fat depots can expand as much as 1000 times at any age, as long as space is available. In a classic study, Björntorp and Sjöström (1971) demonstrated, using weight loss as a result of trauma, illness, or starvation, that fat cell size decreases but cell numbers remain the same.

Fat Storage

Most stored fat comes directly from dietary TGs. The fatty acid composition of adipose tissue mirrors the fatty acid composition of the diet. Even excess dietary carbohydrate and protein are converted to fatty acids in the liver by the comparatively inefficient process of **lipogenesis**. Under conditions of relative energy balance, little dietary carbohydrate is converted to fat for storage. In conditions of positive energy balance, carbohydrate oxidation increases while TGs are preferentially stored and *de novo*-lipogenesis from carbohydrate occurs when more carbohydrate is present than can be either oxidized or stored as (liver or muscle) glycogen (Song et al, 2018).

Semivolatile organic compounds (SVOCs) accumulate in adipose tissues from exposure to toxins, chemicals, and pesticides. When adipose tissue is mobilized during weight loss, SVOCs are released (see *Clinical Insight: What’s in That Fat When You Lose It?*). The effect of SVOCs on the developing fetal brain is not yet known (see Chapter 14), which adds to the health concern about obese pregnant women who lose weight.

CLINICAL INSIGHT**What's in That Fat When You Lose It?**

The role of toxins in obesity development and later fat loss is becoming increasingly concerning as the emerging evidence forms a plausible link between toxins and obesity. Exposure to toxins comes from two main sources: the environment (external or exogenous toxins), which includes environmental pollutants such as pesticides, industrial compounds, solvents, detergents, plasticizers, cosmetic additives, chemical additives, colorings, preservatives, flavorings, microbial toxins such as aflatoxins from peanuts, mycotoxins from molds, and bisphenol-A found in plastic baby bottles, toys, and especially dental sealants; and “lifestyle chemicals,” such as alcohol, over-the-counter (OTC) drugs, and prescription drugs. It can be byproducts from food preparation such as acrylamide from French fries, nitrosamines from cold cuts and sausages, polycyclic aromatic hydrocarbons (PAHs) from charbroiled meats, trans fats from partial hydrogenation of fats and advanced glycosylated end products (AGEs) in foods in which the glucose molecule is brought to high temperatures. Toxins can also originate from the gut (i.e., breakdown products of metabolism, including hormones, internal toxins such as metabolites of yeast [d-arabinitol], or gut bacteria).

Studies show that these toxins, which are often fat soluble and have an affinity for adipose tissue, are often stored in the body's depot fat. Their presence is linked to inflammation, development of type 2 diabetes, and a suppressed resting metabolic rate (post-weight loss). In the case of weight or fat loss, the release of these toxins can interfere with the body's functioning, placing a burden on the liver and even its ability to continue to lose more fat (La Merrill et al, 2013; Lee et al, 2018; Tremblay et al, 2004).

With increasing exposure, toxins may alter metabolism, disrupt endocrine function, damage the mitochondria, increase inflammation and oxidative stress, lower thyroid hormones, and alter circadian rhythms and the autonomic nervous system. These all interfere with key weight control mechanisms in the body. Using a comprehensive approach to obesity, including the assessment and treatment of toxin-mediated effects, may result in more effective body fat and weight management. Lifestyle modifications may be helpful, including reducing exposure to toxins and supporting mobilization and elimination of stored and external toxins; however, the specific mechanisms of support, including promoting normoglycemia and ingestion of cruciferous vegetables and fibrous foods, are still under investigation (Lee et al, 2017).

Sheila Dean, DSc, RDN, LDN, CCN, IFMCP

Lipoprotein Lipase

Dietary TG is transported to the liver by chylomicrons. Endogenous TGs synthesized in the liver from free fatty acids (FFA) travel as part of very-low-density lipoprotein particles. The enzyme **lipoprotein lipase (LPL)** moves lipid from the blood into the adipose cell by hydrolyzing TGs into FFA and glycerol. Glycerol proceeds to the liver; fatty acids enter the adipocyte and are reesterified into TGs. When needed by other cells, TGs are hydrolyzed once again to fatty acids and glycerol by **hormone-sensitive lipase (HSL)** within the adipose cell; they then are released into the circulation.

Hormones affect LPL activity in different adipose tissue regions. Estrogens stimulate LPL activity in the gluteofemoral adipocytes, and thus promote fat storage in this area for childbearing and lactation. In the presence of sex steroid hormones, a normal distribution of body fat exists. With a decrease in sex steroid hormones—as occurs with menopause or gonadectomy—central obesity tends to develop.

REGULATION OF BODY WEIGHT

Body weight is the product of genetic effects (DNA), epigenetic effects (heritable traits that do not involve changes in DNA), and the

environment (Kaplan, 2018). Body weight regulation is usually described in terms of a homeostatic biological feedback system acting on energy intake and energy expenditure to maintain or “defend” a stable body weight. Similarly, **set point theory** originally arose to explain the intractable tendency to regain weight after weight loss. Body weight regulation is asymmetric in that there is little defense against weight gain while conversely both hunger and adaptations in various components of energy expenditure can make weight loss harder.

Observational studies do not provide consistent evidence for a biological control of body weight (Müller et al, 2018). While the complete picture of body weight regulation is not clear, much of what is known falls into the realm of appetite regulation. Adaptation to energy restriction (a drop in RMR beyond what is expected from changes in body weight and composition) is well known, but highly variable and less understood.

Because the precision of appetite control is undermined in the prevailing obesogenic environment that includes psychosocial, behavioral, and environmental factors that affect eating behavior (and therefore energy intake), new models of body weight regulation which also address these missing factors have been called for (Belfort-DeAguiar and Seo, 2018; Hall et al, 2014).

Hunger, Appetite, and Satiety

Satiety is associated with the postprandial state when excess food is being stored. Hunger is associated with the postabsorptive state when those stores are being mobilized. Physical triggers for hunger are much stronger than those for satiety, which external cues for eating can override.

When either overfeeding or underfeeding occurs in children they exhibit spontaneous **hypophagia** (undereating) or **hyperphagia** (overeating) accordingly. Adults, however, are less consistent in naturally compensating for overeating, which can result in body weights slowly creeping up over time. Unexplained weight loss in adults is often a symptom of other factors including stress or underlying disease. See *Focus On: Signals from a Host of Hormones* and **Table 20.2** for further information and detail on the neurochemicals and hormones involved in appetite and satiety.

Metabolic Rate and Voluntary Activity

The RMR (see Chapter 2) explains 60% to 70% of total energy expenditure. RMR declines with age. When the body is deprived of adequate energy from starvation or voluntary energy restriction, RMR drops, therefore conserving energy. The more severe the energy restriction, the greater the potential reduction in RMR; up to 15% with very-low-calorie diets (VLCDs). This suppression of RMR is beyond what is attributable to weight loss (which consists of both LBM and fat mass) and is a form of adaptation to energy scarcity. Most but not all reviews of the subject find RMR normalizes post-weight loss with maintenance level energy intakes (Ostendorf et al, 2018). Ongoing suppression of RMR may result from extreme approaches to weight loss.

Activity thermogenesis (AT) is the energy expended in voluntary activity, the most variable component of energy expenditure. Under normal circumstances physical activity accounts for 15% to 30% of total energy expenditure. **Nonexercise activity thermogenesis (NEAT)** is the energy expended for all activity that is not sleeping, eating, or sports-like exercise. It includes going to work, typing, doing yard work, toe-tapping, even fidgeting (see Chapter 2). NEAT varies as much as 2000 kcal/day between individuals, and it has been theorized to have untapped potential value in weight management. Proponents of NEAT

TABLE 20.2 Regulatory Factors Involved in Eating and Weight Management

Brain Neurotransmitters	Characteristics and Function
Norepinephrine and dopamine	Released by the sympathetic nervous system (SNS) in response to dietary intake; mediates the activity of areas in the hypothalamus that govern feeding behavior. Fasting and semistarvation lead to decreased SNS activity and increased adrenal medullary activity with a consequent increase in epinephrine, which fosters substrate mobilization. Dopaminergic pathways in the brain play a role in the reinforcement properties of food.
Serotonin, neuropeptide Y, and endorphins	Decreases in serotonin and increases in neuropeptide Y have been associated with an increase in carbohydrate appetite. Neuropeptide Y increases during food deprivation; it may be a factor leading to an increase in appetite after dieting. Preferences and cravings for sweet, high-fat foods observed among obese and bulimic patients involve the endorphin system.
CRF Orexin (hypocretin)	Involved in controlling adrenocorticotrophic hormone release from the pituitary gland; CRF is a potent anorexic agent and weakens the feeding response produced by norepinephrine and neuropeptide Y. CRF is released during exercise. Orexin is a neurotransmitter produced by the hypothalamus that has a weak resemblance to secretin produced in the gut and is an appetite stimulant and central regulator of glucose and energy homeostasis.
Gut Hormones	Characteristics and Function
Incretins	Gastrointestinal peptides increase the amount of insulin released from the beta cells of the pancreas after eating, even before blood glucose levels become elevated. They also slow the rate of absorption by reducing gastric emptying and may directly reduce food intake. Incretins also inhibit glucagon release from the alpha cells of the pancreas. (See GLP-1 and GIP.)
CCK	Released by the intestinal tract when fats and proteins reach the small intestine, receptors for CCK have been found in the gastrointestinal tract and the brain. CCK causes the gallbladder to contract and stimulates the pancreas to release enzymes. At the brain level, CCK inhibits food intake.
Bombesin	Released by enteric neurons; reduces food intake and enhances the release of CCK.
Enterostatin	A portion of pancreatic lipase involved specifically with satiety after the consumption of fat.
Adiponectin	An adipocytokine secreted by the adipose tissue that modulates glucose regulation and fatty acid catabolism. Levels of this hormone are inversely correlated with BMI. The hormone plays a role in metabolic disorders such as type 2 diabetes, obesity, and atherosclerosis. Levels drop after gastric bypass surgery for up to 6 months.
Glucagon	Increased secretion of glucagon is caused by hypoglycemia, increased levels of norepinephrine and epinephrine, increased plasma amino acids, and cholecystokinin. Decreased secretion of glucagon occurs when insulin or somatostatin is released.
Apolipoprotein A-IV	Synthesized and secreted by the intestine during lymphatic secretion of chylomicrons. After entering the circulation, a small portion of apolipoprotein A-IV enters the CNS and suppresses food consumption.
Fatty acids	Free fatty acids, triglycerides, and glycerol are factors that also affect uptake of glucose by peripheral tissues.
GLP-1 and GIP	Released by intestinal mucosa in the presence of meals rich in glucose and fat; stimulate insulin synthesis and release; GLP-1 decreases glucagon secretion, delays gastric emptying time, and may promote satiety; examples of incretin hormones.
Insulin	Acts in the CNS and the peripheral nervous system to regulate food intake and is involved in the synthesis and storage of fat. It is possible that obese persons with insulin resistance or deficiency have a defective glucose disposal system and a depressed level of thermogenesis. The greater the insulin resistance, the lower the thermic effect of food. Fasting insulin levels increase proportionately with the degree of obesity; however, many obese persons have insulin resistance because of a lack of response by insulin receptors, impaired glucose tolerance, and associated hyperlipidemia. These sequelae can usually be corrected with weight loss.
Leptin	An adipocytokine secreted by the adipose tissue, correlated with percent of body fat. Primary signal from energy stores; in obesity loses the ability to inhibit energy intake or to increase energy expenditure. Compared with men, women have significantly higher concentrations of serum leptin.
Resistin	An adipocytokine expressed primarily in adipocytes; antagonizes insulin action.
Ghrelin	Produced primarily by the stomach; acts on the hypothalamus to stimulate hunger and feeding. Ghrelin levels are highest in lean individuals and lowest in the obese. Increased levels are seen in people who are dieting, and suppressed levels are noted after gastric bypass, possibly counteracted by adiponectin.
PYY ₃₋₃₆	Secreted by endocrine cells lining the small bowel and colon in response to food; a “middle man” in appetite management. PYY seems to work opposite from ghrelin; it induces satiety.
IL-6 and TNF- α	Both are gut hormones. Cytokines secreted by adipose tissue and participate in metabolic events. Impair insulin signals in muscle and liver. Levels are proportional to body fat mass (Thomas and Schauer, 2010).
Oxyntomodulin	Secreted from L-cells in small intestine in response to a meal. Exerts its biologic effects through activation of GLP-1 and glicentin-related pancreatic peptide (GRPP) (Bray and Bouchard, 2014).

TABLE 20.2 Regulatory Factors Involved in Eating and Weight Management—cont'd

Brain Neurotransmitters	Characteristics and Function
GLP-2	Produced in the L-cells of small intestines and in neurons of CNS. Is an intestinal growth factor. Inhibits gastric emptying and acid secretion while stimulating intestinal blood flow. Decreases gastric acid secretion and gastric emptying and increases mucosal growth (Bray and Bouchard, 2014).
FGF-21	Expressed in the liver and secreted mainly during fasting and after feeding a ketogenic diet. Can decrease body weight without affecting food intake. Increases insulin sensitivity, decreases gluconeogenesis, and increases glucose uptake in adipocytes (Bray and Bouchard, 2014).
Other Hormones	Characteristics and Function
Thyroid hormones	Modulate the tissue responsiveness to the catecholamines secreted by the SNS. A decrease in triiodothyronine lowers the response to SNS activity and diminishes adaptive thermogenesis. Women should be tested for hypothyroidism, particularly after menopause. Weight regain after weight loss may be a function of a hypometabolic state; energy restriction produces a transient, hypothyroid, hypometabolic state.
Visfatin	An adipocytokine protein secreted by visceral adipose tissue that has an insulin-like effect; plasma levels increase with increasing adiposity and insulin resistance.
Adrenomedullin	A new regulatory peptide secreted by adipocytes as a result of inflammatory processes.

BMI, Body mass index; CCK, cholecystokinin; CNS, central nervous system; CRF, corticotropin-releasing factor; GIP, glucose-dependent insulinotropic peptide; GLP-1, glucagon-like peptide 1; IL-6, interleukin-6; PYY₃₋₃₆, peptide YY3-36; SNS, sympathetic nervous system; TNF- α , tumor necrosis.

Thomas S, Schauer P: Bariatric surgery and the gut hormone response, *Nutr Clin Pract* 25:175, 2010; Bray GA, Bouchard C: *Handbook of obesity*, ed 3, Boca Raton, Fla, 2014, CRC Press.

suggest standing and ambulating for 2.5 hours per day, and reengineering work, school, and home environments to support a more active lifestyle (Garland et al, 2011). However, passive compensation, by reducing other forms of physical activity, may prove to balance off increases in NEAT (O'Neal et al, 2017) and there is presently no evidence showing that strategies promoting NEAT are effective for weight loss or obesity treatment (Chung et al, 2018).

FOCUS ON

Signals from a Host of Hormones

A host of hormones—insulin, leptin, adiponectin, and ghrelin, among others—communicate with the hypothalamus to regulate a person's food intake. These regulatory hormones govern feeding in response to signals originated in affected body tissues.

Insulin controls the amount of glucose in the blood by moving it into the cells for energy. **Leptin**, which is produced mainly by fat cells, contributes to long-term fullness by sensing the body's overall energy stores. Adiponectin is also made by fat cells and helps the body respond better to insulin by boosting metabolism. **Ghrelin**, the hunger hormone, tells the brain when the stomach is empty, prompting hunger pangs.

The stomach communicates with the brain via the **vagus nerve**, part of the autonomic nervous system that travels from the brain to the stomach. When filled with food or liquid, the stomach's stretch receptors send a message to the brain indicating satiety (Guo et al, 2018). Gastric bypass surgery reduces the stomach to the size of an egg, and triggers a sharp drop in ghrelin levels, which lessens hunger and oral intake. Traditional dieting, however, tends to boost ghrelin levels.

OVERWEIGHT AND OBESITY

Overweight and obesity occur as a result of an imbalance between total energy intake (food and beverages consumed) and total energy expenditure. Despite this seemingly straightforward model, the factors which act to dysregulate energy balance are complex. Lifestyle,

environmental, and genetic factors have a multifaceted interaction with psychological, cultural, and physiologic influences. Over the years, many hypotheses have evolved however no single theory can completely explain all manifestations of obesity or apply consistently to all persons.

Prevalence

The United States leads the world as far as the total number of persons with obesity. When looked at as a percentage of the population however, the United States ranks 19th after the Oceania Islands, the Middle East, and South America. According to the World Health Organization (WHO), worldwide obesity has nearly tripled since 1975 (WHO, 2018).

In the United States the estimates of overweight and obesity among adults and children are based on measured weights and heights from the National Health and Nutrition Examination Survey (NHANES), conducted by the National Center for Health Statistics, Centers for Disease Control and Prevention (CDC) (Figs. 20.2 and 20.3). The 2015–2016 NHANES findings were that the prevalence of obesity was 39.8% in adults and 18.5% in youth. The prevalence of obesity remains higher among African American and Hispanic populations. The prevalence of obesity by state (based on the ongoing Behavioral Risk Factor Surveillance Study and published by the CDC) can be seen in Fig. 20.4.

ELEMENTS OF ENERGY BALANCE DYSREGULATION

Genetics

With the exception of rare monogenic types of obesity (as in Prader-Willi's syndrome and Bardet-Biedl's syndrome), more and more research shows that the development of obesity involves a complex interaction with numerous genetic variants and environmental factors related to energy intake and expenditure (Goodarzi, 2018). Hormonal and neural factors involved in weight regulation include short-term and long-term "signals" that determine satiety and feeding activity. Small defects in their expression or interaction may contribute significantly to weight gain. **Nutritional genomics** is the study of the

NEW DIRECTIONS

Partnership for a Healthier America Addressing Childhood Obesity

Because the number of obese children in the United States has tripled since 1980, and obesity now rivals smoking as the largest cause of preventable death and disease, a foundation was launched in the spring of 2010 to address this serious epidemic of childhood obesity. This foundation, Partnership for a Healthier America, has as its mission the simple concept that children should have good, nutritious food to eat and the chance to be physically active every day to become healthy adults.

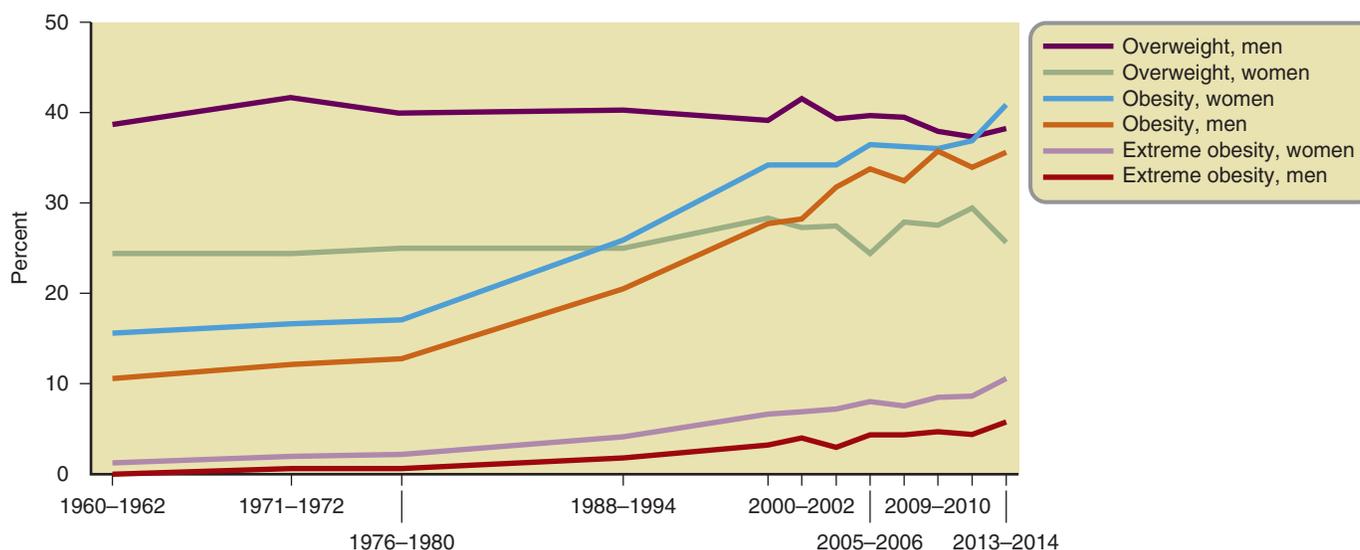

The objectives of the partnership are to support the national goal of solving the childhood obesity challenge “within a generation” set by former First Lady Michelle Obama, who historically has served as Honorary Chairperson of the organization. The Partnership brings together the public and private sectors, organizations, business and thought leaders, the media, and states and local

communities to make meaningful and measurable commitments for fighting childhood obesity. The plan has four pillars:

- Offering parents the tools and information they need to make healthy choices for their children
- Introducing healthier food into the nation’s schools
- Ensuring that all families have access to healthy, affordable food in their communities
- Increasing opportunities for children to be physically active, both in and out of school

The partnership aims to support, unite, and inspire families from every corner of the United States to implement and sustain the four-pillar plan.

Trends in adult overweight, obesity, and extreme obesity among men and women aged 20–74: United States, 1960–1962 through 2013–2014

NOTES: Age-adjusted by the direct method to the year 2000 U.S. Census Bureau estimates using age groups 20–39, 40–59, and 60–74. Overweight is body mass index (BMI) of 25 kg/m² or greater but less than 30 kg/m²; obesity is BMI greater than or equal to 30; and extreme obesity is BMI greater than or equal to 40. Pregnant females were excluded from the analysis.

SOURCES: NCHS, National Health Examination Survey and National Health and Nutrition Examination Surveys.

Fig. 20.2 Trends in adult overweight, obesity, and extreme obesity among men and women aged 20–74; United States 1960–1962 through 2013–2014.

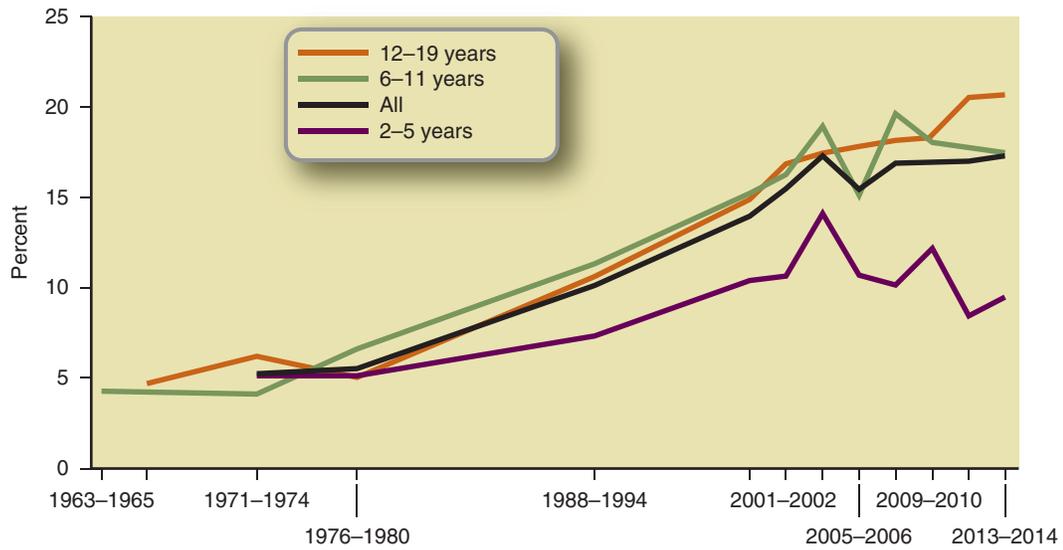

interactions between dietary components and the instructions in a cell or genome, and the resulting changes in metabolites that affect gene expression (Camp and Trujillo, 2014) (see Chapter 6).

The number and size of fat cells, regional distribution of body fat, and RMR also are influenced by genes. Studies of twins confirm that genes determine 50% to 70% of the predisposition to obesity. Although numerous genes are involved, several have received much attention—the *Ob* gene, the *adiponectin* (*ADIPOQ*) gene, the “fat mass and obesity associated” gene or *FTO* gene, and the *beta3-adrenoreceptor* gene. The *Ob* gene produces leptin (Ferguson, 2010). The *beta3-adrenoreceptor* gene, located primarily in the adipose tissue, is thought to regulate RMR and fat oxidation in humans.

Nutritional and/or lifestyle choices can either activate or inhibit these obesity-triggering genes. Thus the formula for successful long-term weight management could necessitate the behavioral application

of individual genetics. Genetic research is currently drawing significant attention from private interests invested in capitalizing on genetic-based “individualized medicine and nutrition” (Loos, 2018). Despite hundreds of “obesity genes” having been identified, however, we are only at the point of being able to apply genetic information to a few individual treatments. One such treatment is congenital leptin deficiency, which can be treated with daily injections of recombinant human leptin (Choquet, 2011). Well known obesity researcher Claude Bouchard, PhD, recently explained that regardless of the growing body of genetic research, “it is hard to see how we can [yet] anchor a prevention or treatment strategy on our genes,” and that, “despite all the noise surrounding this [obesity gene] issue, it still comes down to changing your behavior. It’s diet and exercise” (Endocrine Today, 2018) (see *Clinical Insight: Randomized Controlled Trial Matching Diet to Genetic Predisposition Fails to Improve Weight Loss*).

Trends in obesity among children and adolescents aged 2–19 years, by age: United States, 1963–1965 through 2013–2014

NOTES: Obesity is defined as body mass index (BMI) greater than or equal to the 95th percentile from the sex-specific BMI-for-age 2000 CDC Growth Charts.
 SOURCES: NCHS, National Health Examination Surveys II (ages 6–11) and III (ages 12–17); and National Health and Nutrition Examination Surveys (NHANES) I–III, and NHANES 1999–2000, 2001–2002, 2003–2004, 2005–2006, 2007–2008, 2009–2010, 2011–2012, and 2013–2014.

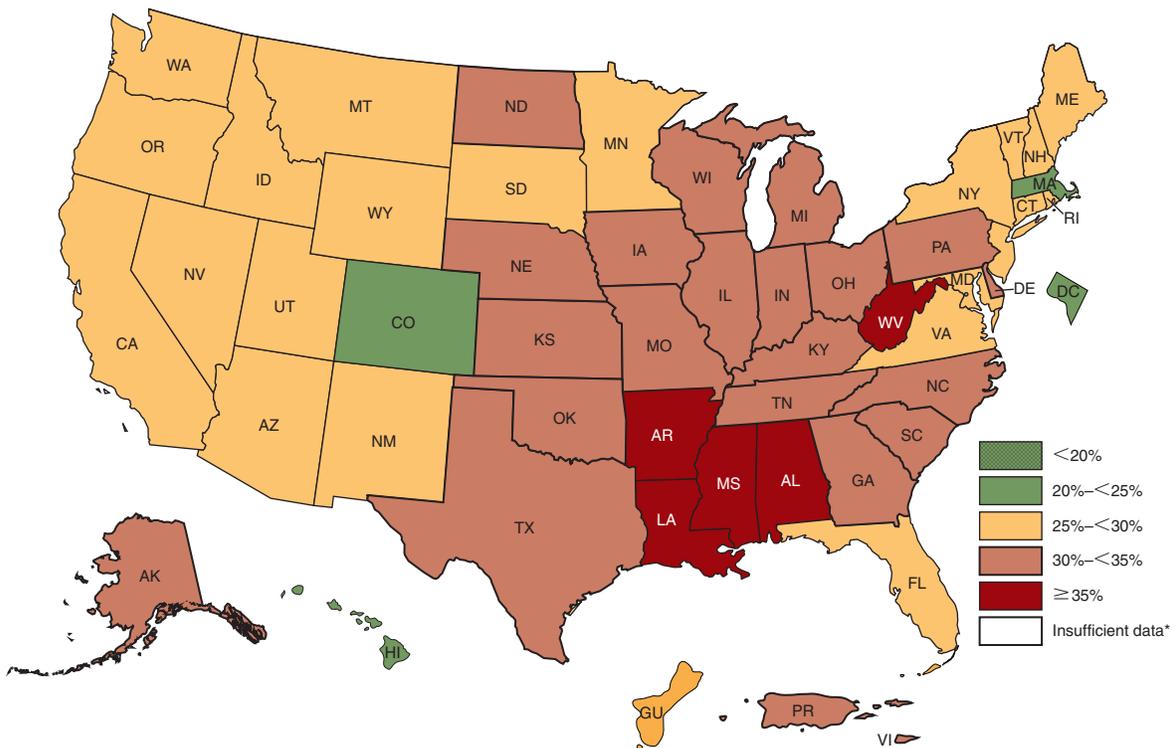

Fig. 20.4 CDC Obesity Prevalence Map Prevalence of obesity among U.S. adults in 2017. (Centers for Disease Control and Prevention [CDC] Behavioral Risk Factor Surveillance System Survey, 2017.)

CLINICAL INSIGHT**Randomized Controlled Trial Matching Diet to Genetic Predisposition Fails to Improve Weight Loss**

The first randomized controlled trial (RCT) to test if genetic predisposition improved weight loss in response to a healthy low-fat vs. healthy high-fat diet showed no difference in weight loss (Gardner et al, 2018). Will personalized medicine and nutrition eventually become the prevailing approach to treatment of disease—including overweight and obesity? This almost certainly will be the case. However, according to a number of scientific papers, the hype surrounding personalized medicine using nutritional genomics remains ahead of the science (Caulfield, 2015; Endocrine Today, 2018; Mozaffarian, 2016).

Inadequate Physical Activity

The view that inactivity is a major factor in the development of overweight and obesity is debated. It is true that lack of regular physical activity is a fact for Americans of all ages. Only 21% of adults meet the recommended levels of weekly physical activity (150 minutes per week of moderate-intensity aerobic activity and two sessions of muscle strengthening) for general health. Meanwhile 250 to 300 minutes of moderate-intensity aerobic activity per week is recommended for weight loss and weight loss maintenance (Chin et al, 2016). However, researchers pushing back on the physical activity emphasis point out that “you can’t outrun a bad diet,” and argue that avoiding sugary drinks, fast food, and overeating in general will save far more calories than people will expend hitting weekly physical activity targets (Fulton, 2016; Malhotra et al, 2015).

Medication Usage and Weight Gain

Although weight gain can be due to disease, clinicians also should consider the possibility that the patient’s medication may be contributing. Diabetes medications, thyroid hormone replacement, psychotropics, antidepressants, steroids, and antihypertensive medications can be problematic. The use of such medications must be considered carefully, and alternatives with less deleterious effects selected when possible (Appendix 13).

Sleep, Stress, and Circadian Rhythms

Lack of adequate sleep alters the endocrine regulation of hunger and appetite. Hormones that affect appetite are activated and may promote excessive energy intake. Recurrent sleep deprivation can modify the amount, composition, and distribution of food intake and may be contributing to the obesity epidemic. It is estimated that more than 50 million Americans suffer from sleep deprivation. Others may have shift work or exposure to bright light at night, increasing the disruption of circadian rhythms and enhancing the prevalence of obesity (Garautet et al, 2013).

There is also a relationship between inadequate sleep, disrupted circadian rhythm, genes, and the development of metabolic syndrome. Stress is another factor. The adrenal hormone cortisol is released when an individual is under stress. Cortisol stimulates insulin release to maintain blood glucose levels in the “fight-or-flight” response; increased appetite eventually follows. Chronic stress with constantly elevated cortisol levels can also lead to appetite changes.

Cortisol levels are typically high in the early morning and low around midnight. Individuals with **night-eating syndrome (NES)** may have a delayed circadian rhythm of meal intake due to genetically

programmed neuroendocrine factors, including altered cortisol levels (Stunkard and Lu, 2010).

Taste, Satiety, and Portion Sizes

Food and its taste elements evoke pleasure responses. The endless variety and reasonable cost of food (especially highly processed food) in the United States contributes to higher calorie intake; people eat more when offered a variety of choices than when a single food is available. Normally, as foods are consumed, they become less desirable; this phenomenon is known as **sensory-specific satiety**. The opposite situation is the “all-you-can-eat buffet,” in which the diner reaches satiety for one food but has many choices remaining for the next course. From an evolutionary perspective sensory-specific satiety promoted the intake of a varied and nutritionally balanced diet; the modern food environment however provides too many (energy-dense, low-nutrient) choices.

Leptin is a hormone, made by fat cells, that decreases appetite. **Ghrelin** is a hormone that increases appetite in response to the time elapsed since the last meal. Levels of leptin, the appetite suppressor, are lower in individuals with a lower body weight and higher in the obese because they correlate to one’s total adipose tissue. However, for reasons yet to be elucidated, people with obesity are seemingly resistant to the appetite-suppressing effects of leptin and are sometimes referred to as leptin resistant.

Passive overeating is partly the result of excessive portion sizes that are now accepted as normal. The portions and calories that restaurants and fast-food outlets commonly serve in one meal can often exceed a person’s energy needs for the entire day.

Obesogens

Endocrine disrupting chemicals (EDCs) are exogenous chemicals that can interfere with any aspect of hormone action. Most EDCs are persistent organic pollutants (POPs), which are manufactured chemicals in the environment (water, food, and food packaging), that are becoming increasingly implicated in bodyweight dysregulation. The original “obesogen hypothesis” (Grün and Blumberg, 2006) pertained to fetal EDC exposure leading to obesity in later life. Most EDCs are lipophilic and stored in adipose tissue. Some EDCs have 3- to 8-year half-lives in the human body. Higher exposure levels may be associated with insulin resistance, expansion of fat storage, alterations in satiety and appetite regulation, greater reductions in RMR with weight loss, and a lesser increase in RMR with weight gain (Liu, 2018). Examples of suspected **obesogens** are bisphenol-A (BPA) and phthalates (in food containers and packaging), organochlorine and organophosphate (banned pesticides), and perfluoroalkyl substances (industrial marine applications) (Nappi, 2016). (See *Clinical Insight: What’s in that Fat When You Lose It?*)

Viruses and Pathogens

In the last two decades, at least 10 adipogenic pathogens have been identified, including viruses, scrapie agents (spongiform encephalopathies from sheep or goats), bacteria, and gut microflora. Whether “infectobesity” is a relevant contributor to the obesity epidemic remains to be determined. A human adenovirus, adenovirus-36 (Ad-36), is capable of inducing adiposity in experimentally infected animals by increasing the replication, differentiation, lipid accumulation, and insulin sensitivity in fat cells and reducing leptin secretion and expression. A growing number of studies have found higher levels of Ad-36 antibodies in subjects with obesity (Ponterio and Gnessi, 2015). To date, three meta-analyses have shown an

association between Ad-36 infection and obesity in both adults and children (Tambo and Pace, 2016).

Gut Microflora and Diet

Researchers studying the microbiome have proposed that the gut may have a bigger role in energy balance than previously thought. A number of theories attempt to explain how this complicated process might work (Krajmalnik-Brown et al, 2012). Essentially, indigestible complex polysaccharides promote and maintain a healthy microbiome. A highly processed-food diet (essentially devoid of indigestible polysaccharides) begins and reinforces a downward spiral of inflammation, increased tendency to store fat, as well as appetite and satiety dysregulation.

Assessment

Overweight and **obesity** are defined as abnormal or excessive fat accumulation that may impair health (WHO, 2018). **Body mass index (BMI)** is calculated by the formula: weight (in kilograms)/height (in meters)². It is possible to be overweight based on BMI but not be “overfat” or obese. It is also possible to have a healthy BMI but still have excessive body fat. In fact, normal weight obesity (NWO) allows patients at greater risk for cardiovascular disease (CVD) and coronary artery disease (CAD) to go unnoticed by their physicians (Ashraf and Baweja, 2013). These situations occur because BMI is only a proxy for adiposity rather than a direct measurement. However, because BMI is derived from readily available measurements of height and weight it is the most convenient clinical approach to estimate body fat. The National Institutes of Health (NIH) guidelines classify individuals with a BMI of ≥ 25 as overweight and those with a BMI of ≥ 30 as obese (Table 20.3). Based on percent body fat content obesity is $\geq 25\%$ in men and $\geq 30\%$ in woman. See Chapter 5 for a detailed discussion of body fat assessment.

Because BMI is a crude proxy for body fat, and also fails to account for body fat distribution, morbidity and mortality studies using BMI consistently produce “J” shaped curves, which at first seem to suggest that lower BMIs are as unhealthy as the higher BMIs (class II obesity or above). When waist-to-hip ratio (WHR) or weight-to-height ratio (WHtR) are substituted for BMI however, both demonstrate positive (linear) relationships with mortality (Carmienke et al, 2013). Similarly, A Body Shape Index (ABSI), which incorporates waist circumference

(WC) with height and weight into one formula, has also been shown to be a better mortality predictor than BMI alone (Krakauer and Krakauer, 2014).

When WC and percentage of fat are both high, they are significant predictors of heart failure and other risks associated with obesity. WC is a strong correlate of insulin sensitivity index in older adults (Huth et al, 2016). A WHR of more than 0.8 for women and 1 for men is associated with high risk for cardiovascular events. Similarly, WC ≥ 40 inches in men and ≥ 35 inches in women signifies increased risk, equivalent to a BMI of 25 to 34.

Health Risks and Longevity

In most people, obesity can be viewed as metabolically unhealthy. Chronic diseases such as heart disease, type 2 diabetes, hypertension, stroke, gallbladder disease, infertility, sleep apnea, hormonal cancers, and osteoarthritis tend to worsen as the degree of obesity increases (Fig. 20.5; see Table 20.3).

There is a subset of obese persons who present as metabolically healthy. This subgroup, the metabolically healthy obese (MHO), has appropriate insulin sensitivity and absence of diabetes, dyslipidemia, and hypertension (Boonchaya-anant and Apovian, 2014). There is currently no universal definition of MHO. However, the idea that MHO might be benign and not require treatment is debatable. In long-term follow-up MHO adults were at increased risk for all-cause mortality and CVD (Kramer et al, 2013). Researchers are urging that treatment of MHO not be ignored until metabolic symptoms occur (Atkinson and Macdonald, 2018).

Inflammation

Obesity is now recognized as a chronic and systemic inflammatory disease whereas it was once believed that excess adipose stores were inert. Adipose tissue is involved in the secretion of a wide range of active substances (tumor necrosis factor, interleukin-6, C-reactive protein [CRP], etc.), most but not all (adiponectin) involved in inflammatory actions. The overall result underlies development of hyperlipidemia, metabolic syndrome, diabetes mellitus, muscle protein loss, CVD, stroke, and some cancers (Buena et al, 2014; Grimbale, 2010; Rocha and Folco, 2011).

Irrespective of the growing body of data on the systemic inflammatory systems set off by obesity, the precise trigger is yet to be determined. One theory is that nutrient overload in adipocytes

TABLE 20.3 Classification of Overweight and Obesity

Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Disease Risk*				
Disease Risk* Relative to Normal Weight and Waist Circumference				
	BMI (kg/m ²)	Obesity Class	Men ≤ 102 cm (≤ 40 in) Women ≤ 88 cm (≤ 35 in)	> 102 cm (>40 in) > 88 cm (>35 in)
Underweight	<18.5		—	—
Normal ⁺	18.5-24.9		—	—
Overweight	25.0-29.9		Increased	High
Obesity	30.0-34.9	I	High	Very High
	35.0-39.9	II	Very High	Very High
Extreme Obesity	≥ 40	III	Extremely High	Extremely High

* Disease risk for type 2 diabetes, hypertension, and CVD.

⁺ Increased waist circumference can also be a marker for increased risk even in persons of normal weight.

From National Institutes of Health, National Heart, Lung, and Blood Institute: Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: Evidence Report, NIH Publication No. 98-4083, 1998.

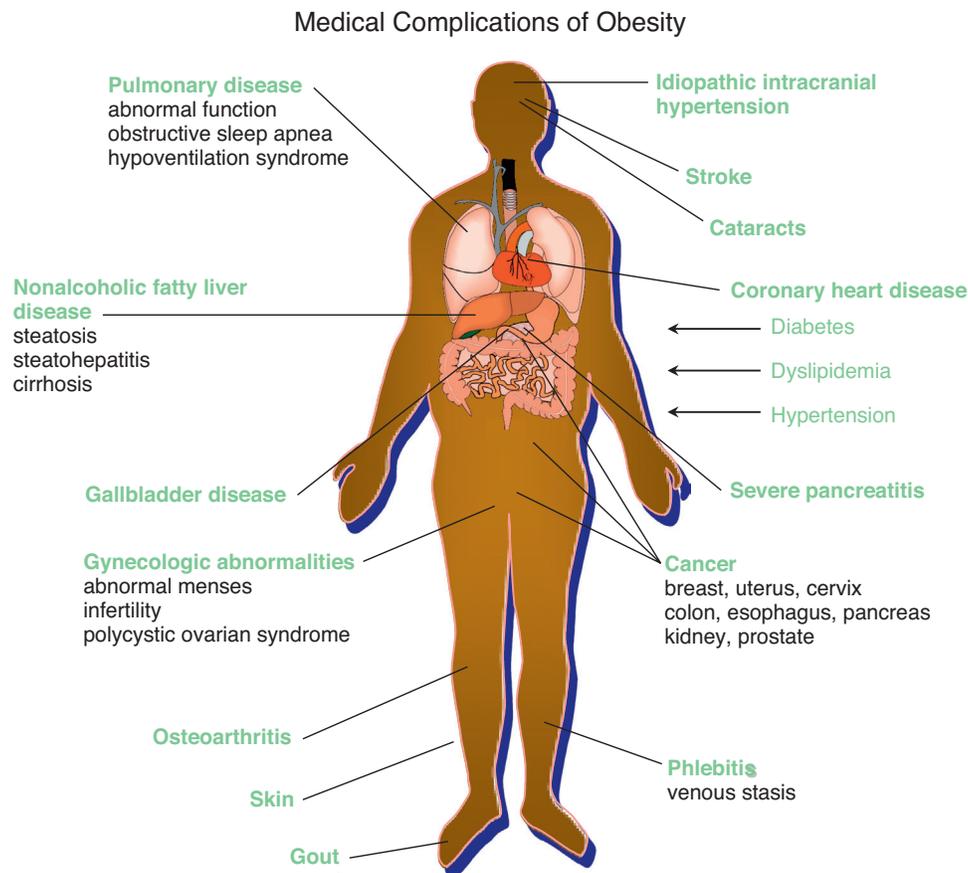

Fig. 20.5 The medical complications of obesity are extensive. (Reprinted with permission from Delichatsios HK: Obesity assessment in the primary care office, Harvard Medical School. 23rd Annual International Conference-Practical approaches to the treatment of obesity, Boston, June 18-20 2009).

induces intracellular stress, which results in activation of inflammatory cascades (Ellulu et al, 2017). As discussed earlier, other factors implicated in the development of inflammation include microbiome-derived endotoxins, environmental chemicals, viruses, saturated fats, and chronic overeating. A dietary change to an antiinflammatory diet and regular physical activity can reduce obesity-related inflammation. (For discussion of inflammation, see Chapter 7.)

Nonalcoholic fatty liver disease (NAFLD) is associated with overweight and obesity and may progress to end-stage liver disease (see Chapter 28). Obesity is also a risk factor for various cancers, infertility, poor wound healing, and poor antibody response to hepatitis B vaccine. Thus the costs of obesity are staggering. The CDC estimates the direct cost of care for obesity at \$147 billion (CDC, 2008). The Internal Revenue Service issued a rule in 2002 qualifying obesity as a disease, allowing taxpayers to claim weight loss expenses as a medical deduction if undertaken to treat an existing disease.

The U.S. government recognizes the immense effect of obesity on the health and financial well-being of its citizens. Healthy People 2020 objectives also identify the implications of overweight and obesity (see Chapter 8). The objectives include targets to increase the proportion of adults who are at a healthy weight and to reduce the proportion of adults, children, and adolescents who are obese. Overweight adolescents often become obese adults; obese individuals

are at increased risk for **comorbidities** of type 2 diabetes, hypertension, stroke, certain cancers, infertility, and other conditions.

Fat Deposition and the Metabolic Syndrome

Regional patterns of fat deposit are controlled genetically and differ between and among men and women. Two major types of fat deposition are excess subcutaneous truncal-abdominal fat (the apple-shaped **android fat distribution**) and excess gluteofemoral fat in thighs and buttocks (the pear-shaped **gynoid fat distribution**). The android shape is more common among men. Gynoid fat deposition in women during child-bearing years is utilized to support the demands of pregnancy and lactation. Women with the gynoid type of obesity do not develop the impairments of glucose metabolism in those with an android deposition (Wajchenberg, 2013). Postmenopausal women more closely follow the male pattern of abdominal fat stores, sometimes referred to as “belly fat.”

Abdominal fat is an indicator of fat surrounding internal organs or visceral fat. According to a major study done through the Brigham and Women’s Hospital in Boston over 7 years and including more than 3000 people (Framingham Study patients were used), those with higher amounts of abdominal fat, versus fat in other parts of the body, were found to have higher risks of cancer and heart disease (Britton et al, 2013). Many other reputable scientific studies have been performed, validating the findings repeatedly.

Visceral obesity, or excessive VAT under the peritoneum and in the intraabdominal cavity, is correlated highly with insulin resistance and diabetes. **Metabolic syndrome (Mets)** consists of three or more of the following abnormalities: waist circumference ≥ 102 cm (40 in) in men and ≥ 88 cm (35 in) in women, serum TGs ≥ 150 mg/dL, high-density lipoprotein (HDL) level less than 40 mg/dL in men and less than 50 mg/dL in women, blood pressure 135/85 mm Hg or higher, or fasting glucose 100 mg/dL or higher. Increased visceral fat is a risk factor for CAD, dyslipidemia, hypertension, stroke, type 2 diabetes, and Mets (Wajchenberg, 2013). By the same token, VAT and low cardiorespiratory fitness (CRF) levels are associated with a deteriorated cardiometabolic risk profile. Achieving a low level of VAT and a high level of CRF is an important target for cardiometabolic health.

Weight Discrimination

Widespread bias and discrimination based on weight have been documented in education, employment, and health care. Like other forms of prejudice, this stems from a lack of understanding of the chronic, complex, and sometimes intractable nature of obesity and its medical consequences. The United States is the first (and only) country that currently classifies obesity as a disease; the disease classification was necessary in order for insurance to cover obesity treatment within the U.S. health care system (Müller and Geisler, 2017). The vast majority of the United States does not consider obesity a protected class and therefore weight-based employment discrimination does not have a basis for a legal claim (Pomeranz and Puhl, 2013). Both adults and children with a larger body size experience adverse social, educational, and psychological consequences as a result of weight bias. They also face discrimination from healthcare providers and this can affect their willingness to seek medical care. It is essential to break down the barriers caused by ignorance and indifference. Patient support groups help to correct the negative effect of this type of discrimination.

MANAGEMENT OF OBESITY IN ADULTS

In 1998 the National Heart, Lung, and Blood Institute (NHLBI) in collaboration with National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) issued the *Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: Evidence Report*. It was the first federal clinical practice guidelines to deal with overweight and obesity issues developed using evidence-based medicine methodology. The guidelines provided the scientific evidence behind the recommendations for weight loss and weight loss maintenance as well as practical strategies for implementing the recommendations. The 1998 clinical guidelines were partially updated in 2013 addressing five specific questions and published in three major medical journals (NHLBI, 2014). The five areas addressed in 2013 were as follows: (1) what are the expected health benefits of weight loss as a function of the amount and duration of weight loss, (2) are current WC and BMI cut points appropriate (defined obesity) for certain population subgroups, (3) which diets—among a handful of popular diets—are effective for weight loss, (4) what is the efficacy and effectiveness of comprehensive lifestyle approaches to weight loss and weight loss maintenance, and (5) what is the efficacy and safety of bariatric surgical procedures.

Before the NHLBI evidence report clinicians focused almost entirely on weight loss via caloric restriction, exercise was not routinely recommended, and weight loss maintenance was generally overlooked. The strategies for weight loss (and weight loss maintenance)

analyzed, reviewed, and outlined in the NHLBI report were dietary therapy (CR), physical activity, behavior therapy (self-monitoring, stress management, stimulus control, problem-solving, contingency management, cognitive restructuring, and social support), combined therapy (dietary, physical activity, and behavioral therapies), pharmacotherapy, and surgery. Today, a chronic disease-prevention model incorporates these interdisciplinary therapies and lifestyle interventions from physicians, dietitians, exercise specialists, and behavior therapists.

Goals of Treatment

The goal of obesity treatment is to achieve enough weight loss to significantly improve overall health. Achieving a moderate loss is beneficial. Obese persons who lose 5% to 10% of initial body weight are likely to improve their blood glucose, blood pressure, and cholesterol levels and reduce various markers of systemic inflammation. Since continual, gradual weight gain is the norm, choosing to maintain present body weight is also beneficial (but also requires vigilance and effort).

Despite the recognition that moderate weight loss is beneficial and may be more easily achievable, patients usually have self-defined goal weights that are considerably higher. Therefore health professionals need to encourage their patients to target more realistic initial weight loss goals.

In general, weight loss after age 65 is not advised; actuarial tables show no benefit and possible harm due to loss of LBM. In fact, in the obese older adult, sarcopenia (loss of muscle mass) is the strongest predictor of disability and inability to perform daily activities. A BMI below 23 is considered below desirable in older adults (see Chapter 19).

Rate and Extent of Weight Loss

Reduction of body weight involves the loss of both protein and fat. The relative proportions of each depend on initial body composition and to some degree by the rate of weight reduction. Strength training can help minimize loss of lean tissue in some subjects. Steady weight loss over a longer period favors reduction of fat stores, limits the loss of vital protein tissues, and minimizes the decline in resting energy expenditure (REE) that can accompany severe energy restriction. Recommended calorie deficit guidelines result in a loss of approximately 0.5 to 1 pound per week for persons with a BMI of 27 to 35, and 1 to 2 pounds per week for those with BMIs greater than 35. These energy deficits need to be individually calculated, and continually adjusted with weight loss in order to maintain the targeted calorie deficits and therefore weekly rates of weight loss (Byrne et al, 2012). When these deficits are maintained, they will lead to an approximately 10% weight loss in 6 months (Academy of Nutrition and Dietetics [AND], 2016). For the next 6 months the focus changes from weight loss to weight maintenance. After this phase, further weight loss may be considered.

Even with the same caloric intake, rates of weight reduction vary. Men reduce weight faster than women of similar size because of their higher LBM and RMR. The heavier person expends more energy than one who is less obese and loses faster on a given calorie intake than a lighter person.

Many people who do not lose weight when following a prescribed energy restriction may be consuming more energy than they report and may also overestimate their physical activity levels. Underreporting of energy intake is the norm and is shown to increase with BMI. Underreporting of estimated intake has been extensively studied; it impacts the reliability of epidemiologic studies and creates the illusion

of resistance to weight loss during energy restriction (Dhurandhar et al, 2015).

Lifestyle Modification

Behavior modification is the cornerstone of lifestyle intervention. It focuses on restructuring a person's environment, dietary intake, and physical activity by using goal setting, stimulus control, cognitive restructuring, and relapse prevention. It also provides feedback on progress and places the responsibility for change and accomplishment on the patient.

Stimulus control involves identifying stimuli that may encourage incidental eating and identifying and limiting exposure to high-risk situations. Examples of stimulus control strategies include learning to shop carefully for healthy foods, shopping when not hungry, keeping high-calorie foods out of the house, limiting the times and places of eating, and consciously avoiding situations in which overeating occurs.

Problem solving is the process of defining a problem, generating possible solutions, evaluating and choosing the best solution, implementing the new behavior, evaluating outcomes, and reevaluating alternative solutions if needed.

Cognitive restructuring teaches patients to identify, challenge, and correct the negative thoughts that frequently undermine their efforts to lose weight and keep it off. A cognitive therapy program that underscores the inextricable connection between emotions and eating, and how to manage that connection successfully using positive long-term mental strategies, has been developed and found useful (Beck, 2011).

Self-monitoring with daily food and activity records is positively associated with greater weight loss. Adding the place and time of food intake, as well as accompanying thoughts and feelings, adds complexity (which reduces compliance) but may help identify the physical and emotional settings in which eating occurs. Physical activity can be tracked in minutes, miles, or calories expended. Self-monitoring can also provide insight into the occurrence of relapses and how they can be prevented.

A comprehensive program of lifestyle modification produced a loss of approximately 10% of initial weight in 16 to 26 weeks in a review of randomized controlled trials, including the Diabetes Prevention Program. Long-term continued patient-therapist contact significantly improves weight-loss maintenance (AND, 2016).

Email and phone consults appear to be useful methods for contact and support as part of structured behavioral weight loss and weight loss maintenance programs. Multiple strategies for behavior therapy often are needed. Self-monitoring with mobile device apps (see Box 4.5 in Chapter 4), pharmacotherapy, targeted educational interventions from the web, meal replacements, and telephone interventions have taken over the weight loss industry. Body monitoring—a new monitoring method to measure weight change—involves wearing a device that tracks body processes like temperature, movement, acceleration, heating fluctuations, and so on—and records calorie burn. Combined with a food log entered into the system, a person can adjust food intake based upon data provided by the system.

Telehealth programs, which provide interaction with health care professionals through visual and verbal communication via phone and computer screens, are exploding in health care, while saving tremendous costs and time. Telehealth is now being used as an effective vehicle with dietitians for one-on-one and group consults and for providing nutrition education programs.

Dietary Modification Recommendations

Weight loss programs should combine a nutritionally balanced dietary regimen with exercise and lifestyle modification. Selecting the appropriate treatment strategy depends on the goals and health risks of the patient. When these approaches fail to bring about the desired reduction in body fat, sometimes medication may be added. For **morbid obesity** (BMI ≥ 40) surgical intervention may be necessary.

Treatment options include the following:

- A balanced reduced-calorie macronutrient adjusted eating plan, increased physical activity, and lifestyle modification
- A balanced reduced-calorie macronutrient adjusted eating plan, increased physical activity, lifestyle modification, and pharmacotherapy
- Surgery plus an individually prescribed eating regimen, physical activity, and lifestyle modification program
- Prevention of weight regain via actively balancing energy intake and output
- Mindset interventions via cognitive restructuring

Restricted-Energy Eating Plan

A balanced, restricted-energy eating plan is the most widely prescribed method of weight reduction. The diet should be nutritionally adequate and meet but not exceed energy needs for weight reduction. A caloric deficit of 500 to 1000 kcal daily usually meets this goal for subjects ≥ 30 BMI. The prescribed energy level varies with the individual's body size and activities. For example, for a 500-calorie deficit the initial daily energy prescription for a 5'5", age 35, 30-BMI female would be approximately 1400 calories, or approximately 1700 calories for a 40-BMI female of the same height and age. Regardless of the level of CR, healthful eating and regular physical activity should be daily goals. All means possible (coaching, motivational interviewing, cognitive restructuring, etc.) should be utilized by the health care team to support healthy lifestyle changes.

All reduced calorie diets (low-fat, low-carbohydrate, balanced) produce similar (long-term) weight loss which means recommendations can be tailored to individual preferences (Hall, 2017; Johnston, 2014). In all cases subjects should be encouraged to consume predominantly whole foods options (fresh, unprocessed vegetables, fruits, beans [legumes], and whole grains plus a variety of seafood, poultry, and lean meats).

The recommended dietary allowance (RDA) for protein is based on maintenance level energy requirements and is not applicable to the situation of energy restriction. Too little attention to protein intake during energy restriction results in undesirable effects on LBM and underlying REE. Protein prescription of 1.2 g per kg appears to be necessary to minimize the loss of LBM, prevent reduced REE, and preserve bone mineral density in situations of energy restriction (Drummen et al, 2018; Leidy, 2015; Westerterp-Plantenga et al, 2012). However, higher levels of protein also tend to blunt improvements in insulin resistance in individuals with insulin resistance.

Alcohol and foods high in sugar, especially beverages, should be limited to small amounts. Alcohol makes up 10% of the diet for many regular drinkers and contributes 7 kcal/g. Heavy drinkers who consume 50% or more of daily calories from alcohol may have a depressed appetite, whereas moderate users tend to gain weight with the added alcohol calories. Habitual use of alcohol may result in lipid storage, weight gain, or obesity.

There is no evidence that using nonnutritive sweeteners reduces food intake or enhances an individual's weight loss. A recent meta

analysis of the available studies on nonnutritive sweeteners concluded that the literature does not clearly support the intended benefits of nonnutritive sweeteners for weight management, and observational data suggest that routine intake of nonnutritive sweeteners may be associated with increased BMI and cardiometabolic risk. Further research is needed to fully characterize the long-term risks and benefits of nonnutritive sweeteners (Azad et al, 2017).

Vitamin and mineral supplements that meet age-related requirements usually are recommended when there is a daily intake of less than 1200 kcal for women and 1800 kcal for men, or when it is difficult to choose foods that will meet all nutrient needs at the restricted energy intake.

Weight Loss Programs

Commercial and Self-Help Programs

Millions of Americans turn to **commercial weight loss centers** (NutriSystems, Jenny Craig, etc.) (Table 20.4) or **self-help programs** (diet book or Internet-based) in search of permanent weight loss each year. Commercial weight loss centers usually require the use of proprietary prepackaged meals. Prepackaged diets allow subjects to avoid food preparation and reduce the number of choices about food (and what to eat) throughout the day. Some provide classes on behavior modification and healthy eating.

Some brands of **meal replacements** are available over the counter (OTC) in drug stores, supermarkets, or via home delivery (e.g., Weight Watchers, SlimFast, HMR, etc.). The goal of using these foods is to provide structure and replace other higher calorie foods. Per serving, most meal replacements include 10 to 20 g of protein, various amounts of carbohydrate, 0 to 10 g of fat, up to 5 g of fiber, and 25% to 30% of RDAs for vitamins and minerals. Usually drinks or shakes are milk (casein or whey), pea protein, rice protein, or soy based; are high in calcium; and have 150 to 250 kcal per serving. They are frequently ready to use, portion controlled, or made with a purchased powder. People who have difficulty with self-selection or portion control may use meal replacements as part of a comprehensive weight management program. Substituting one or two daily meals or snacks with meal replacements is a successful weight loss and weight maintenance strategy (AND, 2016). Meal replacements are also utilized in **medically supervised weight loss programs** (see Very-Low-Calorie Diets).

The Internet has spawned a new generation of web-based weight loss options including Diet.com, NutriSystem.com, SparkPeople.com, SouthBeach.com, MyFitnessPal, and WeightWatchers.com. A handful of randomized controlled clinical trials have attempted to address whether personalization improves outcomes from these programs. However, results have been mixed and it remains to be determined (Collins et al, 2012). Apart from Weight Watchers, there is not a strong base of evidence behind the major commercial and self-help weight loss programs. The Federal Trade Commission (FTC) requires program advertisements to voluntarily include the phrase “results not typical,” but has insufficient resources to further protect consumers from misleading advertising. More controlled trials are needed to assess the efficacy of commercial programs, therefore it is important to evaluate all weight loss programs for sound nutritional and behavioral practices.

Very-Low-Calorie Diets

Diets providing ≤ 800 kcal are classified as **very-low-calorie diets (VLCDs)**. Little evidence suggests that an intake of fewer than 800

calories daily is of any advantage. An example of a significant exception to this would be the hospitalized patient on a metabolic unit who is monitored carefully, is less than 65 years old, and has a condition such as congestive heart failure secondary to obesity. In such a case, immediate and rapid weight loss is considered life saving.

VLCDs are hypocaloric but relatively rich in protein (0.8 to 1.5 g per kg per day). They are designed to include a full complement of vitamins, minerals, electrolytes, and essential fatty acids, but not calories, and they are usually given for a period of 12 to 16 weeks as part of a medically supervised comprehensive lifestyle-modification program requiring regular medical monitoring and attendance of weekly group classes. Their major advantage (with patient compliance) is rapid weight loss.

Physicians often refer patients that would benefit medically (Fig. 20.6) from rapid weight loss (e.g., severe obstructive sleep apnea, congestive heart failure, and severe obesity with multiple comorbidities) to VLCD programs. Because of potential side effects, prescription of these diets is reserved for persons with a BMI of ≥ 30 (or ≥ 27 with at least one comorbidity) for whom other diet programs have been unsuccessful.

An OTC VLCD that first became popular in the early 1970s resulted in several deaths related to its low-quality, incomplete protein profile. The high-quality protein formulations used in medically supervised programs provide efficacy and safety for those with morbid obesity. Adverse side effects to VLCDs include higher risk for gallstones, cold intolerance, fatigue, weakness, lightheadedness, constipation or diarrhea, hair loss, dry skin, menstrual changes,

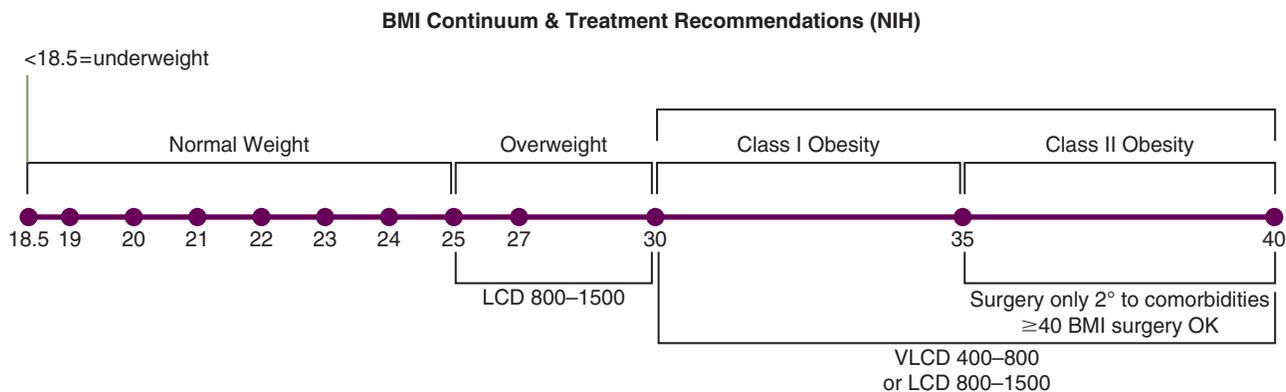

Fig. 20.6 BMI Continuum & Treatment Recommendations (NIH). 1998 National Heart, Lung, and Blood Institute - National Institute of Diabetes and Digestive and Kidney Diseases: Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: Evidence Report.

and gout; some of these may be related to triiodothyronine (thyroid) deficiency (see Chapter 30). Emerging data seem to indicate that as fat stores diminish, molecules are released that can affect further weight loss (see *Clinical Insight: What's in That Fat When You Lose It?*).

The current literature indicates that even though there is significantly greater weight loss with VLCDs in the short term (up to 13% greater than low calorie diets, or LCDs, with behavioral counseling), there are on average no significant differences in the long term (Gudzune et al, 2015). Weight loss maintenance requires ongoing vigilance and permanent lifestyle changes—that target a reduced weight net-energy-balance—regardless of the methods employed to lose weight (Hall et al, 2011).

Popular Diets and Practices

Each year, new books (or websites) promising weight loss find their way to the consumer through the popular press and media. Some of the programs are sensible and appropriate, whereas others emphasize fast results with minimum effort. Some of the proposed diets would lead to nutritional deficiencies over an extended period; however, the potential health risks are seldom realized because the diets usually are abandoned after a few weeks. Diets that emphasize fast results with minimum effort encourage unrealistic expectations, setting the dieter up for failure, subsequent guilt, and feelings of helplessness about managing a weight problem.

Online commercial diet programs have grown dramatically in the past decade. A programmed approach, for people on the run who carry their phones and computers, with a product line offered and accessibility to counselors and health professionals, has made the business of diets a multibillion-dollar industry. One on one and group online counseling, phone access to discuss weight loss progress and setbacks, and delivery of “to-your-door” foods and meals are some of the enticing aspects of joining these programs. Consumers continue to need proper guidance to separate the good, sound diet programs from the bad. Popular diets come and go; some are reviewed or described by various websites (see Table 20.4).

Intermittent Fasting

Traditionally, fasting has been considered primarily the act of willingly abstaining from food, drink, or both, for a set period of time and has

been used at different times of the year in religious observances for centuries. Applying **intermittent fasting (IF)** type regimes as an approach to weight loss has recently been popularized by various diet books which claim there are metabolic advantages to IF leading to faster, or more, weight loss.

In the popular literature IF encompasses a variety of approaches including (1) limiting eating to the same 8 hours daily, (2) an alternating pattern of under- and overeating days, (3) fasting 2 days per week and eating normally the other 5 days, and (4) having regular splurge days (in the middle of stretches of fasting).

While there are multiple studies pertaining to IF in the scientific literature, most are studying biomarkers of cardiovascular disease or longevity and have not looked at weight loss as an outcome. Additionally, many have no control or comparison groups. Reviews of studies that have compared IF with a constant-calorie-restriction group (Davis et al, 2016; Harris et al, 2018; Headland et al, 2016) find no differences in weight loss, body composition, or insulin sensitivity.

Some popular IF regimes have been criticized for promoting an unhealthy “anything goes” diet on nonfasting days, which seems to border on encouragement for bingeing and/or disordered eating. Diet quality, however, becomes more—not less—important during any ongoing period of energy restriction.

In summary, IF is no more effective than other approaches to calorie restriction and the effects of using IF for weight loss maintenance have yet to be studied.

Low-Carbohydrate and Ketogenic Diets

When carbohydrate intake is less than 50 g per day, **ketosis** provides the brain and skeletal muscles with an alternate energy source in the form of **ketones** derived from lipolysis (the breakdown of fat). Ketones are believed to improve satiety (suppress appetite), at least initially.

Low-carbohydrate and ketogenic diets provide rapid initial weight loss from diuresis secondary to the carbohydrate restriction; early weight loss may be $\geq 60\%$ water. This diuretic effect is a result of depleted liver and muscle glycogen which holds three to four times its weight in water.

In a classic energy-nitrogen balance method study comparing an 800-calorie ketogenic diet with an 800-calorie mixed diet, subjects did lose weight more rapidly at the beginning of the ketogenic diet period,

however the extra weight loss was due solely to excess water losses. Both diets led to the same amount of body fat and protein (LBM) losses (Yang and Van Itallie, 1976). A recent much shorter version of this type of study by the NIH also found no advantage to the ketogenic diet (Hall et al, 2015).

The impact of a ketogenic diet on the microbiome and overall nutrient intake are two areas of concern. A recent study on the effect of a ketogenic diet on the gut microbiota found a bacterial group supposed to be involved in the exacerbation of the inflammatory condition of the gut mucosa associated with the ketogenic diet pattern (Tagliabue et al, 2017). The recommended upper limit for dietary fat is 35% of calorie intake per the dietary reference intakes, which are intended to ensure adequate micronutrients and shield against preventable diseases (see Appendix 19 on the ketogenic diet).

High-protein (rather than high-fat) variants of low-carbohydrate and ketogenic diets include the Zone and South Beach Diets, which restrict carbohydrates to no more than 40% of total calories, with fat and protein each providing 30% of total calories. These diets are considered moderate choices within the low-carbohydrate category and include generous amounts of fiber and fresh fruits and vegetables, and they stress the kind of fat, with emphasis on monounsaturated and polyunsaturated fat and limitation of saturated fat. For more information about a ketogenic diet and the conditions for which it has been studied, see Appendix 19.

Unanswered questions about the ketogenic diet include:

- What are the long-term (1 year or longer) effects, is it safe?
- Do the diet's health benefits extend to higher risk individuals with multiple health conditions and the elderly? For which disease conditions do the benefits of the diet outweigh the risks?
- As fat is the primary energy source, what is the effect of such a high-fat diet that includes so much saturated fat?
- Is the high fat, moderate protein intake on a ketogenic diet safe for disease conditions that interfere with normal protein and fat metabolism, such as heart, kidney, and liver diseases?
- Is a ketogenic diet too restrictive for periods of rapid growth?
- Is the ketogenic diet safe and is it effective for athletes?

The **carbohydrate-insulin theory of obesity** is the foundation of low-carbohydrate and ketogenic diets. The basic theory is that carbohydrates stimulate insulin secretion causing increased fat storage, which increases appetite and suppresses metabolism resulting in weight gain. Low carbohydrate intake does decrease insulin secretion (Abassi, 2018). The insulin theory however, only describes postprandial energy metabolism while ignoring the rest of the 24-hour energy metabolism picture. Insulin levels don't remain elevated, and overnight—in the fasting state—fat oxidation increases, reducing fat stores. A net gain in fat stores only occurs with positive energy balance. Recent carefully controlled metabolic laboratory studies appear to have invalidated the insulin theory of obesity (Hall et al, 2015; Hall and Guo, 2017). A recent systematic review of high quality randomized controlled trials (RCTs) comparing low-carbohydrate with isoenergetic (having the same total calories) balanced diets found essentially no difference in weight loss, measures of glycemic control, blood pressure, or blood lipid between the two diets (Naude et al, 2014).

Very-Low-Fat (High-Carbohydrate) Diets

Very-low-fat (high-carbohydrate) diets contain less than 10% of calories from fat, such as the original Dr. Dean Ornish's Program for Reversing Heart Disease and the Pritikin Program. Ten percent of energy from fat however is well below the current acceptable macronutrient distribution range (AMDR) for fat which is 20% to 35% of total calorie intake (National Academy of Sciences Institute of Medicine, 2005).

TABLE 20.5 Acceptable Macronutrient Distribution Ranges (AMDR)% of Total Calorie Intake

	2005	Previous Guidelines
Protein	10% to 35%	10% to 35%
Carbohydrate	45% to 65%	50% or more
Fat	20% to 35%	30% or less

NAS IOM: Dietary Reference Intakes for Energy, Carbohydrate, Fiber, Fat, Fatty acids, Cholesterol, Protein, and Amino Acids (Macronutrients), *The National Academies Press*. 2005.

Less than 20% fat may negatively impact essential fatty acid intake and fat-soluble nutrient absorption (Table 20.5). Less restrictive and more popular variations of these diets do allow fat as 20% of total energy intake. Weight loss on these diets is due solely to energy restriction. Because fat provides more than two times the energy per gram as protein or carbohydrate (9 kcal versus 4 kcal), limiting fat is theoretically the most efficient way to decrease calories. The unforeseen consequence of severe fat restriction however is compensatory intake of sugar and/or processed carbohydrates which can trigger metabolic syndrome.

Balanced Lower Calorie Diets

Balanced-nutrient reduction diets are less common among so-called “popular” diets. The full document of the (2015–2020) Dietary Guidelines for Americans outlines the details of three eating plans in its appendices that qualify: the Healthy U.S.-Style Eating Pattern, Healthy Mediterranean-Style Eating Pattern, and Healthy Vegetarian Eating Pattern.

Reduced-energy diets for weight management should be nutritionally sound, not harmful, and feasible to maintain over time. This requires sustainability in terms of ease of adherence, using readily available and affordable foods, and social and cultural acceptability (Naude et al, 2014). The U.S. Department of Agriculture (USDA) supported a scientific review of popular diets to assess their efficacy for weight loss and weight maintenance, as well as their effect on metabolic parameters, mental well-being, and reduction of chronic disease. A summary is shown in Table 20.6.

Over-the-counter medications and herbal supplements for weight loss have been popular for many years. With some exceptions, the majority of these supplements have limited data with regard to their efficacy and safety, and many of the most effective supplements for weight loss (caffeine and ephedra) have significant cardiovascular and neurologic risks or have been banned by the Food and Drug Administration (FDA) (e.g., ephedra). Dietitians should be aware of popular supplements in order to best serve clients and patients. According to the FDA, a high percentage of weight loss products are adulterated and contain illegal drugs and stimulants that are not listed on the label. See Table 20.7 for popular nutritional supplements used for weight loss. Reliable information on dietary supplements can be obtained from the NIH Office of Dietary Supplements website as well as consumer warnings on recalled and banned products from the FDA's website (see Chapter 11).

Physical Activity

Physical activity is the most variable component of energy expenditure (see Chapter 2). Increases in energy expenditure through exercise and other forms of physical activity are important components of interventions for weight loss and its maintenance. By increasing LBM in proportion to fat, physical activity helps to balance the loss of LBM

TABLE 20.6 Results of U.S. Department of Agriculture Scientific Review of Popular Diets

Area	Finding
Weight loss	Diets that reduce caloric intake result in weight loss; all popular diets result in short-term weight loss if followed.
Body composition	All low-calorie diets result in a loss of body fat. In the short term, high-fat, low-carbohydrate, and ketogenic diets cause a greater loss of body water than body fat.
Nutritional adequacy	<ul style="list-style-type: none"> • High-fat, low-carbohydrate diets are low in vitamins E and A, thiamin, B₆, and folate; and the minerals calcium, magnesium, iron, and potassium. They are also low in dietary fiber. • Very-low-fat diets are low in vitamins E and B₁₂ and the mineral zinc. • With proper food choices, a moderate-fat, balanced-nutrient reduction diet is nutritionally adequate.
Metabolic parameters	<ul style="list-style-type: none"> • Low-carbohydrate diets cause ketosis and may significantly increase blood uric acid concentrations. • Blood lipid levels decline as body weight decreases. • Energy restriction improves glycemic control. • As body weight declines, blood insulin and plasma leptin levels decrease. • As body weight declines, blood pressure decreases.
Hunger and compliance	No diet was optimal for reducing hunger.
Effect on weight maintenance	Controlled clinical trials of high-fat, low-carbohydrate, low-fat, and very-low-fat diets are lacking; therefore no data are available on weight maintenance after weight loss or long-term health benefits or risk.

From Freedman M et al: Popular diets: a scientific review, *Obes Res* 9(Suppl 1):1S, 2001.

TABLE 20.7 Nonprescription Weight Loss Products

Product	Claim	Effectiveness	Safety
Alli: OTC version of prescription drug orlistat (Xenical)	Decreases absorption of dietary fat	Effective; weight loss amounts typically less for OTC versus prescription	FDA investigating reports of liver injury, pancreatitis
Bitter orange (synephrine)	Increases calories burned	Insufficient reliable evidence to rate	Possibly unsafe, increase in heart rate and blood pressure
Chitosan	Blocks absorption of dietary fat	Ineffective for weight loss	Possibly safe, may cause bloating
Chromium	Increases calories burned, decreases appetite, and builds muscle	Insufficient reliable evidence to rate	Likely safe
Conjugated linoleic acid (CLA)	Reduces body fat and builds muscle	Ineffective for weight loss	Possibly safe
Ephedra (Ma Huang)	Decreases appetite and increases fat burned	Possibly effective	Unsafe due to cardiovascular risk and banned by FDA
Green tea extract	Increases calorie and fat metabolism and decreases appetite	Ineffective for weight loss	Possibly safe
Guar gum	Blocks absorption of dietary fat and increases feeling of fullness	Ineffective for weight loss	Likely safe but increased gastrointestinal distress
<i>Hoodia gordonii</i>	Decreases appetite	Insufficient reliable evidence to rate	Insufficient information, high risk of mislabeling
Senna	Cathartic; laxative, causes diarrhea	Insufficient reliable evidence to rate	Likely unsafe, stimulant laxative
Raspberry ketones	Increases lipolysis	Insufficient reliable evidence to rate	Likely unsafe especially for hypertension
<i>Garcinia cambogia</i>	Blocks enzymes in body which convert glucose to fat. Also increases serotonin in brain, limiting appetite and providing extra energy	Ineffective for weight loss (Esteghamati, 2015)	Reports of liver damage associated

FDA, Food and Drug Administration; OTC, over the counter.

Complementary and alternative medicine for the treatment obesity: a critical review. *Int J Endocrinol Metab* 2015; 13:e19678; Pittler MH, Ernst E. Guar gum for body weight reduction: meta-analysis of randomized trials. *Am J Med* 2001; 110:724. Up to Date Obesity in adults: Drug Therapy

and reduction of RMR that inevitably accompany intentional weight reduction. Other positive side effects of increased activity include strengthening cardiovascular integrity, increasing sensitivity to insulin, and expending additional energy and therefore calories.

The CDC's Physical Activity Guidelines for Americans suggest a minimum of 150 minutes of physical activity weekly, with two sessions of weight training, to achieve health benefits. However, recent studies have shown that adhering to physical activity guidelines without adhering to a calorie-restricted diet will lead to only minimal or modest weight loss; proper nutritional intake is crucial for weight loss. For weight maintenance or prevention of weight gain, 200 to 300 minutes of weekly physical activity may be more effective. The majority of participants in the National Weight Control Registry (NWCRC) who have kept off at least 10% of their weight for at least a year report 1 hour per day of physical activity (at least 420 minutes per week).

Overweight and obese adults should gradually increase to optimal levels of physical activity. Even if an overweight or obese adult is unable to achieve this level of activity, there is evidence that significant health benefits can be realized by participating in at least 30 minutes of daily activity of moderate intensity. Targeting these levels of physical activity can improve health-related outcomes and facilitate long-term weight control.

Aerobic exercise and resistance training should be recommended. Resistance training increases LBM, raising the RMR and one's ability to use more of the energy intake, and increases bone mineral density, especially for women (see Chapter 23). Aerobic exercise is important for cardiovascular health through elevated RMR, calorie expenditure, energy deficit, and loss of fat. In addition to the physiologic benefits of exercise, other benefits include relief of boredom, increased sense of control, and improved sense of well-being. The whole family can get involved in pleasurable exercise activities (Fig. 20.7).

The recommendations for exercise from the American College of Sports Medicine differ for weight loss versus weight maintenance. Physical activity of fewer than 150 minutes per week has a minimal effect on weight loss, whereas physical activity of greater than 150 minutes per week usually results in modest weight loss (defined as 2 to 3 kg), and physical activity between 225 and 420 minutes per week is

Fig. 20.7 Group activity classes help build community and can increase motivation to exercise.

likely to result in the greatest weight loss (5 to 7.5 kg). However, this high volume of physical activity may not be practical for the general population. Research on maintaining weight indicates that moderate to vigorous physical activity of 150 to 250 minutes per week, at an energy equivalent of 1200 to 2000 kcal per week (about 12 to 20 miles per week of jogging or running) is sufficient to prevent weight gain (Swift et al, 2014). However, obese individuals who have successfully lost weight may require a substantial amount of physical activity to maintain weight loss.

Failure to meet the recommended levels of aerobic physical activity leads to nearly \$117 billion in annual health care costs and 10% of all premature deaths, according to the Department of Health and Human Services 2018 physical fitness report in the *Journal of the American Medical Association* (Piercy et al, 2018).

Pharmaceutical Management

Appropriate pharmacotherapy can augment diet, physical activity, and behavior therapy as treatment for patients with a BMI of 30 or higher or patients with 27 or higher who also have significant risk factors or disease. These agents can decrease appetite, reduce absorption of fat, or increase energy expenditure. As with any drug treatment, physician monitoring for efficacy and safety is necessary. Pharmacotherapy is not a “magic pill”; dietitians should collaborate with other health professionals regarding the use of FDA-approved pharmacotherapy. Not all individuals respond, but for patients who do respond, weight loss of approximately 2 to 20 kg can be expected usually during the first 6 months of treatment. Medication without lifestyle modification is less effective.

As of April, 2018, five long-term weight loss drugs were listed as approved by the FDA: orlistat (Xenical), liraglutide (Saxenda, Victoza), lorcaserin (Belviq), naltrexone-bupropion (Contrave), and phentermine-topiramate (Qsymia) (Table 20.8 for mechanisms of action and common side effects of prescription weight loss drugs).

The choice of weight loss drug is determined by the physician in partnership with the patient. In general, medications can be categorized as central nervous system (CNS)-acting agents and non-CNS-acting agents. Some CNS-acting agents focus on the brain, increasing the availability of norepinephrine. Drug Enforcement Agency Schedule II anorexic agents such as amphetamines have a high potential for abuse and are not recommended for obesity treatment. Other CNS-acting agents act by increasing serotonin levels in the brain. Two such drugs, fenfluramine (commonly used in combination with phentermine, known as “fen-phen”) and dexfenfluramine, were removed from the market in 1997 after concerns were raised regarding the possible side effects of cardiac valvulopathy, regurgitation, and primary pulmonary hypertension. Common side effects of many CNS-acting agents are dry mouth, headache, insomnia, and constipation.

Vitamins and supplements may be helpful in addressing a patient's nutrition concerns while trying to lose weight. OTC and natural weight loss products hold varying degrees of safety and efficacy. See Table 20.7 for additional information.

Nondiet Approach

The nondiet approach (also known as **Health at Every Size; HAES®**) is described as a weight-neutral approach that proposes that the body will attain its natural weight if the individual eats healthfully, becomes attuned to hunger and satiety cues, and incorporates physical activity. Advocates for this approach promote size acceptance, respect for the diversity of body shapes and sizes, and promotion of intuitive eating. The approach is described as focusing on achieving health rather than attaining a certain weight.

TABLE 20.8 Prescription Drugs Approved for Obesity Treatment*

Weight Loss Drug	Approved For	How It Works	Common Side Effects
Orlistat Sold as Xenical by prescription; over-the-counter version sold as Alli	Xenical: adults and children ages 12 and older Alli: adults only	Inhibits gastrointestinal lipase, which reduces the amount of fat absorbed from food by approximately 1/3—up to 150 to 200 calories less per day.	Stomach pain, gas, diarrhea, and leakage of oily stools Lowered fat-soluble vitamin absorption; supple- ments are typically recommended and should be taken >2 hours apart from drug Note: Rare cases of severe liver injury reported. Should not be taken with cyclosporine.
Lorcaserin Sold as Belviq	Adults	Acts on the serotonin receptors in the brain. This may help you eat less and feel full after eating smaller amounts of food.	Headaches, dizziness, feeling tired, nausea, dry mouth, cough, and constipation. Should not be taken with selective serotonin reuptake inhibi- tors (SSRIs) and monoamine oxidase inhibitor (MAOI) medications
Phentermine-topiramate Sold as Qsymia	Adults	A mix of two drugs: phentermine (sup- presses your appetite and curbs your desire to eat) and topiramate (used to treat seizures or migraine headaches). May make you feel full and make foods taste less appealing.	Tingling of hands and feet, dizziness, taste alterations (particularly with carbonated bever- ages), trouble sleeping, constipation, dry mouth, and increased heart rate Note: Sold only through certified pharmacies. May lead to birth defects. Do not take Qsymia if you are pregnant or planning a pregnancy.
Other appetite suppressant drugs (drugs that curb your desire to eat), which include phentermine benzphetamine diethylpropion phendimetrazine Sold under many names	Adults	Increase chemicals in the brain that affect appetite. Make you feel that you are not hungry or that you are full. Note: Only FDA approved for a short period of time (up to 12 weeks).	Dry mouth, difficulty sleeping, dizziness, head- ache, feeling nervous, feeling restless, upset stomach, diarrhea, and constipation

*Note: *Metformin*, used for type 2 diabetes, is a prescription drug which has been used by physicians as an “off-label” treatment of obesity. Adapted from www.niddk.nih.gov Mar 3, 2014.

Padwal R, Li SK, Lau DC: Long-term pharmacotherapy for obesity and overweight, *Cochrane Database of Syst Rev* (4):CD004094, 2003.
Perrault L: Obesity in adults: Drug Therapy. In Post TW, editor: *UpToDate*, Waltham, MA, 2018, UpToDate.

A fat-acceptance movement responding to weight bias and stigma, which persist both within and outside of the health care system, preceded the nondiet movement (see section on Weight Stigma and Social Justice). Advocates for this approach generally feel that CR is harmful (leading to eating disorders, body dissatisfaction, low self-esteem, and psychological harms). Nondiet advocates do not believe that obesity in and of itself is a risk factor for chronic disease and assert that the medical community is complicit in the “medicalization and pathologizing of fatness” (Ulian et al, 2018a). Nondiet advocates believe that obesity is natural (genetically determined) and unrelated to energy balance, and they point to relapse data as proof that attempts to lose weight often do not work.

To date there have been 10 studies (described in 15 research papers) using a nondiet approach published between 1999 and 2016. Among these 10 studies were a total of 697 subjects who were almost exclusively white women ages 30 to 50. Two of six papers reported a significant improvement in total and low-density lipoprotein (LDL) cholesterol (Bacon et al, 2002; Mensinger et al, 2016), and one paper reported a significant improvement in high-density lipoprotein (HDL) (Carroll et al, 2007). Two of three papers reported a small change in systolic or diastolic blood pressure (Bacon et al, 2002; Carroll et al, 2007). Only one study (which provided supervised exercise) reported a clinically and statistically significant change in

body mass, 3.6% loss of initial body weight (3.5 kgs) (Ulian et al, 2015). Only three trials have compared a nondiet approach with traditional weight loss interventions (Bacon et al, 2002; Mensinger et al, 2016; Steinhardt et al, 1999).

The nondiet studies do consistently show improvements in psychological variables (self-esteem, quality of life, and depression). When behavioral-type weight loss studies collect data on psychological variables (self-esteem, body image, health-related quality of life) they consistently report improvements as well (Blaine et al, 2007; Lasikiewicz et al, 2014). Furthermore, in contrast to the idea that intentional weight loss precipitates mood disturbance, reductions in depressive symptoms are consistent via any active treatment (lifestyle modification, exercise, nondiet, etc.) (Fabricatore et al, 2011).

A 5% weight loss leads to clinically significant improvements in metabolic variables. On average professional weight loss interventions induce a 9.5% weight loss from baseline and maintain 54% of the loss at 1 year (Ramage et al, 2014). Weight regain data from clinical weight loss interventions however are not randomizable (applicable) to the general population. The most recent available data (collected via the NHANES) found that 36.6% of 14,306 U.S. adults were maintaining at least a 5% weight loss (Kraschnewski et al, 2010).

While young women with body image disturbance are at higher risk for the development of eating disorders, intentional weight loss programs, when administered by a trained and empathetic professional, do not appear to increase the incidence of eating disorders. In fact, some studies report increased body satisfaction and a healthier relationship with food in addition to weight loss ([National Task Force on the Prevention and Treatment of Obesity, 2000](#); [Palavras et al, 2017](#); [Wadden et al, 2004](#)).

Well-designed behavioral weight loss interventions are able to reduce weight, improve metabolic profiles, and improve psychological outcomes. Behavioral programs vary but typically address: (1) emotional eating triggers; (2) balanced nutrition; (3) social support; and (4) exercise, and sometimes also include cognitive restructuring via exploration of dysfunctional thoughts regarding weight, body shape, or dieting.

Pursuing weight loss, or not, is an individual choice. For individuals who choose not to focus on weight, a nondiet approach can lead to improved body image and psychological variables. The effects on metabolic variables and the quality of dietary intake are unclear ([Leblanc et al, 2012](#); [Ulian, 2018b](#)) and passive weight loss is not an expected an outcome.

Bariatric Surgery

Bariatric surgery is currently considered the only long-term effective treatment for extreme or class III obesity with a BMI of 40 or greater, or a BMI of 35 or greater with comorbidities. According to the American Society for Metabolic and Bariatric Surgery, 228,000 bariatric surgeries were done in 2017 with an increase of 16% from 2015. Sleeve gastrectomy and Roux-en-Y gastric bypass (RYGB) are the two most common bariatric surgeries in the United States, with 58.1% and 18.7% performed, respectively. The laparoscopic adjustable gastric banding (LAGB) and biliopancreatic diversion with duodenal switch (BPD/DS) are still done, but prevalence is decreasing; with LAGB making up 3.4% of bariatric surgeries, and BPD/DS, 0.6% ([American Society for Metabolic and Bariatric Surgery \[ASMBS\], 2016](#)).

Before any extremely obese person is considered for surgery, failure of a comprehensive program that includes calorie reduction, exercise, lifestyle modification, psychological counseling, and family involvement must be demonstrated. Failure is defined as an inability of the patient to reduce body weight by one third and body fat by one half, and an inability to maintain any weight loss achieved. Such patients have intractable morbid obesity and should be considered for surgery.

If surgery is chosen, the patient is evaluated extensively with respect to physiologic and medical complications, psychological problems such as depression or poor self-esteem, and motivation. Behavioral counseling, especially in the postoperative period, can improve weight loss ([Stewart and Avenell, 2016](#)). Postoperative follow-up requires evaluation at regular intervals by the surgical team and a registered dietitian nutritionist (RDN). In addition, behavioral or psychological support is necessary. Studies indicate some positive physiologic changes in liver fibrosis, BMI, branched chain amino acid production, and reversal of insulin-induced increases in brain glucose metabolism ([Abdenmour et al, 2014](#); [Tuulari et al, 2013](#)).

Sleeve Gastrectomy, Gastric Bypass, and Laparoscopic Adjustable Gastric Banding

Weight loss surgery procedures reduce the amount of food that can be eaten at one time and produce early satiety ([Fig. 20.8](#)). The new

stomach capacity may be as small as 30 mL or approximately 2 tablespoons. After surgery the patient's diet progresses from clear liquid to full liquid to puree, soft, and finally to a regular diet as tolerated, with emphasis on protein and fluid intake ([Table 20.9](#)). The results of gastric surgery are more favorable than those from the intestinal bypass surgery practiced during the 1970s. On average, the reduction of excess body weight after gastric restriction surgery correlates to approximately 30% to 40% of initial body weight. In addition to the greater absolute weight loss observed, the gastric bypass tends to have sustainable results with significant resolution of hypertension, type 2 diabetes mellitus, osteoarthritis, back pain, dyslipidemia, cardiomyopathy, nonalcoholic steatohepatitis, and sleep apnea. However, late complications may be seen, such as vitamin deficiencies, electrolyte problems, or even intestinal failure. Patients should be nutritionally assessed regularly (see Appendices 11 and 12). Thirty-day major complication rates for all bariatric procedures have been found to be 1.15% anastomotic leak, 0.37% myocardial infarction, and 1.17% pulmonary embolism ([Chang et al, 2018](#)).

The **laparoscopic sleeve gastrectomy (LSG)** initially was used for patients with a BMI greater than 60 as a precursor to the BPD/DS, but it is now used as a stand-alone procedure and currently is the most popular bariatric surgery in the United States. The sleeve gastrectomy involves removing approximately 80% of the stomach, creating a long, thin gastric pouch by stapling or sewing the stomach longitudinally. The pyloric sphincter is left intact ([Meek et al, 2016](#)). Complications associated with the LSG can include gastric bleeding, stenosis, leak, and reflux. One of the most common complications from sleeve gastrectomy involves acid reflux, occurring in 20% to 30% of patients ([Braghetto et al, 2012](#)). Occasionally, RYGB is necessary to resolve reflux complications ([Weiner et al, 2011](#)) (see [Fig. 20.6](#)).

Gastric bypass involves reducing the size of the stomach with the stapling procedure but then connecting a small opening in the upper portion of the stomach to the small intestine by means of an intestinal loop. The original operation in the late 1960s evolved into the RYGB. Because use of the lower part of the stomach is omitted, the gastric bypass patient may have dumping syndrome as food empties quickly into the duodenum (see Chapter 26). The tachycardia, sweating, and abdominal pain are so uncomfortable that they motivate the patient to make the appropriate behavioral changes and refrain from overeating and choosing less healthful foods, such as sugar-sweetened beverages. Eventually the pouch expands to accommodate 4 to 5 oz at a time. Sometimes gastric bypass surgery can lead to bloating of the pouch, nausea, and vomiting. A postsurgical food record noting the tolerance for specific foods in particular amounts helps in devising a program to avoid these episodes.

Up to 16% of patients may experience postoperative complications ([Beebe and Crowley, 2015](#)). These include anastomotic leaks, strictures, perforation, gastric fistulas, bowel obstructions, wound infections, respiratory failure, and intractable nausea and vomiting.

Laparoscopic adjustable gastric banding (LAGB), the band creating the reduced stomach pouch, can be adjusted so that the opening to the rest of the stomach can be made smaller or enlarged. The band, filled with saline, has a tube exiting from it to the surface of the belly just under the skin; this allows for the injection of additional fluid or reduction of fluid into the band. Rates of lap-band placement have been decreasing across the United States, with some bariatric centers and surgeons no longer performing the procedure. Many patients are drawn to the band

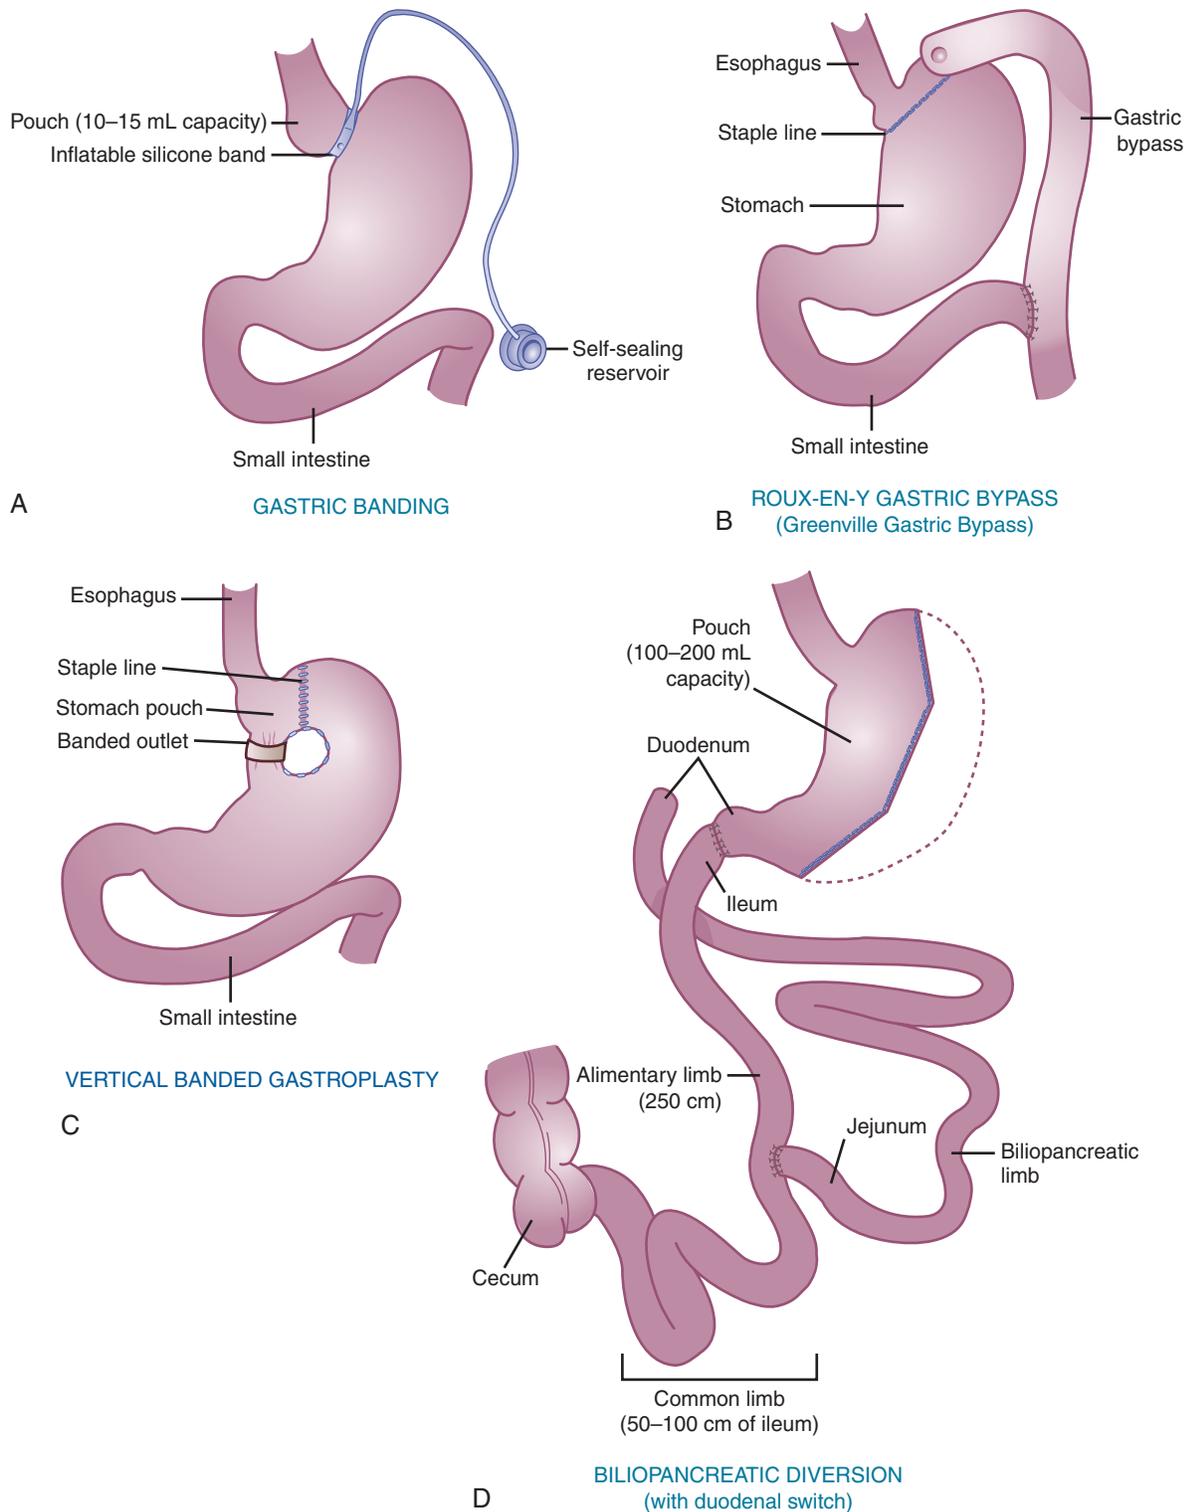

Fig. 20.8 Bariatric surgeries. Dietitians in Nutrition Support newsletter, June 2014, P. 10, Vol. 6, No. 3.

as an option as it is reversible; however, many practitioners and researchers find the complications outweigh the benefits (Ibrahim et al, 2017).

Bariatric surgery places an individual at risk for malnutrition that requires lifelong follow-up and monitoring by the multidisciplinary team. Nutritional status should be frequently evaluated by an RDN. Monitoring should include an assessment of total body fat loss and a

full micronutrient assessment. Pre- and postsurgical micronutrient assessment should include thiamine, vitamin B₁₂, folate, iron, vitamin D, calcium, other fat-soluble vitamins, zinc, and copper. In many cases, a liquid multivitamin mineral supplement is used. Recommended vitamin supplementation after bariatric surgery can be found in Table 20.10 (Parrott et al, 2017).

TABLE 20.9 Diet Progression After Sleeve Gastrectomy and Roux-en-Y Gastric Bypass

Stage of Diet	Duration	Foods Allowed
Clear Liquids	Start within 24 hours after surgery. Duration 2-3 meals	Sugar-free clear liquids, such as water, unsweetened decaffeinated tea, sugar-free gelatin, sugar-free popsicles, broth
Stage 2 – Full Liquid Diet	A few days to 1 week	Protein drink, fat-free (skim) milk, unsweetened nondairy milk, strained cream soups
Stage 3 – Pureed	A few weeks to about 1 month	Foods that are the consistency of a smooth paste or thick liquid, without any solid pieces. Examples include low-fat cottage cheese, low-fat or fat-free ricotta cheese, blended meats, fish, eggs, beans, fruits, and vegetables
Stage 4 – Soft foods	About 1 month	Ground or finely diced meats, canned or soft fresh fruit, cooked vegetables without skin, eggs, beans
Stage 5 – Solid foods	Start about 8 weeks post surgery	Gradually incorporate firmer, diced, or chopped foods.

<https://www.mayoclinic.org/tests-procedures/gastric-bypass-surgery/in-depth/gastric-bypass-diet/art-20048472>

TABLE 20.10 Recommended Vitamin Supplementation After Bariatric Surgery

Supplement	Recommendation
Thiamine	At least 12 mg daily, and preferably a dose of 50 mg thiamine from a B-complex supplement or multivitamin once daily
Vitamin B ₁₂	350-500 µg orally by disintegrating tablet, sublingual, or liquid daily OR nasal spray as directed by manufacturer OR 1000 µg monthly parenterally
Folate (Folic Acid)	400-800 µg daily from a multivitamin. Women of childbearing age should take 800-1000 µg daily.
Iron	Post-RYGB, LSG, and BPD/DS patients should take at least 45-60 mg elemental iron cumulatively daily (from multivitamin and other supplements). Those with low risk of deficiency, such as males with LAGB procedures, should take at least 18 mg from their multivitamin daily. Oral supplementation should be in divided doses, separately from calcium supplement, acid-reducing medications, and foods high in phytates and polyphenols.
Calcium	LAGB, LSG, RYGB: 1200-1500 mg daily BPD/DS: 1800-2400 mg daily Calcium should be given in divided doses to enhance absorption. Calcium carbonate should be taken with meals to increase absorption, calcium citrate has good absorption when taken with meals and also on an empty stomach.
Vitamin D	Dosage of vitamin D is based on 25(OH)D levels. 3000 IU daily of vitamin D is recommended until 25(OH)D levels are >30 ng/L.
Vitamins A, E, and K	LAGB: vitamin A 5000 IU and vitamin K 90-120 µg daily RYGB and LSG: vitamin A 5000-1000 IU and vitamin K 90-120 µg daily BPD/DS: vitamin A 1000 IU and vitamin K 300 µg daily All weight loss surgeries: vitamin E 15 mg daily Special attention should be paid to postsurgical supplementation of vitamins A and K in pregnant women.
Zinc	BPD/DS: Multivitamin with minerals containing 200% of the RDA (1622 mg/d) RYGB: Multivitamin with minerals containing 100%-200% of the RDA (8-22 mg/d) LSG/LAGB: Multivitamin with minerals containing 100% of the RDA (8-11 mg/d) To minimize the risk of copper deficiency in post-WLS patients, it is recommended that the supplementation protocol contain a ratio of 8-15 mg of supplemental zinc per 1 mg of copper.
Copper	BPD/DS or RYGB: 200% of the RDA (2 mg/d) LSG or LAGB: 100% of the RDA (1 mg/d) Copper gluconate or sulfate is the recommended source of copper for supplementation.

BPD/DS, Biliopancreatic diversion with duodenal switch; LAGB, laparoscopic adjustable gastric banding; LSG, laparoscopic sleeve gastrectomy; RDA, recommended dietary allowance; RYGB, Roux-en-Y gastric bypass; WLS, weight loss surgery.

Bariatric surgery is increasing in popularity as a treatment of extreme obesity for the adolescent population. Similar preoperative requirements exist; however, the age and cognitive emotional maturity of the patient need to be taken into consideration given the lifelong nutritional, psychological, and physical ramifications.

Non-Surgical Weight Loss Procedures

Surgical management of weight continues to evolve. Select bariatric surgery centers across the United States have started utilizing the **intra-gastric balloon (IGB)**. The IGB, which is made of silicone, is endoscopically placed in the stomach for 6 months. During the

6 months in which the balloon resides in the stomach, patients are expected to learn and develop healthy eating habits that persist after the balloon has been removed. Complications include abdominal pain, nausea, esophagitis, flatulence, and gastric ulcer. An IGB can increase weight loss by 14.25% (Saber et al, 2017). There is currently insufficient evidence regarding the IGB's efficacy or safety. The Aspire Assist is a gastrostomy tube placed during gastroscopy. Patients can aspirate contents of a meal approximately 20 minutes after eating, thus decreasing caloric absorption.

Maintaining Reduced Body Weight

Energy requirements for weight maintenance after weight reduction are lower than at the original weight because smaller bodies have smaller energy requirements. Most studies show that the RMR of reduced weight subjects versus stable-weight-controls (of the same height, weight, and gender) are not different (Clamp et al, 2018). A follow-up study of participants in *The Biggest Loser* television show (who lost significant amounts of weight) found that after weight regain, RMR remained suppressed (Fothergill et al, 2016). These results open questions about possible long-term effects of extreme energy restriction—especially coupled with extreme levels of physical activity—on eventual RMR. People who have lost weight will always have reduced energy requirements due to reduced body mass, which necessitates permanent lifestyle changes to maintain the net energy balance supporting their reduced body weight (Hall et al, 2011).

The NWCR consists of more than 5000 individuals who have been successful in long-term weight loss maintenance. The purpose of establishing the NWCR is to identify the common characteristics of those who succeed in long-term weight loss maintenance. There is very little similarity in how these individuals lost weight, but there are some common behaviors they all have for keeping the weight off. Lifestyle modification and a sense of self-efficacy appear to be essential. To maintain weight loss, NWCR participants report the following:

1. Eating a relatively low-fat (24%) diet
2. Eating breakfast almost every day
3. Weighing themselves regularly, usually once per day to once per week
4. Engaging in high levels (60 to 90 minutes per day) of physical activity

A national weight loss registry is contributing to our understanding of those tactics that lead to long term success. Dietary restriction of fat, frequent self-weighing, and ongoing leisure time physical activity were factors associated with maintaining weight loss (Thomas et al, 2014). Support groups are valuable for obese persons who are maintaining a new lower weight; they help individuals facing similar problems. Two self-help support groups are Overeaters Anonymous (OA) and Take Off Pounds Sensibly (TOPS). These groups are inexpensive, continuous, include a “buddy system,” and encourage participation on a regular basis, or as often as needed. Weight Watchers programs offer free lifelong maintenance classes for those who have reached and are maintaining their goal weights.

Interestingly, “boring” and “monotonous” diets can provide a strategy for reducing food intake. Diets that are repetitious (without change from meal to meal) are a useful consideration for controlling intake, because people tend to overeat when they have many mealtime choices. This can be a particular problem in a society where one in three meals is eaten away from home. Restaurants and vending trucks or machines generally offer many options, most high in calories (see *Focus On: Restaurant and Vending Machine Nutrition Labeling*).

Overall, a common sense approach is needed. Some phrases can be shared with individuals who are trying to maintain their weight loss, including the following: (1) The best diet is “make it, don't buy it,” (2) “Easy does it”—use moderation at all meals and snacks, and (3) “Avoid drinking your calories.”

FOCUS ON

Restaurant and Vending Machine Nutrition Labeling

When the Affordable Care Act was signed into law in 2010, restaurant labeling laws were included as part of the legislation for health care reform (Federal Register, 2014). Because many Americans eat one third of their calories away from home, the intent of this public health effort was to provide consumers with the food label as an educational tool to make healthier eating choices when dining out. It took 8 years to bring this to fruition, with many delays and interruptions due to government and industry controversies.

In 2018, the FDA enacted the following legislation:

1. In restaurants and in similar food establishments with greater than 20 locations serving the same menu, all menu items must list the calorie content of foods.
2. Vending machine labeling operators who own or operate 20 or more vending machines must disclose their vending machine calorie information, subject to certain exemptions as determined by the FDA.

Although other data like fat, saturated fat, cholesterol, sodium, total carbohydrates, sugar, fiber, and total protein were eliminated during the many years it took to get this legislation enacted, we can now finally provide—through this labeling—an educational tool to the public for making more informed food choices. It is up to us, as nutrition professionals, to be persistent and work with our legislators on the enactment of future nutrition labeling rules and education. For more detailed information about timing and implementation of the labeling rule, you may contact www.fda.gov.

Plateau Effect

A common experience for the person in a weight reduction program is arrival at a weight plateau, as weight loss slows and eventually seems to stop. Recent research explains that the plateau effect is mainly due to a lack of ongoing energy deficit. Subjects tend to maintain an energy deficit for only about 6 weeks, then gradually return to their baseline energy intake. This means a state of equilibrium has been reached at which the energy intake is equal to energy expenditure. To move out of this phase, reestablishing an energy deficit is required.

There are several factors that reduce RMR and total energy expenditure (TEE) during energy restriction and weight loss, including: energy restriction—RMR can decrease at the onset of energy restriction by as much as 15% within 2 weeks, which varies with the magnitude of energy restriction; loss of metabolically active body tissue—weight loss consists of both LBM and fat, and less of either (but especially LBM) reduces RMR; the cost of physical activity is also less because a body that weighs less requires less energy expenditure to move around; and the thermic effect of food is generally about 10% of energy intake, which is automatically less with energy restriction. These are not the major factors stalling weight loss however; it is necessary to reestablish an energy deficit.

Weight Cycling

Repeated bouts of weight loss and regain, known as weight cycling or the **yo-yo effect**, occurs in men and women and is common

in overweight and lean individuals. Research is mixed on whether weight cycling results in increased body fatness and weight with the end of each cycle. Undesirable psychological effects are less disputed.

WEIGHT MANAGEMENT IN CHILDREN AND ADOLESCENTS

About one third of U.S. children ages 2 to 19 are overweight or obese (State of Obesity, 2018). Childhood obesity increases the risk of obesity in adulthood. For the child who is obese after 6 years of age, the probability of obesity in adulthood is significantly greater if either the mother or the father is obese.

The BMI tables for determining childhood obesity are available for use by health care practitioners (see Appendix 8). High preschool BMI is consistently associated with adult obesity, central obesity, and early onset MetS (Lloyd et al, 2012).

Children or adolescents with a BMI in the 85th percentile or higher with complications of obesity, or with a BMI in the 95th percentile or higher with or without complications, should be carefully assessed for genetic, endocrinologic, and psychological conditions, and secondary complications such as hypertension, dyslipidemias, type 2 diabetes, sleep apnea, and orthopedic problems.

Assessment involves investigating all of the social and environmental factors, including family dynamics, that influence eating and activity habits as well as readiness for change. The primary goal of treatment is to achieve healthy eating and activity, not to achieve an ideal body weight (IBW). For children aged 2 to 5, the goal is prolonged weight maintenance or slowing of the rate of weight gain, which allows for a gradual decline in BMI as children grow in height. This is an appropriate goal in the absence of any secondary complication of obesity. However, if secondary complications are present, children in this age group may benefit from weight loss if their BMI is at the 95th percentile or higher. For children aged 6 and older, prolonged weight maintenance is appropriate if their BMI is between the 85th and 95th percentile and if they have no secondary complications. If a secondary complication is present, or if the BMI is at the 95th percentile or above, weight loss may be advised. Comprehensive, intensive behavioral interventions should be offered (Kaiser Permanente, 2012).

If the weight appropriate for the child's or teen's anticipated adult height has already been reached, maintenance at that weight should be the lifetime goal. The child who already exceeds an optimal adult weight can safely experience a slow weight loss of 10 to 12 pounds per year until the optimal adult weight is reached. Balanced micronutrient intake for children includes 45% to 60% of kilocalories from carbohydrates, 25% to 40% from fat, and 10% to 35% from protein. New directions in childhood obesity research since the turn of the 21st century have uncovered 25(OH)D deficiency (defined as a level less than or equal to 57 nmol/L or 20 ng/mL). This has been manifested by a lack of sun exposure and the increase in use of sunscreen—blocking the skin's absorption of ultraviolet light. Low vitamin D is predominant in obese children. The accompanying proinflammatory association with diabetes and atherogenic pathways has prompted recommendations to test kindergarten and first grade children. Children with low levels of vitamin D could have the systemic inflammatory mediators and reduced insulin sensitivity pathways inhibited by vitamin D supplementation (Reyman et al, 2014).

The child or adolescent who needs to reduce weight requires attention from family and health professionals. This attention should be

directed to all the areas mentioned previously, with family modification of eating habits and increased physical activity. The program should be long term, over the entire growth period of the child and perhaps longer.

Inactivity often is coupled with sedentary hobbies, excessive TV watching, or prolonged sitting in front of a computer or game screen. Some theorize that physical inactivity appears to be the result of fatness rather than its cause (Metcalf et al, 2011), however others have postulated that environmental factors, such as a decrease in active commuting, high school physical education, and outdoor play, are contributing factors as well (Bassett et al, 2015). Additional research is required, however it is possible that factors other than inactivity may be more important in obesity development in children (see *New Directions: Partnership for a Healthier America Addressing Childhood Obesity*).

EXCESSIVE LEANNESS OR UNINTENTIONAL WEIGHT LOSS

Almost eclipsed by the attention focused on obesity is the need for some people to gain weight. The term **underweight** is applicable to those who are 15% to 20% or more below accepted weight standards. Because underweight is often a symptom of disease, it should be assessed medically. A low BMI, less than 18.5 in adults, a BMI of less than 5% for children, and less than 23 in older adults, is associated with greater mortality risk than that of individuals with optimal BMI. Undernutrition may lead to under functioning of the pituitary, thyroid, gonads, and adrenals. Other risk factors include loss of energy and susceptibility to injury and infection, as well as a distorted body image and other psychological problems (see Chapter 21).

Cause

Underweight or unintentional weight loss can be caused by (1) inadequate oral food and beverage intake, with insufficient quantities to match activity; (2) excessive physical activity, as in the case of compulsive athletic training; (3) inadequate capacity for absorption and metabolism of foods consumed; (4) a wasting disease that increases the metabolic rate and energy needs, as in cancer, acquired immune deficiency syndrome (AIDS), or hyperthyroidism; or (5) excess energy expenditure during psychological or emotional stress.

Assessment

Assessing the cause and extent of underweight before starting a treatment program is important. A thorough history and pertinent medical tests usually determine whether underlying disorders or food insecurity are causing the underweight. From anthropometric data such as arm muscle and fat areas, it is possible to determine whether health-endangering underweight really exists (see Appendix 11). Assessment of body fatness is useful, especially in dealing with the patient who has an eating disorder. Biochemical measurements indicate whether malnutrition accompanies the underweight (see Chapter 5 and Appendix 11).

Management

Any underlying cause of unintentional weight loss or low BMI must be the first priority. A wasting disease or malabsorption requires treatment. Nutrition support and dietary changes are effective, along with treatment of the underlying disorder (Table 20.11).

TABLE 20.11 Nutrition Management of Unintentional Weight Loss

Concern	Tips
Anxiety, stress, depression	Antidepressants can help; monitor choice to be sure they do not contribute to weight fluctuations. Ensure adequacy of physical activity as well as folate, B6, B12 and essential fatty acids. See Chapter 40.
Cancer	Gastrointestinal cancers are especially detrimental. Some treatments and medications can cause loss of appetite, as can the cancer itself. See Chapter 35.
Celiac disease	Ensure that all gluten-containing foods and ingredients are eliminated from the diet.
Changes in activity level or dietary preparation methods	Avoid skipping meals; prepare foods with high energy density; add snacks between meals.
Diabetes, new onset	See a physician; monitor medications and ensure adequate intake. See Chapter 29.
Dysphagia or chewing difficulties	Alter food and liquid textures accordingly to improve chewing and swallowing capability. See Chapter 39.
Hyperthyroidism	Too much thyroxine can cause weight loss. See Chapter 30.
Inflammatory bowel disease	Small frequent protein and calorie rich meals, low residue, may need enteral or parenteral nutrition. See Chapter 27.
Intestinal ischemia	Needs medical intervention and potentially enteral or parenteral feedings. See Chapters 12, 26, and 27.
Medications	Some medications can cause weight loss; check with physician; add protein and calorie rich meals and snacks, manage GI side effects like nausea, constipation and diarrhea.
Nausea and vomiting	Infections, other illnesses, hormonal changes, and some medications cause nausea and vomiting; small, frequent meals; serve liquids between meals instead of with meals to reduce fullness. See Chapters 26 and 35.
Pancreatitis and cystic fibrosis	Monitor for sufficiency of pancreatic enzyme replacement, easy to digest, small frequent meals and snacks, lower fat if steatorrhea is present. See Chapters 28 and 33.
Food insecurity	Provide resources for food assistance programs

If the cause of the underweight is inadequate oral food and beverage intake, activity should be limited, and psychological counseling initiated if necessary. If the cause is food insecurity, provide local resources for food assistance.

Appetite Enhancers

The FDA has approved orexigenic agents that include corticosteroids, cyproheptadine, loxiglumide (cholecystokinin antagonist), megestrol acetate, mirtazapine, dronabinol, oxoglutarate, anabolic agents (testosterone or Anadrol), Oxandrin (oxandrolone or oxandrolona), and growth hormone. Use of orexigenic agents for weight loss in seniors is saved for those whose conditions are refractory to usual treatments. One third of older adults, especially women, exhibit weight loss in combination with depression. Mirtazapine is an effective antidepressant that is well tolerated and increases appetite. It is particularly effective in elderly patients with dementia-related weight loss (Fox et al, 2009). Dronabinol is used for chemotherapy-induced nausea and vomiting in cancer and AIDS patients; it has been shown to induce weight gain in patients with dementia. For older adults, moderate amounts of alcohol can also help to increase appetite.

High-Energy Diets

A careful history may reveal inadequacies in dietary habits and nutritional intakes. Meals should be scheduled and eaten when relaxed instead of hastily planned or quickly eaten. The underweight person frequently must be encouraged to eat, even if not hungry.

The secret is to individualize the program with readily available foods that the individual enjoys, with a plan for regular eating times throughout the day. In addition to meals, snacks are usually necessary to adequately increase the energy intake. High-calorie liquids taken with meals or between meals are often effective in those who have loss of appetite or early satiety. Everyday foods can be fortified to increase the calories and protein (see *Focus On: Food First!* in Chapter 19).

The energy distribution of the diet should be approximately 30% of the kilocalories from fat, with the majority from monounsaturated or polyunsaturated sources and at least 12% to 15% of the kilocalories from protein. In addition to an intake according to estimated energy requirements for the present weight, 500 to 1000 extra kcals per day should be planned. If 2400 kcal maintains the current weight, 2900 to 3400 kcal would be required for weight gain.

The intake should be increased gradually to avoid gastric discomfort, discouragement, electrolyte imbalances, and cardiac dysfunction. Step-up plans are outlined in Table 20.12. In underweight children, nonnutritional factors, insufficient caloric intake, excessive nutrient losses, and abnormal energy metabolism may contribute to growth failure and morbidity. Thus adequate nutritional support should be an integral part of the management plan. Lipid-based nutrient supplements are fortified products that are often ready-to-use therapeutic foods or highly concentrated supplements that can be administered at “point of service” or emergency settings (Chaparro and Dewey, 2010).

TABLE 20.12 Suggestions for Increasing Energy Intake

Additional Foods	kcal	Protein (g)	Additional Foods	kcal	Protein (g)
Plus 500 kcal (Served Between Meals)			B. Instant breakfast with whole milk		
A. whole grain fruit and nut cereal	270	5		280	15
1 banana	80		1 c cottage cheese	239	31
1 c whole milk	160	8	½ c pineapple	95	
Total	510	13	1 c apple juice	117	
B. Milkshake made with ½ cup ice cream			6 graham cracker squares	165	3
1 tablespoon peanut butter	90	4	1 pear	100	1
1 medium banana	105	8	Total	996	50
1 cup whole milk	160	8	Plus 1500 kcal (Served Between Meals)		
Total	500	23	A. 2 slices whole grain bread		
C. 6 graham cracker squares			2 T peanut butter	180	8
2 T peanut butter	172	8	1 T jam	110	
1 c orange juice	122		6 whole grain crackers	120	3
2 T raisins	52		8 oz fruit on the bottom Greek whole milk yogurt	260	18
Total	511	11	¾ c roasted peanuts	630	28
Plus 1000 kcal (Served Between Meals)			½ c apricot nectar	70	
A. 8 oz fruit on the bottom Greek whole milk yogurt			Total	1510	63
1 slice whole grain bread	70	3	B. 1 medium fruit muffin		
2 oz cheese	226	14	2 tsp. butter	70	6
1 medium apple	87		4 oz fruit on the bottom Greek whole milk yogurt	130	10

CLINICAL CASE STUDY

Norma is a 45-year-old Latina woman who has tried numerous weight loss programs. She has followed strict diets and has never exercised in previous weight loss attempts. She was prescribed lisinopril but forgets to take it regularly. Her blood pressure is 160/90, she is 5 ft 4 in, and she weighs 195 lb. Her lowest body weight was 130 lb at age 30, maintained for 2 years by increasing physical activity and reducing portions and between meal snacking. Since that time her weight has slowly increased to its current level, which Norma reports as her highest ever weight. She reports struggling with motivation and falling back on old habits of not watching portions and eating in front of the TV. Physical activity often falls off when life gets busy and Norma reports putting the needs of others in her family before her own. She tried numerous diets as teenager, when she weighed 170 lb for 3 years but had a hard time staying on them due to the abundance of food at family and social gatherings. What guidelines would you offer to Norma at this time?

Nutrition Diagnostic Statements

- Excessive kcal intake related to difficulty with motivation for health behavior changes as evidence by gradual weight gain of 65 lbs over 15 years and current BMI of 33.5.

- Physical inactivity related to busy schedule and not prioritizing self-care as evidenced by not being physically active for many years and steady weight gain.

Nutrition Care Questions

- How would you address the concern that she is not taking her medication regularly?
- What dietary recommendations would you have for Norma?
- Which macro- and micronutrients would you discuss with Norma (e.g., total fat, saturated fat, protein, sodium, potassium, calcium)?
- How would you bring up exercise and what would you recommend for Norma?
- What would you recommend if she wanted to take a dietary supplement for weight loss?

Nutrition in Eating Disorders

Janet E. Schebendach, PhD, RDN
Justine Roth, MS, CEDRD

KEY TERMS

anorexia nervosa (AN)	cognitive-behavioral therapy (CBT)	other specified feeding or eating disorder (OSFED)
avoidant/restrictive food intake disorder (ARFID)	<i>Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5)</i>	purging
binge	diet-induced thermogenesis (DIT)	refeeding syndrome (RFS)
binge eating disorder (BED)	family-based therapy (FBT)	Russell's sign
bulimia nervosa (BN)		

Feeding and eating disorders (EDs) are characterized by a persistent disturbance of eating or eating-related behavior that results in significantly impaired physical health and psychosocial functioning. Diagnostic criteria (Box 21.1) are published in the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5)* (American Psychiatric Association [APA], 2013). Revised DSM-5 criteria are available for anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED); new criteria have been established for other specified feeding or eating disorder (OSFED), avoidant/restrictive food intake disorder (ARFID), pica, and rumination disorder.

Anorexia Nervosa

Essential features of **anorexia nervosa (AN)** include persistent energy intake restriction; intense fear of gaining weight or of becoming fat or persistent behavior that interferes with maintenance of appropriate weight; and a disturbance in self-perceived weight or shape. The two diagnostic subtypes are restrictive eating only (AN-R) and restrictive eating interspersed with binge eating or **purging** (AN-BP); crossover between the subtypes is possible over the course of illness. The DSM-5 allows clinicians to document a severity rating for a case of AN: mild, moderate, severe, and extreme. Severity ratings are differentiated based on current body mass index (BMI, adults) or BMI percentile (children/adolescents); however, the rating may be increased at the clinician's discretion to reflect clinical symptoms, degree of functional disability, and the need for supervision. In the general population, lifetime prevalence of AN is about 1% in women and less than 0.5% in men (Hay et al, 2014). Presentation typically occurs during adolescence or young adulthood, but prepubertal and late-onset (after age 40) cases have been described. Although AN occurs across culturally and socially diverse populations, increased prevalence occurs in postindustrialized, high-income countries. Within the United States, presentation of weight concerns among individuals with EDs may vary across cultural and ethnic groups (Becker, 2016; Sala, 2013). Body image dissatisfaction, dangerous weight control behaviors, and EDs are emerging issues for lesbian, gay, bisexual, transgender and queer (LGBTQ) youth

(McClain and Peebles, 2016), but prevalence and incidence rates for AN in these populations are not currently reported. Risk and prognostic factors associated with AN include genetic, physiologic, environmental, and temperamental characteristics (Table 21.1). The crude mortality rate is about 5% per decade with death attributed to medical complications directly related to AN or suicide (APA, 2013).

Bulimia Nervosa

Features of **bulimia nervosa (BN)** include recurrent episodes of binge eating followed by inappropriate compensatory behaviors in an effort to prevent weight gain, and self-evaluation that is unduly influenced by body shape and weight (APA, 2013). A **binge** consumption is an episode of uncontrollable eating of an excessive amount of food in a discrete period of time. Inappropriate compensatory mechanisms include self-induced vomiting, misuse of laxatives, diuretics, fasting, and excessive exercise. An individual may employ one or more methods. The DSM-5 includes four levels of severity ratings based on frequency of inappropriate compensatory behaviors: mild, moderate, severe, extreme. Although the default level of severity is based on the frequency of these episodes, the level of severity may be increased at the clinician's discretion to reflect other symptoms and the degree of functional disability. Lifetime prevalence of BN is approximately 2% in women and 0.5% in men (Hay et al, 2014). Initial presentation typically occurs during adolescence or young adulthood; prepubertal and late onset (after age 40) cases are uncommon. Diagnostic crossover from BN to AN occurs in 10% to 15% of cases. However, individuals who cross over to AN often revert back to BN, and some experience multiple crossovers between these disorders. BN occurs at similar frequencies in industrialized countries (APA, 2013). The prevalence of BN is similar among ethnic groups (APA, 2013). Risk and prognostic factors associated with BN include genetic, physiologic, environmental, and temperamental characteristics (see Table 21.1). BN is associated with a significantly elevated risk for mortality (all-cause and suicide), with a crude mortality rate of approximately 2% per decade (APA, 2013).

BOX 21.1 American Psychiatric Association (DSM-5) Diagnostic Criteria

Anorexia Nervosa (AN)

- A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal, or for children and adolescents, less than that minimally expected.
- B. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Specify whether:

1. Restricting type: During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise.
2. Binge-eating/purging type: During the last 3 months, the individual has engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Specify current severity:

The minimum level of severity is based, for adults, on current body mass index (BMI) (see below) or, for children and adolescents, on BMI percentile. The ranges below are derived from World Health Organization categories for thinness in adults; for children and adolescents, corresponding BMI percentiles should be used. The level of severity may be increased to reflect clinical symptoms, the degree of functional disability, and the need for supervision.

Mild: BMI ≥ 17 kg/m²

Moderate: BMI 16-16.99 kg/m²

Severe: BMI 15-15.99 kg/m²

Extreme: BMI <15 kg/m²

Bulimia Nervosa (BN)

- A. Recurrent episodes of binge eating at least once a week for 3 months. An episode of binge-eating is characterized by both of the following:
 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of AN.

Specify current severity:

The minimum level of severity is based on the frequency of inappropriate compensatory behaviors (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: An average of 1-3 episodes of inappropriate compensatory behaviors per week.

Moderate: An average of 4-7 episodes of inappropriate compensatory behaviors per week.

Severe: An average of 8-13 episodes of inappropriate compensatory behaviors per week.

Extreme: An average of 14 or more episodes of inappropriate compensatory behaviors per week.

Binge Eating Disorder (BED)

- A. Recurrent episodes of binge eating. An episode of binge-eating is characterized by both of the following:
 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. The binge-eating episodes are associated with three (or more) of the following:
 1. Eating more rapidly than normal.
 2. Eating until feeling uncomfortably full.
 3. Eating large amount of food when not physically hungry.
 4. Eating alone because of feeling embarrassed by how much one is eating.
 5. Feeling disgusted with oneself, depressed, or very guilty afterward.
- C. Marked distress regarding binge eating is present.
- D. The binge eating occurs, on average, at least once a week for 3 months.
- E. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of BN or AN.

Specify current severity:

The minimum level of severity is based on the frequency of episodes of binge eating (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: 1-3 binge-eating episodes per week.

Moderate: 4-7 binge-eating episodes per week.

Severe: 8-13 binge-eating episodes per week.

Extreme: 14 or more binge-eating episodes per week.

Other Specified Feeding and Eating Disorder

This category applies to presentations in which symptoms characteristic of a feeding and eating disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functions predominate but do not meet the full criteria for any of the disorders in the feeding and eating disorders diagnostic class. The other specified feeding and eating disorder category is used in situations in which the clinician chooses to communicate the specific reason that the presentation does not meet the criteria for any specific feeding and eating disorder. This is done by recording "other specified feeding or eating disorder" followed by the specific reason (e.g., "bulimia nervosa of low frequency"). Examples of presentations that can be specified using the "other specified" designation include the following:

1. Atypical AN: All of the criteria for AN are met, except that despite significant weight loss, the individual's weight is within or above the normal range.
2. BN (of low frequency and/or limited duration): All of the criteria from BN are met, except that the binge eating and inappropriate compensatory behaviors occur, on average, less than once a week and/or for less than 3 months.
3. BED (of low frequency and/or limited duration): All of the criteria for BED are met, except that the binge eating occurs, on average, less than once a week and/or for less than 3 months.
4. Purging disorder: Recurrent purging behavior to influence weight or shape (e.g., self-induced vomiting; misuse of laxatives, diuretics, or other medications) in the absence of binge eating.
5. Night eating syndrome: Recurrent episodes of night eating, as manifested by eating after awakening from sleep or by excessive food consumption after the evening meal. There is awareness and recall of the eating. The night eating is not better explained by external influences such as changes in the individual's sleep-wake cycle or by local social norms. The night eating causes significant distress and/or impairment in functioning. The disordered pattern of eating is not better explained by BED or another mental disorder, including substance use, and is not attributable to another medical disorder or to the effect of medication.

BOX 21.1 American Psychiatric Association (DSM-5) Diagnostic Criteria—cont'd**Unspecified Feeding or Eating Disorder**

This category applies to presentations in which symptoms characteristic of a feeding and eating disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for any of the disorders in the feeding and eating disorders diagnostic class. The unspecified feeding and eating disorder category is used in situations in which the clinician chooses *not* to specify the reason that the criteria are not met for a specific feeding and eating disorder, and includes presentations in which there is insufficient information to make a more specific diagnosis (e.g., in emergency room settings).

Avoidant/Restrictive Food Intake Disorder*

- A. An eating or feeding disturbance (e.g., apparent lack of interest in eating or food; avoidance based on the sensory characteristics of food; concern about aversive consequences of eating) as manifested by persistent failure to meet appropriate nutritional and/or energy needs associated with one (or more) of the following:
1. Significant weight loss (or failure to achieve expected weight gain or faltering growth in children).
 2. Significant nutritional deficiency.
 3. Dependence on enteral feeding or oral nutritional supplements.
 4. Marked interference with psychosocial functioning.
- B. The disturbance is not better explained by lack of available food or by an associated culturally sanctioned practice.
- C. The eating disturbance does not occur exclusively during the course of AN or BN, and there is no evidence of a disturbance in the way in which one's body weight or shape is experienced.
- D. The eating disturbance is not attributable to a concurrent medical condition or not better explained by another mental disorder. When the eating

disturbance occurs in the context of another condition or disorder, the severity of the eating disturbance exceeds that routinely associated with the condition or disorder and warrants additional clinical attention.

Pica

- A. Persistent eating of nonnutritive, nonfood substances over a period of at least 1 month.
- B. The eating of nonnutritive, nonfood substances is inappropriate to the developmental level of the individual.
- C. The eating behavior is not part of a culturally supported or socially normative practice.
- D. If the eating behaviors occur in the context of another mental disorder (e.g., intellectual disability [intellectual developmental disorder], autism spectrum disorder, schizophrenia) or medical condition (including pregnancy), it is sufficiently severe to warrant additional clinical attention.

Rumination Disorder

- A. Repeated regurgitation of food over a period of at least 1 month. Regurgitated food may be rechewed, reswallowed, or spit out.
- B. The repeated regurgitation is not attributable to an associated gastrointestinal or other medical condition (e.g., gastroesophageal reflux, pyloric stenosis).
- C. The eating disturbance does not occur exclusively during the course of AN, BN, BED, or avoidant/restrictive food intake disorder.
- D. If the symptoms occur in the context of another mental disorder (e.g., intellectual disability [intellectual developmental disorder] or another neurodevelopmental disorder), they are sufficiently severe to warrant additional clinical attention.

*A change to criterion A has been proposed. The stem includes the clause, "as manifested by persistent failure to meet appropriate nutritional and/or energy needs;" however, criterion A.4 does not describe a manifestation of a nutritional problem. The APA proposes to delete the clause in the stem, so that marked psychosocial impairment alone would satisfy criterion A.

American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 5, Arlington, VA, 2013, American Psychiatric Association.

TABLE 21.1 Risk and Prognostic Factors Associated With Anorexia Nervosa and Bulimia Nervosa

Diagnosis	Temperament	Environment	Genetic and Physiologic
AN	Obsessional traits in childhood Anxiety disorders	Cultures/settings that value thinness Occupations/avocations that encourage thinness, (e.g., modeling, elite athletics)	First-degree biological relative with AN, BN, bipolar disorder, or depressive disorder Higher concordance rates in monozygotic vs. dizygotic twins Functional imaging studies indicate a range of brain abnormalities but unclear if changes are primary anomalies or secondary to malnutrition
BN	Weight concerns Low self-esteem Depressive symptoms Social anxiety disorder Overanxious disorder of childhood	Internalization of thin body ideal Increased weight concerns Childhood sexual abuse Childhood physical abuse	Childhood obesity/large body size Early pubertal maturation Genetic vulnerabilities

AN, Anorexia nervosa; BN, bulimia nervosa.

American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 5, Arlington, VA, American Psychiatric Association, 2013.

Binge Eating Disorder

A major change in the DSM-5 is the official recognition of **binge eating disorder (BED)** as a clinical disorder. Although BED was included in the DSM-IV (APA, 2000), those criteria were established only for research purposes. The essential feature of BED is recurrent episodes of binge eating without inappropriate compensatory measures (such as purging) intended to prevent weight gain. BED diagnostic criteria

include four levels of severity ratings (mild, moderate, severe, and extreme) that are based on the frequency of binge episodes. The level of severity may be increased at the clinician's discretion to reflect other symptoms as well as the degree of functional disability. The lifetime prevalence of BED is approximately 3.5% in women and 2% in men (Hay et al, 2014). BED occurs at similar frequencies in most industrialized countries. In the United States, prevalence rates appear comparable

among Caucasians, Latinos, Asians, and African Americans. BED is more prevalent among individuals seeking weight loss treatment than in the general population. Crossover from BED to other EDs is uncommon. Binge eating disorder appears to run in families, which may reflect additive genetic influences (APA, 2013); less is known about temperamental and environmental risk and prognostic factors.

Other Specified Feeding or Eating Disorder

Other specified feeding or eating disorder (OSFED) applies to atypical AN (restrictive eating in the presence of normal weight), atypical BN and atypical BED (episodes are less frequent or of limited duration), purging disorder (i.e., recurrent purging in the absence of binge eating), and night eating syndrome. Treatment of subclinical AN, BN, and BED is similar to that used for full criteria presentation, but the frequency of therapeutic interventions (e.g., psychotherapy, nutrition therapy, medical management) and the treatment setting (e.g., inpatient hospitalization, day hospital/partial hospitalization, intensive outpatient treatment, outpatient treatment) may differ. Patients with a purging disorder and night eating syndrome often benefit from psychotherapeutic approaches used in the treatment of BN and BED.

Avoidant/Restrictive Food Intake Disorder

Patients with **avoidant/restrictive food intake disorder (ARFID)** exhibit restrictive/avoidant eating behaviors that result in significant weight loss, impaired growth, nutritional deficiencies, and reliance on enteral feedings/supplements, as well as impaired psychosocial functioning (Norris et al, 2016). These restrictive eating behaviors are not associated with body image dissatisfaction or fear of weight gain. Compared with patients with AN and BN, these individuals tend to be younger and have higher proportion of males; be selective (picky) eaters since early childhood; have fears of choking or vomiting; and avoid foods based on their appearance, texture, and smell (Fisher et al, 2014).

CLINICAL CHARACTERISTICS AND MEDICAL COMPLICATIONS

Although EDs are classified as psychiatric illnesses, they are associated with significant medical complications, morbidity, and mortality. Numerous physiologic changes result from the dysfunctional behaviors associated with AN, BN, and BED. Some are minor changes related to excessive or inadequate nutrient intake; some are pathologic alterations with long-term consequences; a few represent potentially life-threatening conditions.

Anorexia Nervosa

Initially, individuals with AN may simply appear underweight. As the disease progresses, patients appear increasingly cachectic and prepubescent in their appearance (Fig. 21.1). Common physical findings at this stage include lanugo (i.e., a soft, downy hair growth on the face and extremities), dry skin and hair, cold intolerance, cyanosis of the extremities, edema, and primary or secondary amenorrhea. The degree of symptomatology varies person to person and with duration of illness; for example, some women with anorexia experience amenorrhea, some do not.

Cardiovascular complications may include bradycardia, orthostatic hypotension, cardiac arrhythmias, and pericardial effusion. Protein-energy malnutrition (PEM) with resultant loss of lean body mass is associated with reduced left ventricular mass and systolic dysfunction; however, cardiac function is largely reversible with nutritional rehabilitation and weight restoration.

Gastrointestinal complications secondary to starvation include delayed gastric emptying, decreased small bowel motility, and

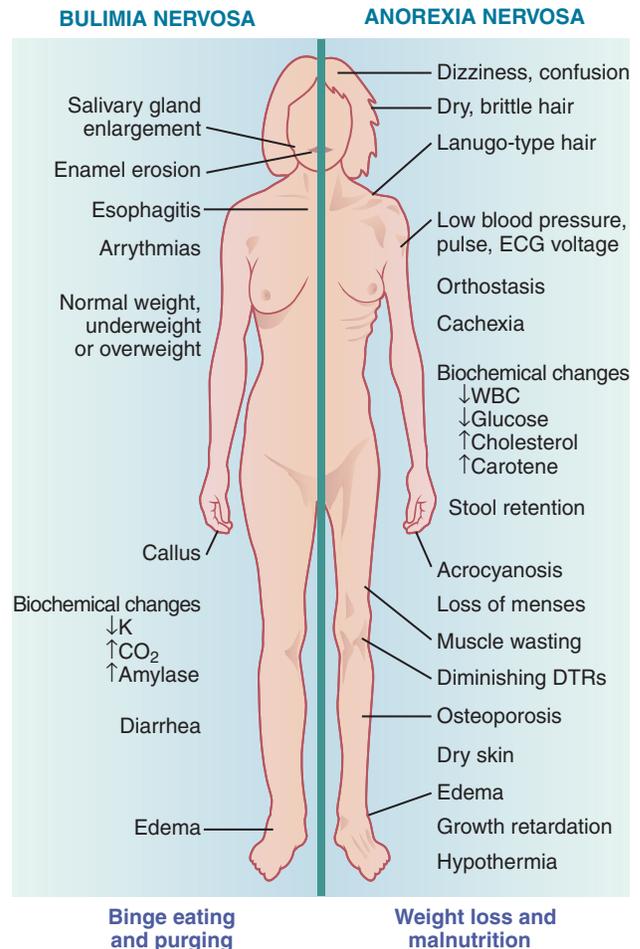

Fig. 21.1 Physical and clinical signs and symptoms of bulimia nervosa and anorexia nervosa. *DTRs*, Deep tendon reflexes; *ECG*, electrocardiogram; *WBC*, white blood cell.

constipation. Complaints of abdominal bloating and a prolonged sensation of abdominal fullness complicate the refeeding process. Lactose intolerance may develop secondary to malnutrition and will usually resolve after weight gain. Oral enzyme supplements and lactose-free dairy products may be beneficial during the refeeding process. A nationwide study conducted in Sweden found a positive association between celiac disease (CD) and AN both before and after CD diagnosis (Marild et al, 2017); this bidirectional association may be attributed to misdiagnosis, shared risk factors, and shared genetic susceptibility.

Osteopenia, osteoporosis, and increased risk of bone fractures occur in males and females with AN (Westmoreland et al, 2016). Adolescents with AN have decreases in biochemical markers of both bone formation and resorption, indicative of reduced bone turnover, whereas adults with AN have decreased bone formation and increased resorption markers, indicative of an uncoupling of bone turnover, both of which lead to reductions in bone mineral density (BMD) (Robinson et al, 2017). In a sample of predominantly female adults, osteopenia was diagnosed in 25.9% of AN-R patients and 34.8% of AN-BP patients and osteoporosis was diagnosed in 34.3% of AN-R and 21.1% of AN-BP patients (Mehler et al, 2018). Although weight gain and resumption of menses in AN patients are associated with increased spine and hip BMD, permanent deficits are likely. No specific therapies are currently approved for treatment of osteoporosis secondary to AN.

Patients with AN have thyroid hormones levels consistent with the nonthyroidal illness syndrome: thyroxin (T4) and triiodothyronine (T3) are low or low normal, reverse T3 is elevated, and thyroid-stimulating hormone (TSH) is normal or elevated (Winston, 2012). This syndrome is likely an adaptive response to conserve energy during chronic undernutrition, and these abnormalities typically normalize with weight gain.

Abnormal liver function tests may occur in AN (Mehler et al, 2018). Hepatic changes are generally asymptomatic and self-limiting, but rare cases of liver damage and liver failure have been reported. Elevated enzymes that result from malnutrition will improve during nutritional rehabilitation. Less frequently, elevated liver transaminases secondary to steatosis may occur during the refeeding process (Westmoreland et al, 2016).

Renal complications include renal insufficiency, decreased renal concentrating ability, increased urine output, proteinuria, and hematuria. In general, these symptoms ameliorate with adequate hydration and treatment of malnutrition (Campbell and Peebles, 2014).

Hematologic abnormalities include anemia, leukopenia, and thrombocytopenia. Anemia reportedly occurs in 20% to 40% of malnourished AN patients, yet iron deficiency is not typically found (Mehler et al, 2018; Westmoreland et al, 2016).

Bulimia Nervosa

Clinical signs and symptoms of BN are more difficult to detect because patients are usually of normal weight and secretive in behavior. When vomiting occurs, there may be clinical evidence such as (1) scarring of the dorsum of the hand used to stimulate the gag reflex, known as Russell's sign (Fig. 21.2); (2) parotid gland enlargement; and (3) erosion of dental enamel with increased dental caries resulting from the frequent presence of gastric acid in the mouth.

Gastrointestinal symptoms occur in individuals with BN who use vomiting as a purging method (Westmoreland et al, 2016). These

Fig. 21.2 Russell's sign. Calluses on the knuckles or the back of the hand resulting from repeated self-induced vomiting over a long period of time.

include sore throat, dysphagia, gastrointestinal reflux, esophagitis, mild hematemesis (vomiting of blood), and more serious but considerably less frequent complications like Mallory-Weiss esophageal tears, esophageal rupture, and acute gastric dilation or rupture. Symptoms associated with laxative misuse vary with type, dose, and duration of use. Patients may present with diarrhea, abdominal cramping, rectal bleeding, and rectal prolapse. Abuse of stimulant laxatives (i.e., those containing bisacodyl, cascara, or senna) can damage intestinal nerve fibers in the bowel wall, whereby the colon becomes increasingly dependent on these stimulants to propulse fecal material; this results in cathartic colon syndrome (Westmoreland et al, 2016). Cessation of laxatives, particularly of the stimulant type, may result in severe rebound constipation that requires ongoing medical management.

Self-induced vomiting and abuse of stimulant laxatives account for 90% of the purging behaviors found in BN (Westmoreland et al, 2016). Vomiting results in decreased potassium (hypokalemia), decreased chloride, and increased bicarbonate, resulting in metabolic alkalosis. Excessive laxative abuse initially results in hyperchloremic metabolic acidosis; however, this reverts to a state of metabolic alkalosis after a chronic volume depleted state evolves (Westmoreland et al, 2016). Hypokalemia also occurs secondary to laxative misuse. Hypokalemia from purging is associated with increased risk of atrial and ventricular arrhythmias (Trent et al, 2013).

Individuals with BN may experience menstrual irregularity, leading to the mistaken belief that they are unable to conceive. Unplanned pregnancies, miscarriages, and babies born with a lower birthweight and smaller head circumference are documented in BN patients (Koubaa et al, 2013; Linna et al, 2013). It is unknown if negative outcomes are associated with malnutrition, inadequate prenatal care, or another mechanism specific to bulimic behavior.

Binge Eating Disorder

The predominant feature of BED is episodes of excessive eating. In many cases, but not all, this binge eating results in overweight or obesity, yet causes greater functional impairment, decreased quality of life, and greater levels of psychiatric comorbidity (depression and anxiety) than obesity without BED (Kornstein et al, 2016). Ingestion of large amounts of food may cause considerable upper and lower gastrointestinal distress. Symptoms include abdominal pain, fullness, delayed gastric emptying, bloating, acid regurgitation, heartburn, dysphagia, nausea, diarrhea, constipation, fecal urgency, fecal incontinence, and anal blockage. BED is associated with an increased lifetime risk of type 2 diabetes, hypertension, and metabolic syndrome (Kornstein et al, 2016).

TREATMENT APPROACH

Treatment of EDs requires a multidisciplinary approach that includes psychiatric, psychological, medical, and nutrition interventions, ideally provided at a level of care appropriate to the severity of the illness. Levels of care offered by facilities in the United States include inpatient hospitalization, residential treatment, partial or day hospitalization, intensive outpatient treatment, and outpatient treatment (APA, 2006; Steinglass et al, 2016). Treatment guidelines and policy statements on the necessary components of treatment are available from the APA (APA, 2006; APA, 2012), the Society for Adolescent Health and Medicine (SAHM) (SAHM, 2015), the American Academy of Pediatrics (Rosen and American Academy of Pediatrics Committee on Adolescence, 2010), the Academy of Nutrition and Dietetics (Ozier et al, 2011), and the Royal Australian and New Zealand College of Psychiatrists (Hay et al, 2014).

Inpatient hospitalization may be provided on a psychiatric or medical unit that utilizes a behavioral protocol developed for ED patients. Specialized residential treatment programs also provide 24-hour care but are less likely to admit the medically or psychiatrically unstable patient because of their location outside of a hospital setting. That said, some residential treatment programs are adding acute medical stabilization units to their facility. Partial and day hospital programs typically provide 6 to 8 hours of specialized multidisciplinary treatment 5 to 7 days per week, depending on an individual patient's need for supervision. Intensive outpatient treatment programs provide several hours of multidisciplinary care each week. This may be scheduled in the late afternoon or early evening so that the patient can attend after school or work. The least intensive treatment setting is outpatient care. Psychotherapist, medical doctor, and registered dietitian nutritionist (RDN) appointments are typically scheduled at different times and locations; this necessitates a coordinated effort at communication among all clinicians. The APA (2006, 2012) level of care guidelines recommends that the treatment setting be selected in accordance with a patient's medical status, suicidality, body weight, motivation to recover, presence of comorbid conditions, need for supervision and structure, ability to control compulsive exercising, and purging behavior.

PSYCHOLOGIC MANAGEMENT

EDs are complex psychiatric illnesses that require psychological assessment and ongoing treatment. Evaluation of the patient's cognitive and psychological stage of development, family history, family dynamics, and psychopathologic condition is essential for the development of a comprehensive psychosocial treatment program.

The long-term goals of psychosocial interventions in AN are (1) to help patients understand and cooperate with their nutritional and physical rehabilitation, (2) to help patients understand and change behaviors and dysfunctional attitudes related to their EDs, (3) to improve interpersonal and social functioning, and (4) to address psychopathologic and psychological conflicts that reinforce or maintain eating-disordered behaviors (APA, 2006).

In the acute stage of illness, malnourished AN patients are obsessive and negativistic, making it difficult to conduct formal psychotherapy. It is therefore recommended that intensive, highly structured psychological therapies be initiated after the medical and cognitive effects of acute starvation have been stabilized (Hay et al, 2014).

Behavioral management is often used for individuals with low weight and restrictive eating behaviors (Attia and Walsh, 2009; Steinglass et al, 2016). These protocols encourage the achievement of normal weight and healthy eating through the use of reinforcements for healthy behavioral choices. Treatment typically includes the supervision of all meals and snacks, as well as postmeal psychological support for "having eaten" and monitoring to prevent compensatory behaviors like vomiting, standing, and exercising. Behavioral management can be used in inpatient, residential, and outpatient treatment settings; however, effectiveness depends on consistency of expectations and supervision, which can be more challenging on an outpatient basis.

Once acute malnutrition has been corrected and weight restoration is underway, the AN patient is more likely to benefit from psychotherapy. Psychotherapy can help the patient understand and change core dysfunctional thoughts, attitudes, motives, conflicts, and feelings related to the ED. Associated psychiatric conditions, including deficits in mood, impulse control, and self-esteem, as well as relapse prevention, should be addressed in the psychotherapeutic treatment plan.

No consensus has been reached on the best overall approach to psychotherapy in AN; however, studies suggest that **family-based therapy (FBT)** is the treatment of choice in adolescents with relatively brief AN (Gur et al, 2018). FBT for AN is a 3-phase manualized outpatient treatment consisting of 10 to 20 sessions conducted over 6 to 12 months (Lock and Le Grange, 2013). Phase 1 aims to empower parents to play an active role in the weight restoration of their adolescent; it focuses on the dangers associated with severe malnutrition and emphasizes the need for parents to take immediate action to reverse this. In phase 1, the FBT therapist assists parents in refeeding their child using parental coaching techniques. In phase 2, the parents are encouraged to help their adolescent gradually resume control over eating again. Phase 3 begins once the adolescent is able to maintain a stable weight $\geq 95\%$ of ideal body weight (IBW) independently. At this point, the focus of treatment shifts toward the establishment of a healthy adolescent identity, increased adolescent autonomy, and the development of appropriate parental boundaries. It is noteworthy that FBT certification is limited to licensed mental health professionals and that the RDN plays no formal role in the FBT process.

If FBT is contraindicated, then enhanced cognitive behavioral therapy (CBT-E) may be an effective alternative for adolescents, and a good option for adults with AN (Fairburn, 2008). Two versions of CBT-E are available: focused (the core treatment) and broad (includes clinical perfectionism, core low self-esteem, and interpersonal difficulties modules). Treatment intensities include a 20-session version for patients with a BMI > 17.5 and a 40-session version for patients with a BMI between 15.0 and 17.5. CBT-E is a manualized therapy provided by psychotherapists on inpatient units as well as in outpatient settings. CBT-E typically includes the self-monitoring of food intake and eating behaviors (binge eating, purging, restricting). The role of the RDN in CBT-E is minimal and will vary with the treatment setting (i.e., greater involvement on inpatient units). On an outpatient basis, consultation with a nutritionist may be limited to patients with complicated diet issues (e.g., diabetes mellitus, CD, vegan diet) and challenging work/sleep schedules (e.g., individuals who work overnight shifts).

Classic **cognitive behavioral therapy (CBT)** is a 20-session structured therapy that includes behavioral and cognitive interventions. CBT directs the client toward modifying dysfunctional thinking and behavior (see Chapter 13). Current data suggest that CBT is the recommended treatment for BN and BED, with interpersonal therapy (IPT) considered a strong treatment alternative (Gurr et al, 2018). CBT consists of three distinct and systematic phases of treatment: (1) establishing a regular eating pattern, (2) evaluating and changing beliefs about shape and weight, and (3) preventing relapse. Similar to CBT-E, classic CBT is manualized psychotherapeutic intervention provided by a trained psychotherapist. The role of the RDN is limited to patients with comorbid medical diagnoses and eating issues that require more advanced nutrition training.

Dialectical behavioral therapy (DBT), a skill-based therapy that focuses on mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness, may be helpful in BN cases in which comorbid psychiatric disorders (e.g., depression and mood disorders, personality disorders, and substance abuse disorders), self-injurious behaviors (e.g., cutting), and greater impulsivity are manifested (Berg and Wonderlich, 2013). In some instances, an antidepressant medication (typically a selective serotonin reuptake inhibitor [SSRI] such as fluoxetine) is prescribed adjunctive to psychotherapy.

Technology-based assessments and interventions are being tested in patients with EDs (Ellison et al, 2016). Smartphone "apps" like *Recovery Record* and *Rise UP + Recover* have been specifically developed

BOX 21.2 Recovery Apps

New technology offers eating disorder recovery focused tools in the form of applications or “apps.” The distinction between a “fitness app” and an eating disorder recovery app is significant for the treatment of those with eating disorders. While they may both focus on logging and recording, eating disorder apps discourage the tracking of calories and activity and rather promote the self-monitoring of thoughts and feelings around food intake. Utilizing a self-monitoring platform on a smart phone offers several advantages over paper monitoring as many people keep their phones on them majority of the time. Using the apps may be more convenient which lends itself to real-time monitoring, accuracy, and more consistency in records.

The following apps provide helpful tools to support the efforts of eating disorder recovery:

1. **Recovery Record:** This app allows you to connect with multiple treatment team members for a real-time tracking and monitoring setting. It provides personalized coping strategies, meal plans, tracking of feelings, urges to use behaviors as well as components of cognitive-behavioral-based interventions.
2. **Rise UP + Recover:** This app has a comparable self-monitoring feature that allows for recording of intake, emotions, and “target behaviors” such as bingeing and purging. It does not allow for an interactive experience with your treatment team, but you can export meal data and share with others through email. Users can also share motivational quotes, images, and affirmations.

Fairburn CG, Rothwell ER: Apps and eating disorders: a systemic clinical appraisal, *Int J Eat Disord* 48:1038, 2015.

Juarascio AS, Manasse SM, et. al. Review of smartphone applications for the treatment of eating disorders. *Eur Eat Disord Rev* 23:1, 2014.

to complement face-to-face psychotherapy and medical nutrition therapy (MNT) for EDs (Box 21.2).

Validated instruments and questionnaires are available for screening and diagnosis of patients with EDs. The Eating Disorder Examination - 17.0D (Fairburn et al, 2014) is a structured interview that takes approximately 1 hour to administer by a trained clinician; it can be used to diagnose DSM-5 AN, BN, BED, and OSFED in individuals ages 14 and up. The Eating Disorder Assessment for DSM-5 (EDA-5) is an interview-based semistructured interview that takes approximately 15 minutes to administer by a clinician with modest training; it can be accessed at www.eda5.org to diagnose DSM-5 AN, BN, BED, ARFID, OSFED, pica, and rumination disorder in adults (Sysko et al, 2015). Self-report measures may be used for screening purposes. Representative instruments include the Eating Attitudes Test (Eat-26), Eating Disorder Inventory, and the Eating Disorder Examination-Questionnaire (APA, 2006). The SCOFF (Morgan et al, 1999), a brief and effective screening tool that is easy to administer and score, is highlighted in Box 21.3.

BOX 21.3 The SCOFF Questionnaire*

1. Do you make yourself sick because you feel uncomfortably full?
2. Do you worry you have lost control over how much you eat?
3. Have you recently lost more than one stone (14 lb) in a 3-month period?
4. Do you believe yourself to be fat when others say you are too thin?
5. Would you say that food dominates your life?

* Two or more “yes” answers suggest the presence of an eating disorder.

From Morgan JF, Reid F, Lacey JH: *BMJ* 4:1467, 1999.

NUTRITION MANAGEMENT

Roles and responsibilities of the RDN in the treatment of individuals with EDs include assessment, intervention, monitoring, evaluation, and care coordination. Although AN, BN, and BED have different presenting features, similarities exist in the assessment and management of these disorders.

Nutrition Assessment

Nutrition assessment should include a thorough diet history, as well as the evaluation of biochemical, energy metabolism, and anthropometric markers of nutritional status.

Diet History

The diet history should include assessment of energy; macronutrient, micronutrient, and fluid intakes; energy density; diet variety; and an evaluation of eating attitudes, behaviors, and habits (see Chapter 4). Patients with a shorter duration of illness should be queried about their premorbid diet and eating habits as this may be a useful benchmark by which to gauge recovery.

Anorexia Nervosa

Patients with restricting type AN typically eat fewer than 1200 kcal/day. Patients with binge-purge type AN have more variable diet patterns, and energy intake should be assessed across the spectrum of restriction and binge eating. Although the early literature often described AN patients as carbohydrate “phobic” (Russell, 1967), more recent studies suggest greater dietary fat avoidance (Forbush and Hunt, 2014). Percent of calories contributed by protein may be in the average to above-average range, but adequacy of protein intake becomes marginalized as caloric intake decreases. A vegetarian or vegan diet may not contain adequate high-biologic value protein in the presence of low calorie intake.

Inadequate calories, limited diet variety, and poor food group representation increase risk for deficient micronutrient intakes. In general, micronutrient intake parallels macronutrient intake, and AN patients who consistently restrict dietary fat are at greater risk for diets that are deficient in essential fatty acids and fat-soluble vitamins. Based on a 30-day diet history, Hadigan et al (2000) found that more than 50% of 30 AN patients failed to meet recommended dietary allowances (RDA) for vitamin D, calcium, folate, vitamin B12, magnesium, copper, and zinc (see inside cover for dietary reference intake [DRIs]). Abnormal fluid intake is common, and the diet history should query patients about types, amounts, and rationale for fluid consumption. Some individuals restrict fluid intake because they find it difficult to tolerate feelings of fullness afterward; others drink excessive amounts to feel full and suppress appetite. Extremes in fluid restriction or ingestion may require monitoring of urine specific gravity and serum electrolytes. Many AN patients consume excessive amounts of artificially sweetened beverages and artificial sweeteners. Use of these products should be addressed during the course of nutrition therapy.

Bulimia Nervosa

Chaotic eating, ranging from restriction to normal eating to binge eating, makes it difficult to assess total energy intake in BN. The caloric content of a binge, the degree of caloric absorption after a purge, and the extent of calorie restriction between binge episodes must be evaluated. Patients with BN assume that vomiting is an efficient mechanism for eliminating calories consumed during binge episodes; however, this is a common misconception. In a study of the caloric content of foods ingested and purged in a feeding laboratory, it was determined that, as a group, BN subjects consumed a mean of 2131 kcal during a binge

BOX 21.4 Determination of Average Daily Energy Intake in the Individual with Bulimia Nervosa (BN)

1. Keep a record of patient intake for 7 days.
2. Out of the 7 days, determine the number of nonbinge days (which may include restrictive and normal intake days).
3. Approximate the total caloric content for the week.
4. Determine the number of binge days.
5. Determine the approximate caloric content of the binge days and then deduct 50% of the caloric content of binges that are purged (vomited).
6. Finally, average the caloric intake over the 7-day period. Determination of this average energy intake, as well as the range of intake, will be useful information for the assessment process.

and vomited only 979 kcal afterward (Kaye et al, 1993). As a rule of thumb, RDNs can estimate that about 50% of energy consumed during a binge is retained.

In a similar manner, patients misusing laxatives believe that catharsis will prevent the absorption of food and calories; however, laxatives do not act on the small intestine, where the majority of absorption occurs. In a laboratory study that was conducted by Bo-Linn et al (1983), two BN participants ate a standardized diet and took their regular daily dose of laxatives (35 and 50 tablets, accordingly). Results indicated that despite outputs of 4 to 6 L of diarrhea per day, these participants decreased calorie absorption by only 12%. Because of day-to-day variability, a 24-hour recall is not a particularly useful assessment tool. To assess energy intake, it is helpful to estimate daily food consumption over the course of a week using the method outlined in Box 21.4.

Nutrient intake in patients with BN varies with the cycle of binge eating and restriction, and it is likely that overall diet quality and micronutrient intake is inadequate. A 14-day dietary intake study of 50 BN patients revealed that at least 50% of participants consumed less than two thirds of the RDA for calcium, iron, and zinc on nonbinge days. Furthermore, 25% of participants had inadequate intakes of zinc and iron when overall intake (i.e., binge and nonbinge days) was assessed (Gendall et al, 1997). Even when the diet appears adequate, nutrient loss occurs secondary to purging, thus making it difficult to assess true adequacy of nutrient intake. Use of vitamin and mineral supplements also should be determined but, once again, retention after purging must be considered.

Eating Behavior

Characteristic attitudes, behaviors, and eating habits seen in AN and BN are shown in Box 21.5. Food aversions, common in this population, include red meat, baked goods, desserts, full-fat dairy products, added fats, fried foods, and caloric beverages. Patients with EDs often incorrectly regard specific foods or groups of foods as absolutely “good” or absolutely “bad.” Irrational beliefs and dichotomous thinking about food choices should be identified and challenged throughout the treatment process.

In comparison to healthy individuals, patients with AN exhibit characteristic mealtime behaviors that include staring at food, tearing food, nibbling/picking, dissecting food, napkin use, inappropriate utensil use, hand fidgeting, eating latency, and nibbling/picking latency (Gianini et al, 2015). In the assessment process, the RDN may discover unusual or ritualistic behaviors the patient practices, unusual food combinations, and excessive use of spices, vinegar, lemon juice, and artificial sweeteners. Meal spacing and length of time allocated for a meal also should be determined. Many patients save their self-allotted food ration until late in the day; others are fearful of eating past a

BOX 21.5 Assessment of Eating Attitudes, Behaviors, and Habits

1. Eating attitudes
 - A. Food aversions
 - B. Safe, risky, forbidden foods
 - C. Magical thinking
 - D. Binge trigger foods
 - E. Ideas on appropriate amounts of food
 - F. Refusal to eat a food item that does not have a nutrition facts label
2. Eating behaviors
 - A. Ritualistic behaviors
 - B. Unusual food combinations
 - C. Atypical use of condiments (e.g., mustard, lemon juice, vinegar) and seasonings (e.g., black pepper)
 - D. Atypical use of eating utensils and use of utensils to consume a finger food (e.g., using a knife and fork to eat a muffin)
 - E. Excessive use of artificial sweeteners
3. Eating habits
 - A. Intake pattern
 - (1) Number of meals and snacks
 - (2) Time of day, including times when eating may be restricted (e.g., patients will not permit themselves to eat before or after a certain time in the day).
 - (3) Duration of meals and snacks
 - (4) Eating environment—where and with whom
 - (5) How consumed—sitting or standing or while looking at a screen
 - B. Food group avoidance; particularly those with higher energy density
 - C. Diet variety from all food groups, including those with a low energy density content
 - D. Fluid consumption:
 - Restricted vs. excessive
 - Types: caloric, noncaloric, beverage water, alcohol

certain time of day. AN patients often eat in an excessively slow manner. This may be a tactic to avoid food intake, but it also may be an effect of starvation (Keys, 1950). Time limits for meal and snack consumption frequently are incorporated into behavioral treatment plans and FBT.

Many BN patients eat quickly, reflecting their difficulties with satiety cues. In addition, BN patients may identify foods they fear will trigger a binge episode. The patient may have an all-or-nothing approach to “trigger” foods. Although the patient may prefer avoidance, assistance with reintroduction of controlled amounts of these foods at regular times and intervals is helpful.

Patients may feel a sense of shame about particular food and eating practices, so these behaviors may not be identified during the initial assessment period. The assessment process continues during subsequent meetings and, in some cases, will not be complete until the RDN has observed the patient during a meal time.

Biochemical Assessment

The marked cachexia of AN may lead one to expect many biochemical indices of malnutrition (see Chapter 5), but this is rarely the case. Compensatory mechanisms are remarkable, and laboratory abnormalities may not be observed until the illness is far advanced.

Significant alterations in visceral protein status are less common than expected in AN. Indeed, adaptive phenomena that occur in chronic starvation are aimed at the maintenance of visceral protein metabolism at the expense of the somatic compartment. Although

serum albumin is usually normal (Mehler et al, 2018; Barron et al, 2017; Achamrah et al, 2017), when hypoalbuminemia does occur, it is associated with a poorer prognosis (Winston, 2012). Prealbumin is a more sensitive marker of malnutrition, and a low serum prealbumin level may be associated with the development of serious complications of refeeding (i.e., hypophosphatemia and hypoglycemia) in extremely underweight individuals (Gaudiani et al, 2014) (see Appendix 12).

Despite typical consumption of a very low-fat, low-cholesterol diet, malnourished AN patients often manifest elevated total cholesterol, low-density lipoprotein (LDL) cholesterol, and high-density lipoprotein (HDL) cholesterol levels (Winston, 2012). Although the cause is unclear and cardiovascular risk is uncertain, the bulk of available evidence suggests that lipid abnormalities improve or normalize after recovery and a low-fat, low-cholesterol diet is not warranted during the weight restoration process. If hyperlipidemia predates the development of AN, or a strong family history of hyperlipidemia is identified, the patient can be reassessed after nutritional rehabilitation. Lipid profiles routinely are included in laboratory assessments; however, a fasting lipid profile is not warranted until the patient is restored to a healthy and stable body weight.

Individuals with BN also may have elevated lipid levels, but the validity of the test must be questioned if the patient is actively binge eating. Furthermore, some BN patients cannot comply with the abstinence period required for a fasting lipid profile. Patients with BN eat chaotically, consuming a high-fat, high-calorie diet during binge episodes, and a low-fat, low-calorie diet during intermittent periods of restriction. An inaccurate lipid profile may lead to the unnecessary prescription of a restricted diet, which in turn may exacerbate binge eating episodes and reinforce an all-or-nothing approach to eating. If hyperlipidemia predates the development of BN, or if a strong family history of hyperlipidemia is identified, the patient should be reassessed after eating behavior and diet are stabilized (see Chapter 32).

Hypoglycemia results from a deficit of precursors that are needed for gluconeogenesis and glucose production. Patients with mild hypoglycemia are often asymptomatic; however, severe hypoglycemia is associated with increased risk of the refeeding syndrome (Gaudiani et al, 2014) and hospitalization may be warranted (Winston, 2012; see Chapter 12).

Vitamin and Mineral Deficiencies

Despite obviously deficient diets, surprisingly few studies address biochemical markers of micronutrient status in patients with EDs. Laboratory values are not always accurate in assessing micronutrient deficiencies because blood values in many cases do not reflect the full extent of depletion of total body nutrient stores. The decreased need for micronutrients in a catabolic state, possible use of vitamin supplements, and the selection of micronutrient-rich foods may afford some degree of protection in low weight patients; however, the shift from catabolic to anabolic processes may precipitate micronutrient deficiencies during refeeding and weight restoration. Study findings conflict, but zinc, copper, vitamin C, vitamin A, vitamin D, riboflavin, folate, and vitamin B6 deficiencies have been reported in AN (Mehler et al, 2018; Barron et al, 2017; Achamrah et al, 2017). Thiamin deficiency, prevalent among low-weight AN patients, may be exacerbated by increased carbohydrate intake during refeeding, and a thiamin supplement may be warranted (Winston, 2012). Given that assays for some vitamins and trace elements may not always be readily available, and that the relationship between blood concentrations and whole-body status is unclear, it may be more practical to prescribe a prophylactic vitamin/mineral supplement during refeeding and weight restoration (Winston, 2012).

Hypercarotenemia, attributed to mobilization of lipid stores, catabolic changes caused by weight loss, and metabolic stress, may occur in AN; excessive dietary intake of carotenoids is less likely (Winston,

2012). Hypercarotenemia resolves during weight restoration and measurement of serum carotene levels is unnecessary.

Iron requirements are decreased in AN secondary to amenorrhea and the overall catabolic state. At treatment onset, the hemoglobin level may be falsely elevated as a result of dehydration resulting in hemoconcentration. Malnourished patients may also have fluid retention, and associated hemodilution may falsely lower the hemoglobin level.

Low zinc levels in patients with AN have been reported by some investigators (Barron et al, 2017) but not by others (Achamrah et al, 2017). Zinc deficiency may result from inadequate energy consumption and transition to a vegetarian diet. Although zinc deficiency may be associated with altered taste perception and weight loss, there is no evidence that deficiency causes or perpetuates symptoms of AN. Supplemental zinc is purported to enhance food intake and weight gain in AN patients, but there is limited evidence to support this claim (Lock and Fitzpatrick, 2009).

Low 25-hydroxy vitamin D (25[OH]D) levels have been reported in low-weight AN patients (Mehler et al, 2018; Modan-Moses et al, 2014). Although vitamin D and calcium contribute to healthy bone development, there is no evidence to suggest that calcium or vitamin D supplementation increases BMD in AN (Robinson et al, 2017). Nevertheless, some researchers suggest routine assessment of 25(OH) D levels (Mehler et al, 2018; Modan-Moses et al, 2014). To date, adequate energy intake and normalization of body weight are the primary agents of bone health in AN. Supplements, like calcium and vitamin D, are variably prescribed among treatment programs and clinicians.

Fluid and Electrolyte Balance

Vomiting and laxative and diuretic use can result in significant fluid and electrolyte imbalances in patients with EDs (Trent et al, 2013). Baseline potassium, chloride, sodium, and CO₂ levels should be obtained in patients with purging and restricting behaviors, with monitoring based on symptomatology.

Urine concentration is sometimes decreased, and urine output increased in semistarvation. Edema can occur in response to malnutrition and refeeding. An increase in extracellular water frequently occurs in AN patients with a BMI less than 15 to 16 kg/m² (Rigaud et al, 2010). Although fluid retention usually dissipates with refeeding, limiting sodium intake to 2 g/day may be helpful (Rigaud et al, 2010). Depletion of glycogen and lean tissue is accompanied by obligatory water loss that reflects characteristic hydration ratios. For example, the obligatory water loss associated with glycogen depletion may be in the range of 600 to 800 mL. Varying degrees of fluid intake, ranging from restricted to excessive, may affect electrolyte values in patients with EDs (see Chapter 3).

Energy Expenditure

Metabolic adaptation to starvation occurs in malnourished AN patients (Kosmiski et al, 2014) and results in reduced resting energy expenditure (REE) in the range of 50% to 93% of predicted values (Haas et al, 2018b). Weight loss, decreased lean body mass, energy restriction, low T₃, and decreased leptin levels have been implicated in the pathogenesis of this hypometabolic state. At the completion of refeeding, REE reportedly increases to 94% to 119% of predicted values (Haas et al, 2018b). In addition to increased REE, AN patients often exhibit exaggerated **diet-induced thermogenesis (DIT)** in response to refeeding and this metabolic resistance to weight gain may contribute to the high-calorie prescriptions needed during nutritional rehabilitation (Kosmiski et al, 2014). Findings on REE in BN patients are contradictory, with investigators finding reduced levels, normal levels, and elevated levels of REE at baseline (de Zwaan et al, 2002). Proposed causes of a decreased REE include metabolic adaptation to intermittent periods of dietary restraint and fasting interfaced with binge eating and purging,

as well as a history of weight suppression. Increased REE may be caused by a preabsorptive release of insulin that activates the sympathetic nervous system during binge eating. Patients with BN may also find it difficult to fast for the requisite 10- to 12-hour period before REE testing. Although baseline and follow-up measurements of REE may be useful during the nutritional rehabilitation process (Mehler et al, 2010), access to indirect calorimetry equipment is often limited. Handheld calorimeters are readily available, but data on their accuracy in this patient population are limited (Hipskind et al, 2011; see Chapter 2).

Anthropometric Assessment

Patients with AN have PEM, characterized by significantly depleted adipose and somatic protein stores but a relatively intact visceral protein compartment. These patients meet the criteria for a diagnosis of severe PEM. A goal of nutritional rehabilitation is restoration of body fat and fat-free mass. Although these compartments do regenerate, the extent and rate vary.

Body composition studies of eating disordered patients have utilized underwater weighing, dual-energy x-ray absorptiometry (DEXA) equipped with body composition software, and skinfold thicknesses. Imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) also have been used to obtain detailed measurements of specific regions or tissues (e.g., visceral adipose fat) or fat infiltration of tissues. Total body protein assessment using *in vivo* neutron activation analysis (IVNAA) has recently been described in adolescents with AN (Haas et al, 2018a). Most body composition methodologies are limited to the research setting. Bioelectrical impedance analysis (BIA) is more clinically available, but shifts in intracellular and extracellular fluid compartments in patients with severe EDs may affect the accuracy of body fat estimate (see Chapter 5 and Appendix 11).

Careful assessment of height and weight are essential components of clinical management in all ED diagnostic groups. In AN and ARFID, weight restoration, followed by weight maintenance (adults) or age-appropriate weight gain (children/adolescents), is critical for recovery. In BN, cessation of binge/purge episodes with concurrent weight maintenance is the primary treatment goal. In BED, cessation of binge eating along with weight stabilization (size acceptance) or weight loss may be recommended (Grilo, 2017).

In hospitalized/residential treatment, an early morning, preprandial, gownned body weight measurement is recommended. The patient should be advised to empty bowel and bladder before weight assessment. Urine specific gravity can be checked if water loading is suspected. Patients may resort to deceptive tactics (water loading, hiding heavy objects like rolls of coins and marine diving weights on their person, and holding urine and bowel content) to reach a mandated weight goal. Frequency of weight checks varies among treatment programs but is typically every 1 to 3 days; known versus blind weight protocols also vary. On an outpatient basis, a gownned weight should be obtained on the same scale, at approximately the same time of day, at least once a week in early treatment. If the patient is seeing multiple health care professionals, only one should be weighing the patient.

Body weight, as a metric for assessment and a goal for recovery, is measured and monitored throughout treatment. However, “healthy” or “ideal” reference weights, like the Metropolitan Life Insurance Company tables and the Hamwi* method, provide widely varying and empirically unsupported results. Due to these limitations, BMI has

become increasingly accepted in the management of ED patients (see Chapter 5 and Appendix 11). In AN, four categories of BMI severity ratings, based on the World Health Organization categories for thinness in adults, have been incorporated into the DSM-5 (APA, 2013).

Delayed growth and stunting can occur in adolescents with AN. Height and weight data should be obtained from the primary medical record and replotted on the National Center Health Statistics (NCHS) weight-for-age and height-for-age percentiles growth chart and the BMI-for-age percentiles growth chart to determine whether linear growth has deviated from premorbid trajectories. Age at pubertal onset and current pubertal stage provide information about actual versus expected development. Assessment of a deficit in linear growth and potential for catch-up should be determined by a pediatrician or adolescent medicine specialist. In the older patient, a height deficit is likely permanent. In all age groups, height should be carefully measured using a stadiometer rather than a scale-anchored measuring rod (see Appendix 5).

BMI should be calculated and plotted on the NCHS BMI-for-age percentiles growth chart. The BMI percentile does not, however, describe how far an adolescent’s BMI deviates from the norm. The BMI z-score is therefore recommended to assess the degree of deviation from the median, as well as to categorize the degree of malnutrition (SAHM, 2015). Median BMI, defined as the 50th percentile BMI for age and sex, can also be used to compare the adolescent to the reference population. Percent median BMI (current BMI/50th percentile, BMI for age and sex \times 100) is also used to categorize mild, moderate, and severe degrees of malnutrition (SAHM, 2015). For adolescents, weight recovery is typically defined as 95% of the median BMI (Garber et al, 2016). BMI-for-age data tables providing the 50th percentile BMI value (median BMI) are available at the Centers for Disease Control and Prevention (CDC) website using the search term “growth charts.”

Rate of weight gain in AN may be affected by hydration status, glycogen stores, metabolic factors, and changes in body composition (Box 21.6). Rehydration and replenished glycogen stores contribute to

BOX 21.6 Factors Affecting Rate of Weight Gain in Anorexia Nervosa

1. Fluid balance
 - A. Polyuria seen in semistarvation
 - B. Edema
 - (1) Starvation
 - (2) Refeeding
 - C. Hydration ratios in tissues
 - (1) Glycogen: 3-4:1
 - (2) Protein stores: 2-3:1
2. Metabolic rate
 - A. Resting energy expenditure (REE): Low weight: REE 30% to 40% below predicted value for height, weight, age, gender
Refeeding: progressive increases in REE
Weight restoration: REE normalizes
 - B. Postprandial energy expenditure (PPEE)
Under normal metabolic conditions: PPEE approx. 10% greater than REE
In AN: PPEE may be 30% to 40% greater than REE
Duration of exaggerated response varies among individuals
 - C. Respiratory quotient
3. Energy cost of tissue gained
 - A. Fat-free mass
 - B. Adipose tissue
4. Previous obesity associated with decreased metabolic resistance to weight gain
5. Physical activity: time standing, volitional activity, fidgeting behavior

*Hamwi Method for women: 100 lb for the first 5 feet of height plus 5 lb per inch for every inch over 5 feet plus 10% for a large frame and minus 10% for a small frame. For men: 106 lb for the first 5 feet of height plus 6 lb per inch for every inch over 5 feet plus 10% for a large frame and minus 10% for a small frame.

weight gain during the first few days of refeeding. Thereafter, weight gain results from increased lean and fat stores. A general assumption is that someone has to increase or decrease caloric intake by 3500 kcal to cause a 1-lb change in body weight, but the true energy cost depends on the type of tissue gained. More energy is required to gain fat versus lean tissue, but weight gain may be a mix of fat and lean tissues. In adult women with AN, short-term weight restoration has been associated with a significant increase in truncal fat and central adiposity; this distribution, however, appears to normalize within 1 year of weight maintenance (Mayer et al, 2009). Short-term weight restoration in

adolescent females has been associated with and without central adiposity (de Alvaro et al, 2007; Franzoni et al, 2013).

MEDICAL NUTRITION THERAPY AND COUNSELING

Treatment of an ED may begin at one of five levels of care: outpatient, intensive outpatient, partial or day treatment, inpatient, or residential. The RDN is an essential part of the treatment team at all levels of care; roles and responsibilities of caring for individuals with EDs are summarized in Table 21.2.

TABLE 21.2 Roles and Responsibilities of Registered Dietitian Nutritionists Caring for individuals with Eating Disorders

<p>Nutrition Assessment: Identify nutrition problems that relate to medical and physical condition, including eating disorder symptoms and behaviors.</p>	<p>Specific Activities: Eating patterns Core eating attitudes Core attitudes regarding body weight and shape Assess behavioral-environmental symptoms: Food restriction Binge eating Preoccupation Rituals Secretive eating Affect and impulse control Vomiting or other purging behaviors Excessive exercise Anthropometric assessment: Measure height, weight, calculate BMI Obtain height and weight history Adolescents and young adults up to age 20: Plot on NCHS growth charts Assess growth patterns Calculate BMI z-score, percent of median BMI Assess degree of malnutrition: Adults: BMI Adolescents: BMI z-scores and percent of median BMI Interpret biochemical data and assess risk of refeeding syndrome Apply diagnosis, plan intervention, coordinate with treatment team</p>
<p>Nutrition Intervention: Calculate and monitor energy and macronutrient intake to establish expected rates of weight change, and body composition and health goals. Guide goal setting to normalize eating patterns for nutrition rehabilitation and weight restoration or maintenance as appropriate.</p>	<p>Ensure diet quality, regular eating pattern, increased amount and variety of foods, normal perceptions of hunger and satiety, provide suggestions about supplement use Provide a structured meal plan Provide psychological support and positive reinforcement Counsel patients and caregivers on food selection with consideration given to individual preferences, health history, physical factors, psychological factors, and resources</p>
<p>Nutrition Monitoring and Evaluation: Monitor nutrient intake and adjust as needed.</p>	<p>Monitor rate of weight gain Upon weight restoration, adjust food plan for weight maintenance Communicate progress with the treatment team Adjust treatment plan as needed</p>
<p>Care Coordination: Provide counsel to team about protocols to maximize tolerance of feeding regimen or nutrition recommendations, guidance about supplements to ensure maximum absorption, minimize drug nutrient interactions, and referral for continuation of care as needed.</p>	<p>Work collaboratively with the treatment team, delineate roles and tasks, communicate nutrition needs across treatment settings (i.e., inpatient, day patient, outpatient) Function as a resource and educator for other health care professionals and family members Advocate for evidence-based treatment and access to care</p>
<p>Advanced Training: Seek specialized training in other counseling techniques, such as cognitive behavioral therapy, dialectical behavioral therapy, and motivational interviewing.</p>	<p>Use advanced knowledge and skills relating to nutrition Seek supervision and case consultation from a licensed health professional to gain and maintain proficiency in eating disorders treatment</p>

BMI, Body mass index; NCHS, National Center for Health Statistics.

BOX 21.7 Guidelines for Medical Nutrition Therapy for Anorexia Nervosa

1. Caloric prescription
 - A. Initial prescription
 - APA (2006): 30 to 40 kcal/kg/day (approx. 1000 to 1600 kcal/day)
 - Higher kcal prescriptions require monitoring for refeeding syndrome (RFS)
 - Types of feedings: meal based, liquid supplements, tube feedings; total parenteral nutrition (TPN) (rare)
 - B. Weight gain phase:
 - Assess for individualized versus standardized approach
 - Progressive increases in kcal prescription to promote desired rate of weight gain
 - Late treatment: 70 to 100 kcal/kg/day (APA, 2006); approx. 3000 to 4000 kcal/day for females and 4000 to 4500 kcal/day for males
 - C. Weight maintenance phase:
 - Adults: 40 to 60 kcal/kg/day
 - Children/adolescents: kcal intake sufficient for normal growth and development
2. Macronutrient intake
 - A. Protein
 - 15% to 20% kcal
 - Minimum intake = Recommended dietary allowance (RDA) in g/kg ideal body weight
 - Promote high biologic value sources; avoid vegetarian diets
 - B. Carbohydrate
 - 50% to 60% kcal
3. Micronutrient intake:
 - A. 100% RDA multivitamin/mineral supplement.
 - B. Avoid supplemental iron during initial phase of refeeding and if patient is constipated.
 - C. Assess need for additional thiamin supplement.
 - D. Assess need for additional calcium supplementation.
4. Energy density
 - A. Promote intake of energy dense foods and beverages
 - If nutrient intake is assessed by computer analysis, calculate a Dietary Energy Density Score (DEDS): $DEDS = \text{kcal intake} / \text{weight (g)}$ of food and beverage
 - B. Goal for DEDS: ≥ 1.0
5. Diet variety
 - A. Promote intake of a wide variety of foods and beverages within all food groups.
 - B. Pay particular attention to the variety of complex carbohydrates, caloric beverages, and added fats.

In AN, the chosen level of care is determined by the severity of malnutrition, degree of medical and psychiatric instability, duration of illness, growth failure, and ability to manage recovery in the home. In some instances, treatment begins on an inpatient unit but is stepped down to a less intensive level of care as weight restoration progresses. In other instances, treatment begins on an outpatient basis; however, if progress is absent or considered inadequate, care is stepped up to a more intensive level.

In BN, treatment typically begins and continues on an outpatient basis. On occasion a patient with BN may be directly admitted to an intensive outpatient or day treatment program. However, inpatient hospitalization is relatively uncommon and generally is of short duration and for the specific purpose of fluid and electrolyte stabilization.

Anorexia Nervosa

Guidelines for MNT for AN are summarized in [Box 21.7](#). Goals for nutrition rehabilitation include restoration of body weight and normalization of eating patterns and behaviors. Although MNT is an essential component of treatment, guidelines are based largely on clinical experience rather than scientific evidence ([Rocks et al, 2014](#)).

Refeeding may occur in a variety of settings including inpatient medical units, inpatient psychiatric units, residential programs, day treatment/partial hospitalization, and outpatient settings. For adolescents engaged in FBT, the family home is the primary setting for refeeding. Refeeding may include combinations of meal-based feedings, liquid calorie supplements, tube feedings (continuous or bolus); parenteral nutrition (PN) is rarely used and not recommended unless no other form of refeeding is possible ([Garber et al, 2016](#)).

Weight restoration for medically unstable, severely malnourished ($BMI < 15 \text{ kg/m}^2$ in adult and $< 70\%$ median BMI in adolescents), or growth-impaired adolescents may require supervised weight gain in a specialized inpatient unit or residential treatment program. A few programs incorporate weight stabilization, weight gain, and weight maintenance phases into their treatment programs, but most initiate weight shortly after admission. Treatment includes a targeted rate of

expected weight gain. The APA (2006) recommends a targeted weight gain of 2 to 3 lbs. per week, others, including the SAHM, consider this rate of weight gain too conservative ([SAHM, 2015](#); [Garber et al, 2012](#); [Golden et al, 2013](#); [Katzman, 2012](#); [Kohn et al, 2011](#)).

Initial calorie prescriptions, and subsequent caloric adjustments, are also not widely agreed upon. The current standard of care for refeeding is to “start low” (approximately 1200 kcal/day) and “advance slow” (200 kcal increases every other day), the purpose of which has been to minimize the risk of refeeding syndrome, which is defined below ([Garber et al, 2016](#)). The tendency for conservative refeeding approaches to result in slower rates of weight gain and longer hospitalizations has prompted some treatment programs to use more aggressive “standardized” approaches to refeeding, which includes a higher initial calorie prescription and more rapid advancement during the refeeding process. An example of a standardized approach described by Haynos et al (2016) is provided in [Table 21.3](#). This type of protocol may be safe and effective in clinical settings that include a highly skilled eating disorder treatment team. In a clinical setting that is less specialized, it may be safer to prescribe an initial diet in accordance with the APA practice guideline (2006) recommendation of 30 to 40 kcal/kg of body weight per day (approximately 1000 to 1600 kcal/day) followed by progressive calorie increases (e.g., 200 kcal) at a frequency that will promote a consistent rate of weight gain. A systematic review of feeding approaches in AN conducted by Garber et al (2016) resulted in the following evidence-based conclusions: (1) lower calorie refeeding is too conservative in mildly (80% to 89% median BMI) and moderately (70% to 79% median BMI) malnourished adolescents; (2) there is insufficient evidence to support changing the current standard of care for refeeding (i.e., start low, go slow) in severely malnourished adolescents ($< 70\%$ median BMI) and adults ($BMI < 15 \text{ kg/m}^2$).

Risk of hypophosphatemia and complications associated with the **refeeding syndrome (RFS)** may present during the first few weeks of nutritional rehabilitation. Manifestations of RFS include fluid and electrolyte imbalance; cardiac, neurologic, and hematologic complications;

TABLE 21.3 Example of a Standardized Refeeding Protocol for Hospitalized Patients with Anorexia Nervosa

Days Since Admission	Meal Prescription (kcal)	Liquid Supplement (Ensure Plus) Prescription (kcal)	Total Prescription (kcal)
0	1800	0	1800
7	2200	0	2200
9	2220	350	2550
12	2600	350	2950
15	2600	700	3300
17	3000	700	3700

Haynos A, Snipes C, et al. *Int J Eat Disord* 49:50, 2016.

and sudden death. Risk for the development of RFS may depend more on the degree of malnutrition rather than caloric intake and rate of weight gain (Agostino et al, 2013; Garber et al, 2012; Golden et al, 2013; Kohn et al, 2011). At-risk individuals must be monitored carefully with daily measurements of serum phosphorus, potassium, and magnesium for the first 5 to 7 days of refeeding, and every other day for several weeks thereafter. Supplemental phosphorus, magnesium, and potassium may be given orally or intravenously. In some instances, prophylactic supplementation is provided to high-risk individuals; in other cases, supplementation is based on serum levels. Thiamin (B1) supplementation may be required at the onset and throughout the course of nutritional rehabilitation. Plasma glucose levels must be closely monitored for hypo- and hyperglycemia (Boateng et al, 2010). A systematic review of approaches to refeeding was conducted by Garber et al (2016). A position statement on the management of RFS in hospitalized adolescents is available from the SAHM (2014), and guidelines for identification of adults at high risk for RFS are available from the National Institute for Health and Clinical Excellence (NICE) (NICE, 2009).

Later in the course of weight restoration, caloric prescriptions in the range of 70 to 100 kcal/kg of body weight per day (approximately 3000 to 4000 kcal/day) may be needed, and male patients may require as much as 4000 to 4500 kcal/day (APA, 2006). Changes in REE, DIT, and the type of tissue gained contribute to high energy requirements. Patients who require extraordinarily high energy intakes should be questioned or observed for discarding of food, vomiting, exercising, and excessive physical activity, including fidgeting.

After the goal weight is attained, the caloric prescription may be slowly decreased to promote weight maintenance. Weight maintenance requirements are generally higher than expected and are usually in the range of 2200 to 3000 kcal/day. Caloric prescriptions may remain at higher levels in adolescents with the potential for continued growth and development.

AN patients receiving care in less-structured environments, such as an outpatient treatment program or a private nutrition practice, may be challenging and resistant to following formalized meal plans. A practical approach is the addition of 200 to 300 calories per day to the patient's typical (baseline) energy intake; however, the RDN must be mindful that these patients tend to overestimate their energy intake (Schebendach et al, 2012).

Once the energy prescription is calculated, a reasonable distribution of macronutrients must be determined. Patients may express multiple food aversions. Extreme avoidance of dietary fat is common, but continued omission will make it difficult to provide concentrated sources of energy needed for weight restoration. A dietary fat intake of at least 30% of calories is recommended. This can be accomplished easily when AN patients are treated on inpatient units or in day

hospital programs. On an outpatient basis, however, small, progressive increases in the dietary fat prescription may elicit more cooperation and less resistance. Although some patients will accept small amounts of added fat (such as salad dressing, mayonnaise, or butter), many do better when the fat content is less obvious (as in cheese, peanut butter, granola, and snack foods). Encouraging the gradual change from fat-free products (fat-free milk) to low-fat products (1% or 2% milk) and finally to full-fat items (whole milk) is also acceptable to some patients.

Protein intake in the range of 15% to 20% of total calories is recommended. To ensure adequacy the minimum protein prescription should equal the RDA for age and sex in gram per kilogram (g/kg) IBW (see inside cover). Vegetarian diets often are requested but should be discouraged during the weight restoration phase of treatment.

Carbohydrate intake in the range of 50% to 60% of calories are generally well tolerated. A lower carbohydrate diet (e.g., 40% of calories) may be indicated for a hyperglycemic patient. Constipation is a common problem in early treatment, and food sources of insoluble fiber may be beneficial (see Appendix 28).

Although vitamin and mineral supplements are not universally prescribed, the potential for increased needs during the later stages of weight gain must be considered. Prophylactic prescription of a vitamin and mineral supplement that provides 100% of the RDA may be reasonable, but iron supplementation may be contraindicated early in treatment (Royal College of Psychiatrists, 2005). Owing to the increased risk of low BMD, calcium and vitamin D-rich foods should be encouraged; there is no consensus on the use of calcium and vitamin D supplements in this population.

Delayed gastric emptying and resultant early satiety with complaints of abdominal distention and discomfort after eating are common in AN. In early treatment intake is generally low and can be tolerated in three meals per day. However, as the caloric prescription increases, between-meal feedings become essential. The addition of an afternoon or evening snack may relieve the physical discomfort associated with larger meals, but some patients express feelings of guilt for "indulging" between meals. Commercially available, defined-formula liquid supplements containing 30 to 45 calories per fluid ounce often are prescribed once or twice daily. Patients are fearful that they will become accustomed to the large amount of food required to meet increased caloric requirements; thus use of a liquid supplement is appealing because it can easily be discontinued when the goal weight is attained. The consumption of meals, snacks, and liquid supplements must be supervised during intake and immediately after (1-hour per-riod) intake to prevent purging.

Claims of lactose intolerance, food allergies, and gluten sensitivity complicate the refeeding process. These may be legitimate or simply a

covert means of limiting food choice. To the extent possible, all claims should be verified by prior or current medical testing. Lactose intolerance secondary to malnutrition may occur but typically resolves during the course of weight restoration. If medically warranted, lactose-free whole milk products and the prescription of an oral enzyme supplement before meals and snacks can be easily accommodated.

Food allergies and a gluten-free diet are far more challenging. Many patients claim to be vegetarians; however, the adoption of this dietary practice usually occurs in close proximity to the onset of AN. Many treatment programs prohibit vegetarian diets during the weight restoration phase of treatment; others allow a lacto-ovo vegetarian diet. The relationship of social, cultural, and family influences and religious beliefs relative to the patient's vegetarian status must be explored.

Institutions vary with respect to their menu-planning protocol. In some institutions the meal plan and food choices are fixed initially without patient input; as treatment progresses and weight is restored, the patient generally assumes more responsibility for menu planning. In other inpatient programs the patient participates in menu planning from the beginning of treatment. Some institutions have established guidelines that the patient must comply with to maintain the "privilege" of menu planning. Guidelines may require a certain type of milk (e.g., whole vs. low-fat) and the inclusion of specific types of foods such as added fats, animal proteins, desserts, and snacks. A certain number of servings from the different food groups may be prescribed at different calorie levels.

Meal planning methods vary among treatment programs, but data to suggest that one method is superior to another is lacking. Some programs use food group exchanges, others customize their approach. Regardless of the method, AN patients find it difficult to make food choices and plan menus. The RDN can be extremely helpful in providing a structured meal plan and guidance in the selection of nutritionally adequate meals and a varied diet. In a study of recently weight-restored, hospitalized AN patients, those who selected more energy-dense foods and a diet with greater variety had better treatment outcomes during the 1-year period immediately after hospital discharge, and this effect was independent of total caloric intake (Schebendach et al, 2008).

In an outpatient setting, the treatment team has less control over energy intake, food choice, and macronutrient distribution. Under these circumstances the RDN must use counseling skills to begin the process of developing a plan for nutritional rehabilitation. AN patients are typically precontemplative and, at best, ambivalent about making changes in eating behavior, diet, and body weight; some are defiant and hostile on initial presentation. Motivational interviewing and CBT techniques may be useful in the nutrition counseling of AN patients (Ozier et al, 2011); the reader is referred to Fairburn (2008) for a thorough review of CBT techniques.

Effective nutritional rehabilitation and counseling must ultimately result in weight gain and improved eating attitudes and behaviors. A comprehensive review of nutrition counseling techniques can be found in Chapter 13 and in Herrin and Larkin (2013) and Stellefson Myers and Caperton-Kilburn (2017).

Avoidant/Restrictive Food Intake Disorder

Patients with ARFID restrict/avoid their food intake to the extent that it is clinically significant; however, food restriction is not associated with shape and weight concerns. Patients may have sensory problems related to appearance, taste, smell, color, or texture of food. Others have a fear of swallowing/vomiting and they may have difficulty with solid foods or foods with a lumpy texture. There are currently no evidence-based guidelines specific to ARFID (Kohn, 2016). Since ARFID is associated with reluctance to normalize eating behaviors, behavioral management may be the first-line treatment. Behavioral management

should include: (1) an individualized assessment of the restrictive behaviors that includes a detailed history of symptoms that interfere with normal eating and food choice, (2) a plan that specifically reinforces the successful eating of restricted foods, and (3) a plan that specifically reinforces the reversal of avoidant/restrictive behaviors (Steinglass et al, 2016). Treatment needs to include individualized goals appropriate for specific symptoms. For example, discomfort with oral sensations may require graded exposure to novel foods, and fear of choking or vomiting may require specific swallowing exercises targeted to these symptoms (Steinglass et al, 2016), and collaboration with occupational therapists who specialize in feeding disorders may be necessary. The Nine Item Avoidant/Restrictive Food Intake Disorder Screen (NIAS) may be useful in the assessment of ARFID-related eating behaviors in this patient population (Zickgraf and Ellis, 2018)

Bulimia Nervosa

Guidelines for MNT in BN are summarized in Box 21.8. BN is described as a state of dietary chaos characterized by periods of uncontrolled, poorly structured eating, followed by periods of restrained food intake. The RDN's role is to help develop a reasonable plan of controlled eating while assessing the patient's tolerance for structure.

During the initial onset of BN, much of the patient's eating and purging behavior is aimed at weight loss. Later in the process, the behaviors may be habitual and out of control. Even if the patient is legitimately overweight, immediate goals must be interruption of the binge-and-purge cycle, restoration of normal eating behavior, and stabilization

BOX 21.8 Guidelines for Medical Nutrition Therapy of Bulimia Nervosa

1. Caloric prescription for weight maintenance
 - A. If metabolic rate appears normal, provide dietary reference intake (DRI) for energy (approximately 2200 to 2400 kcal/day).
 - B. If there is strong evidence of a hypometabolic rate:
 - Start at 1600 to 1800 kcal/day
 - Increase in 100 to 200 kcal/week increments up to 2200 to 2400 kcal/day
 - B. Monitor body weight and adjust caloric prescription for weight maintenance.
 - C. Avoid low-calorie diets as these may exacerbate bingeing and purging behaviors.
2. Macronutrients
 - A. Protein
 - (1) 15% to 20% kcal
 - (2) Minimum: recommended dietary allowance (RDA) in g/kg of ideal body weight
 - (3) High biological value sources
 - D. Carbohydrate
 - (4) 50% to 60% kcal
 - (5) Provide insoluble fiber sources for treatment of constipation
 - E. Fat
 - (6) 30% kcal
 - (7) Provide source of essential fatty acids
3. Micronutrients
 - A. 100% RDA multivitamin/mineral supplement
 - B. Avoid supplemental iron if patient is constipated
4. Energy density
 - C. Provide foods with a range of energy densities
 - D. Provide an overall diet with an energy density of approximately 1.0
5. Diet variety
 - E. Promote intake of a wide variety of foods and beverages within all food groups

of body weight. Attempts at dietary restraint for the purpose of weight loss typically exacerbate binge-purge behavior in BN patients.

Patients with BN have varying degrees of metabolic efficiency, which must be taken into account when prescribing the baseline diet. Assessment of REE along with clinical signs of a hypometabolic state, such as a low T_3 level and cold intolerance, are useful in determining the caloric prescription. If a low metabolism is suspected, a caloric prescription of 1600 to 1800 calories daily is a reasonable place to start; however, this prescription should be titrated upwards, in 100 to 200 calorie per week increments, to stimulate the metabolic rate. Ultimately, a weight maintenance diet of 2200 to 2400 kcal/day is attainable and well tolerated. If a patient is willing and able to provide a detailed diet history or a 7-day food record, the initial caloric prescription can also be calculated by the method described in Box 21.4.

Body weight should be monitored with a goal of stabilization; however, BN patients need a great deal of encouragement to follow weight maintenance versus weight loss diets. They must be reminded that attempts to restrict caloric intake may only increase the risk of binge eating and that their pattern of restrained intake followed by binge eating has not facilitated weight loss in the past.

A balanced macronutrient intake is essential for the provision of a regular meal pattern. This should include sufficient carbohydrates to prevent craving and adequate protein and fat to promote satiety. In general, a balanced diet providing 50% to 60% of the calories from carbohydrate, 15% to 20% from protein, and approximately 30% from fat is reasonable.

Adequacy of micronutrient intake relative to the caloric prescription, macronutrient distribution, and diet variety should be assessed. A multivitamin and mineral preparation may be prescribed to ensure adequacy, particularly in the initial phase of treatment.

Bingeing, purging, and restrained intake often impair recognition of hunger and satiety cues. The cessation of purging behavior coupled with a reasonable daily distribution of calories at three meals and prescribed snacks can be instrumental in strengthening these biologic cues. Many patients with BN are afraid to eat earlier in the day because they are fearful that these calories will contribute to caloric excess if they binge later. They also may digress from their meal plans after a binge, attempting to restrict intake to balance out the binge calories. Patience and support are essential in this process of making positive changes in their eating habits.

When the BN patient is receiving CBT, the RDN may assist the CBT therapist in the phase 1 goal of establishing a regular meal pattern. The RDN and the psychotherapist must, however, maintain active communication to avoid overlap in the counseling sessions. If the BN patient is engaged in a type of psychotherapy other than CBT, the RDN should incorporate more CBT skills into the nutrition counseling sessions (Herin and Larkin, 2013; Stellefson Meyers and Caperton-Kilburn, 2017).

Patients with BN are typically more receptive to nutrition counseling than AN patients and less likely to present in the precontemplation stage of change. Suggested strategies for nutrition counseling at the precontemplation, contemplation, preparation, action, and maintenance stages are given in Table 21.4 (see Chapter 13).

TABLE 21.4 Counseling Strategies Using the Stages of Change Model in Eating Disorders

Stage of Change	Counseling Strategies
Precontemplation	<ul style="list-style-type: none"> Establish rapport. Assess nutrition knowledge, beliefs, attitudes. Conduct thorough review of food likes and dislikes, safe and risky foods, forbidden foods (assess reason), binge and purge foods. Assess physical, anthropometric, metabolic status. Assess level of motivation. Use motivational interviewing techniques. Decisional balance: weigh costs and benefits of maintaining current status versus costs and benefits of change.
Contemplation	<ul style="list-style-type: none"> Identify behaviors to change; prioritize. Identify barriers to change. Identify coping mechanisms. Identify support systems. Discuss self-monitoring tools: food and eating behavior records. Continue motivational interviewing technique.
Preparation	<ul style="list-style-type: none"> Implement nutrition-focused CBT. Implement self-monitoring tools: food and eating behavior records. Determine list of alternative behaviors to bingeing and purging.
Action	<ul style="list-style-type: none"> Develop a plan of healthy eating. Reinforce positive decision making, self-confidence, and self-efficacy. Promote positive self-rewarding behaviors. Develop strategies for handling impulsive behaviors, high-risk situations, and "slips." Continue CBT. Continue self-monitoring.
Maintenance and relapse	<ul style="list-style-type: none"> Identify strategies; manage high-risk situations. Continue positive self-rewarding behaviors. Reinforce coping skills and impulse-control techniques. Reinforce relapse prevention strategies. Determine and schedule follow-up sessions needed for maintenance and reinforcement of positive changes in eating behavior and nutrition status.

CBT, Cognitive behavioral therapy.

Modified from Stellefson Myers E: *Winning the war within: nutrition therapy for clients with anorexia or bulimia nervosa*, Dallas, 2006, Helm Publishing.

Binge Eating Disorder

Strategies for treatment of BED include nutrition counseling and dietary management, individual and group psychotherapy, and medication management. Size-acceptance (HAES; Health At Every Size), improved body image, increased physical activity, and improved health and nutrition are treatment goals for BED. Some treatment programs focus primarily on nutrition counseling and weight loss. Unfortunately, behavioral weight loss therapy may be effective in attaining short-term rather than long-term weight loss in these individuals (Wilson, 2011). Results of a 6-month combined CBT and dietary counseling intervention (provided by RDs) conducted in obese BED patients indicated improved psychological functioning and a significant decrease in binge eating episodes, but no clinically meaningful weight loss (Masheb et al, 2016). MNT counseling for the BED patient requires ongoing communication with the psychotherapist and a clear intervention goal (i.e., nutrition counseling based on wellness and size-acceptance or behavioral weight loss treatment). Guided self-help CBT (Fairburn, 1995) is also a treatment option (Striegel-Moore et al, 2010).

Orthorexia Nervosa

Numerous studies have provided evidence for the condition of orthorexia nervosa (ON), an eating pattern characterized by an obsession for and fixation on healthy eating. It is currently not categorized as an

eating disorder, and the current scientific debate is whether this is a behavioral or lifestyle phenomenon or a true mental disorder. Although being aware of and concerned with the nutritional quality of the food eaten is not a problem in and of itself, people can become fixated on so-called healthy eating (often characterized as clean eating) and actually damage their own well-being by adherence to strict food rules. While ON is not clinically defined and is not included in the DSM-5, the National Eating Disorders Association states that it is currently being treated by eating disorder experts who treat ON as a variety of anorexia and/or obsessive-compulsive disorder (Esposito and Fierstein, 2018).

Preliminary criteria for the diagnosis of ON were proposed in 2004 (Donini et al, 2004). Since that time diagnostic criteria have been proposed for the condition (Dunn and Bratman, 2016). A recent large cross-sectional study (Strahler et al, 2018) explored whether ON is of epidemiologic and clinical relevance, and whether it can be distinguished from other mental health disorders and healthy lifestyle features. They confirmed the epidemiologic and clinical relevance of orthorexic behaviors but found strong conceptual overlap with other mental health problems and ultimately challenged the idea that ON is a distinct mental health disorder category.

Monitoring Nutritional Rehabilitation

Guidelines for patient monitoring are indicated in Box 21.9. The health professional, patient, and family must be realistic about

BOX 21.9 Patient Monitoring

1. Body weight
 - A. Establish treatment goal weight and body mass index (BMI)
 - B. Determine:
 - a. Acceptable rate of weight gain in anorexia nervosa (AN)
 - b. Maintenance weight in bulimia nervosa (BN)
 - C. Children and adolescents:
 - c. Plot weight on National Center for Health Statistics (NCHS) weight-for-age percentile growth chart
 - d. Determine weight percentile
 - D. Monitor weight:
 - (1) Inpatient and partial hospitalization
 - a. Frequency: Inpatient: daily or every other day; partial hospitalization: varies with diagnosis, age of patient, phase of treatment (i.e., daily, several times per week, once per week)
 - b. Gowned
 - c. Morning weight
 - d. Preprandial
 - e. Postvoid
 - f. Same scale
 - g. Check urine specific gravity if fluid loading is suspected
 - h. Additional random weight checks if fluid loading is suspected
 - (2) Outpatient treatment:
 - a. Once every 1 to 2 weeks in early treatment, less frequently in mid- to late treatment
 - b. Gowned
 - c. Postvoid
 - d. Same time of day
 - e. Same scale
 - f. Check urine specific gravity if fluid loading is suspected
2. Height
 - A. Measure baseline height using a stadiometer
 - B. Children and adolescents:
 - (1) Plot height on NCHS stature-for-age percentile growth chart
 - (2) Determine height percentile
 - (3) Assess for growth impairment
 - (4) Monitor height every 1 to 2 months in patients with growth potential
3. BMI:
 - A. Adults: calculate BMI using Centers for Disease Control and Prevention (CDC) online calculator for adults: https://www.cdc.gov/healthyweight/assessing/bmi/adult_bmi/english_bmi_calculator/bmi_calculator.html
 - B. Children and adolescents:
 - (1) Calculate BMI, BMI percentile, and BMI z-score using CDC online calculator for children and adolescents at <https://www.cdc.gov/healthyweight/bmi/calculator.html>
 - (2) Plot BMI on NCHS body mass index-for-age percentile chart
 - (3) Determine median BMI (50th percentile BMI for age and sex) using CDC Data Table of BMI-for-age charts
 - (4) Calculate percent median BMI [(current BMI/median BMI) x 100]
4. Outpatient diet monitoring
 - A. AN

Daily food record to include:*

 - (1) Food
 - (2) Fluid: caloric, noncaloric, alcohol
 - (3) Artificial sweeteners
 - (4) Eating behavior: time, place, how eaten, with whom
 - (5) Dietary energy density
 - (6) Diet variety
 - B. BN

Daily food record to include:*

 - (1) Food
 - (2) Fluid: caloric, noncaloric, alcohol
 - (3) Artificial sweeteners
 - (4) Eating behavior: time, place, how eaten, with whom
 - (5) Emotions and feelings when eating
 - (6) Foods eaten at a binge
 - (7) Time and method of purge
 - (8) Dietary energy density
 - (9) Diet variety
 - (10) Exercise

*Consider having patient monitor intake with an app (see Box 21.2).

treatment, which is often a long-term process. Although outcomes may be favorable, the course of treatment is rarely smooth and linear, and clinicians must be prepared to monitor progress with patience and compassion.

Nutrition Education

Patients with EDs may appear knowledgeable about food and nutrition. Despite this, nutrition education is an essential component of their treatment plan. Indeed, some patients spend significant amounts of time reading nutrition-related information, but their sources may be unreliable, and their interpretation potentially distorted by their illness. Malnutrition may impair the patient's ability to assimilate and process new information. Early and middle adolescent development is characterized by the transition from concrete to abstract operations in problem solving and directed thinking, and normal developmental issues must be considered when teaching adolescents with EDs (see Chapter 17).

Nutrition education materials must be assessed thoroughly to determine whether language and subject matter are bias free and appropriate for AN and BN patients. For example, literature provided by many health organizations promotes a low-fat diet and low-calorie lifestyle for the prevention and treatment of chronic disease. This material is in direct conflict with a treatment plan that encourages increased caloric and fat intake for the purpose of nutritional rehabilitation and weight restoration.

Although the interactive process of a group setting may have advantages, these topics can also be effectively incorporated into individual counseling sessions. Topics for nutrition education are suggested in [Box 21.10](#).

Prognosis

The course and outcome of AN are highly variable. Some individuals fully recover, some have periods of recovery followed by relapse, and others are chronically ill for many years (APA, 2013). Although approximately 70% of individuals with BN achieve remission, those who have not achieved remission after 5 years of illness may demonstrate a chronic course (Keel and Brown, 2010).

CLINICAL CASE STUDY 1

Anorexia Nervosa

Melissa is in her second week of hospitalization in an inpatient eating disorder specialized hospital unit. She is a 15-year-old Hispanic female who immigrated to the United States 6 years ago. Her parents report preoccupation with her body and food intake beginning at 12 years of age. Upon admission, Melissa's weight is 78 pounds, her height is 62.25 inches, and her body mass index (BMI) is 14.2.

Patient began menses at the age of 12 and, due to typical adolescent developmental changes, reported feeling uncomfortable in her body. At this time, she measured 58 inches and weighed 93 pounds, 76th percentile BMI for age). She learned she could restrict through seeing her mom diet at home and began counting her calories. She would aim for less than 1000 calories per day and began walking for 30 to 60 minutes daily. After 6 months, halfway through her sixth-grade year, Melissa had dropped to 82 pounds and did not grow in height during this time; she dropped to the 46th percentile (BMI for age) and stopped menstruating. Melissa's parents began worrying and started to adapt a Maudsley/family-based therapy approach that included eating all meals at home with them. She would continue to restrict at school and exercise as much as she could but was able to gain weight back and by the beginning of 7th grade was up to 105 pounds and grew 2 inches.

BOX 21.10 Topics for Nutrition Education

- Guidelines for recovery: energy, macronutrient, vitamin, mineral, and fluid intakes
- Impact of malnutrition on adolescent growth and development
- Physiologic and psychological consequences of malnutrition
- Set point theory and the determination of a healthy body weight
- Impact of energy restriction on the metabolic rate
- Ineffectiveness of vomiting, laxatives, and diuretics in long-term weight control
- Causes of bingeing and purging, and techniques to break the cycle
- Changes in body composition that occur during weight restoration
- Exercise and energy balance
- What does "healthy eating" mean to you?
- Challenging food rules
- Emotional undereating and overeating
- Intuitive eating: how to get in touch with hunger and satiety cues
- Meal planning strategies for recovery and maintenance of a healthy body weight
- Social and holiday dining
- Interpreting food labels
- Strategies for food shopping

SUMMARY

The clinical care of patients with EDs requires a collaborative treatment team at all levels of care. Specialized treatment programs (inpatient, day patient, outpatient) typically provide ready access to mental health professionals who can assist and support the RDN in the management of this challenging patient population. When the team consists of independent practitioners, communication and professional support may be more challenging. In this case the RDN may benefit from membership in an organization of eating disorder professionals that provides ongoing educational opportunities, as well as mentorship, support, and case supervision.

Melissa continued to be monitored by her pediatrician and entered high school with a height of 61 inches and weighed 112 pounds. Entering high school, Melissa quickly became stressed with the high demand of her classes and began restricting again, this time down to approximately 500 to 800 calories per day. By January of this year Melissa's weight had dropped to 89 pounds, so she began outpatient treatment. Her typical daily intake before admission was 1 cup coffee in the morning with an apple. For lunch she had salad that she packed from home with 3 ounces of sliced turkey on it and a ½ cup of brown rice with balsamic vinegar. For dinner she had two pieces of Laughing Cow cheese with steamed vegetables in her room, telling her parents she had too much work to do to sit at the table. If she got hungry at night, she would have an individual bag of fat-free popcorn. She also reported 60 to 90 minutes of walking or running per day at the gym after school. Since her first onset of menses, Melissa was getting her period on average 4 to 5 times per year; however, it has now been 6 months since her last period. Melissa denies any purging or laxative abuse. At her most recent pediatrician appointment, Melissa lost another 2 pounds since the week prior, and her heart rate was 68. The doctor recommended inpatient hospitalization for refeeding.

Continued

CLINICAL CASE STUDY 1

Anorexia Nervosa—cont'd

Since being in the hospital, Melissa has struggled with eating 100% of her meals and has been caught hiding food in her napkin and spilling her supplements out in the garbage when staff is not looking. The staff report she is consuming on average 60% to 75% of her three meals and two snacks. She reports fearing any foods high in fat such as cheese, fried foods, desserts of any kind, meat, oils, and potato chips.

Medical history: Amenorrhea, hypokalemia

Current medications: MVI with trace minerals, thiamine daily

Inpatient calorie prescription: 3000 kcal/day + 8 fl oz Ensure Plus

B/P: 89/58

Pulse: 58

Laboratory Values:

Test	Result	Reference Range
Sodium	129	135-147 mEq/L
Potassium	3.3	3.5-5.2 mEq/L
Chloride	94	95-107 mEq/L
Calcium	8.2	8.7-10.7 mg/dL
CO ₂	32	22- 29 mmol/L
Glucose	65	60- 69 mg/dL (fasting)
BUN	23	8-21 mg/dL
Creatinine	1.2	0.65-1.00 mg/dL
Phosphorous	3.2	2.5-4.6 mg/dL
Magnesium	2.2	1.7-2.3
Cholesterol	240	<200

Nutrition Diagnostic Statement

- Underweight related to abnormal eating pattern as evidenced by restrictive caloric intake and excessive exercise in the setting of a 14.2 BMI for age.

Nutrition Care Questions

1. List the essential criteria for the diagnosis of anorexia nervosa (AN). Indicate Melissa's AN subtype.
2. What indications supporting hospitalization did Melissa meet before her admission?
3. Would you classify Melissa as malnourished? What criteria did you use to make this determination?
4. What are the significant physical findings from a nutrition-focused physical examination of Melissa? What are some other symptoms commonly seen in AN?
5. Assess Melissa's laboratory values and indicate what other values also may be altered in her condition.
6. What are the primary nutrition therapy goals for Melissa? How will these goals change as treatment progresses?
7. Plot anthropometric data on National Center for Health Statistics (NCHS) weight-for-age, height-for-age, and BMI-for-age percentiles charts for females, age 2 to 20 years. Calculate BMI, BMI percentile, BMI z-score, and percentile median BMI. Based on these criteria, what is Melissa's initial treatment goal weight and BMI? How often would you recommend reassessing these goals?
8. What are some behavioral or psychological treatment approaches that could be used to help Melissa?

CLINICAL CASE STUDY 2

Bulimia Nervosa

Kristin is a 34-year-old white female who has come to see you in your outpatient private practice. Her chief complaint is that she feels "out of control and wants to stop bingeing."

Kristin currently is employed as a marketing director at a company in New York City. She describes her life to be very stressful: working approximately 50 to 55 hours per week in the office and has several social engagements in the evenings. She reports an "unhealthy" relationship with food since she was a teenager, when she was a "yo-yo dieter," and would take various diet pills to lose weight. Her weight as a teenager fluctuated between slightly underweight to normal. Kristin began to purge in college after some of her friends introduced her to the idea of vomiting. Later, after moving to New York City and becoming stressed with life events, she began to purge more often after what she describes as "binges."

Currently Kristin reports skipping breakfast most days but has a large cup of coffee, black, with five packets of artificial sweetener. She has a snack around 10 AM of a handful of almonds and sometimes a fruit. She usually goes to the gym during her lunch hour, where she does 45 to 55 minutes of cardio. For lunch Kristin has two hardboiled eggs, a piece of toast, and a diet soda. A few times per week after client lunches Kristin feels stressed that she ate "fear foods," so she binges on cookies or candy and afterward purges in her private bathroom. In the afternoon Kristin usually has another coffee or diet soda and a protein bar. After work Kristin goes home with plans of eating a normal dinner but, after ordering takeout from the local Chinese, Italian, or sushi restaurant, binges on approximately 2000 to 3000 calories' worth of food before purging.

Kristin has a hard time at social events that occur several times a week and binges or purges after them as well. In total Kristin estimates she is binge/purging

five times per week, sometimes twice per day. Kristin is frustrated with the binge/purge cycle she is caught in and is requesting guidance for a meal plan.

Medical history: Dental caries requiring three root canals and two implants; irritable bowel syndrome with constipation

Current medications: Fluoxetine 40 mg, Colace 100 mg once daily

Height: 5'5", weight: 138 lb (BMI: 23.0)

Laboratory data:

Test	Result	Reference Range
Sodium	139	135-147 mEq/L
Potassium	3.3	3.5-5.2 mEq/L
Chloride	94	95-107 mEq/L
Calcium	8.2	8.7-10.7 mg/dL
CO ₂	29	22-29 mmol/L
Glucose	85	60-99 mg/dL (fasting)
BUN	15	8-21 mg/dL
Creatinine	1.2	0.65-1.00 mg/dL
Phosphorous	3.6	2.5-4.6 mg/dL
Magnesium	2.2	1.7-2.3
Amylase	105	25-100 units/L
Cholesterol	210	<200 mg/dL
Bicarbonate	16.5	18.0-23.0 mmol/L

Nutrition Diagnostic Statement

- Disordered eating pattern (NB-1.5) related to bingeing and purging as evidenced by a pattern of restrictive eating, bingeing, and self-induced vomiting.

CLINICAL CASE STUDY 2

Bulimia Nervosa—cont'd**Nutrition Care Questions**

1. What are the medical complications Kristin is experiencing secondary to her bingeing and purging? What are some others she could develop if she does not stop?
2. Discuss which laboratory values are abnormal.
3. What are your main goals for nutrition therapy while working with Kristin?
4. How might you approach meal planning with Kristin?
5. How might you help Kristin talk about her fear foods and set goals for including them in her diet without bingeing on them?
6. What techniques would be helpful for Kristin to challenge her urges to binge and purge during stressful work situations?

Nutrition in Exercise and Sports Performance

Lisa Dorfman, MS, RDN, CSSD, CCMS, LMHC, FAND

KEY TERMS

actomyosin	exercise related transient abdominal pain (ETAP)	microbiome
adenosine diphosphate (ADP)	fat adaptation strategy	mitochondria
adenosine triphosphate (ATP)	female athlete triad (FAT)	muscle dysmorphia (MD)
aerobic metabolism	glycemic index	myoglobin
anabolic effects	glycogen	nutrition periodization
anaerobic metabolism	glycogen loading (glycogen supercompensation)	oxidative phosphorylation
androgenic effects	glycogenolysis	pseudoanemia
anorexia athletica (AA)	glycolysis	relative energy deficit in sports (RED-S)
athletic energy deficit (AED)	high-intensity interval training (HIIT)	respiratory exchange ratio (RER)
creatine phosphate (CP)	hypohydration	reactive oxygen species (ROS)
dehydration	human growth hormone (HGH)	sports anemia
dehydroepiandrosterone (DHEA)	lactic acid	thermoregulation
eating, exercise, and body image (EEBI) disorders	metabolic equivalents (METs)	Vo ₂ max
ergogenic aid		

Optimal athletic performance is the culmination of genetics, proper training, adequate nutrition, hydration, desire, and adequate rest. Nutrition is especially important to recreational and competitive athletes regardless of age or gender. Understanding sport-specific physiologic requirements for training and competition is integral to obtaining sufficient energy, optimal levels of macronutrients and micronutrients, and adequate levels of fluids. A balanced dietary intake is vital for supporting energy needs and stamina for training hard, achieving target performance, body composition and weight goals, adequate recovery, and reducing the incidence of illness and injury. In some cases, the use of supplements and sports foods is also helpful (Hosseinzadeh et al, 2017; International Olympic Committee [IOC], 2018; Mielgo-Ayuso et al, 2015).

BIOENERGETICS OF PHYSICAL ACTIVITY

Exercise nutrition requires essential elements from food to fuel muscle contractions, build new tissue, preserve lean muscle mass, optimize skeletal structure, repair existing cells, maximize oxygen transport, maintain favorable fluid and electrolyte balance, and regulate metabolic processes.

The human body must be supplied continuously with energy to perform its many complex functions. Three metabolic systems supply energy for the body: one dependent on oxygen (**oxidative phosphorylation** or **aerobic metabolism**) and the other two independent of oxygen (creatine phosphate and anaerobic glycolysis or **anaerobic metabolism**). The use of one system over the other depends on the duration, intensity, and type of physical activity.

Adenosine Triphosphate: Ultimate Energy Source

Regardless of the energy system used to generate power for exercise, the body relies on a continuous supply of fuel through **adenosine triphosphate (ATP)**, found within the mitochondria of the body. The energy produced from the breakdown of ATP provides the fuel that activates muscle contraction. The energy from ATP is transferred to the contractile filaments (myosin and actin) in the muscle, which form an attachment of actin to the cross-bridges on the myosin molecule, thus forming **actomyosin**. Once activated the myofibrils slide past each other and cause the muscle to contract.

Although ATP is the main currency for energy in the body, it is stored in limited amounts. Approximately 3 oz of ATP is stored in the body at any one time (McArdle et al, 2014). This provides only enough energy for several seconds of exercise, and yet ATP must be resynthesized continually to provide a constant energy source. When ATP loses a phosphate, thus releasing energy, the resulting **adenosine diphosphate (ADP)** is combined enzymatically with another high-energy phosphate from **creatine phosphate (CP)** to resynthesize ATP. The concentration of high-energy CP in the muscle is five times that of ATP.

Creatine kinase is the enzyme that catalyzes the reaction of CP with ADP and inorganic phosphate. This is the fastest and most immediate means of replenishing ATP, and it does so without the use of oxygen (anaerobic). Although this system has great power, it is time limited because of the limited concentration of CP found in the muscles (see Creatine later in the chapter).

The energy released from this ATP-CP system will support an all-out exercise effort of only a few seconds, such as in a power lift, tennis

serve, or sprint. If the all-out effort continues for longer than 8 seconds, or if moderate exercise is to proceed for longer periods, an additional source of energy must be provided for the resynthesis of ATP. The production of ATP carries on within the muscle cells through either the anaerobic or aerobic pathways.

Anaerobic or Lactic Acid Pathway

The next energy pathway for supplying ATP for more than 8 seconds of physical activity is the process of **glycolysis**. In this pathway the energy in glucose is released without the presence of oxygen. **Lactic acid** is the end product of glycolysis. Without the production of lactic acid, glycolysis would shut down. The coenzyme called nicotinic acid dehydrogenase (NAD) is in limited supply in this pathway. When NAD is limited, the glycolytic pathway cannot provide constant energy. By converting pyruvic acid to lactic acid, NAD is freed to participate in further ATP synthesis. The amount of ATP furnished is relatively small; the process is only 30% efficient. This pathway contributes energy during an all-out effort lasting up to 60 to 120 seconds. Examples are a 440-yard sprint and many sprint-swimming events (Powers et al, 2018).

Although this process provides immediate protection from the consequences of insufficient oxygen, it cannot continue indefinitely. When exercise continues at intensities beyond the body's ability to supply oxygen and convert lactic acid to fuel, lactic acid accumulates in the blood and muscle, lowers the pH to a level that interferes with enzymatic action, and causes fatigue. Lactic acid can be removed from the muscle, transported into the bloodstream, and converted to energy in muscle, liver, or brain. Otherwise, it is converted to glycogen. Conversion to **glycogen** occurs in the liver and to some extent in muscle, particularly among trained athletes.

The amount of ATP produced through glycolysis is small compared with that available through aerobic pathways. Substrate for this reaction is limited to glucose from blood sugar or the glycogen stored in the muscle. Liver glycogen contributes but is limited.

Aerobic Pathway

Production of ATP in amounts sufficient to support continued muscle activity for longer than 90 to 120 seconds requires oxygen. If sufficient oxygen is not present to combine with hydrogen in the electron transport chain, no further ATP is made. Thus the oxygen furnished through respiration is of vital importance. Here, glucose can be broken down far more efficiently for energy, producing 18 to 19 times more ATP. In the presence of oxygen, pyruvate is converted to acetyl coenzyme A (CoA), which enters the **mitochondria**. In the mitochondria acetyl CoA goes through the Krebs cycle, which generates 36 to 38 ATP per molecule of glucose (Fig. 22.1).

Aerobic metabolism is limited by the availability of a continuous and adequate supply of oxygen, and the availability of coenzymes. At the onset of exercise and with the increase in exercise intensity, the ability of the cardiovascular system to supply adequate oxygen is a limiting factor, and this is largely due to the level of conditioning. The aerobic pathway provides ATP by metabolizing fats and proteins. A large amount of acetyl CoA, which enters the Krebs cycle and provides enormous amounts of ATP, is provided by beta-oxidation of fatty acids. Proteins may be catabolized into acetyl CoA or Krebs cycle intermediates, or they may be directly oxidized as another source of ATP.

Energy Continuum

A person who is exercising may use one or more energy pathways. For example, at the beginning of any physical activity, ATP is produced anaerobically. As exercise continues, the lactic acid system produces

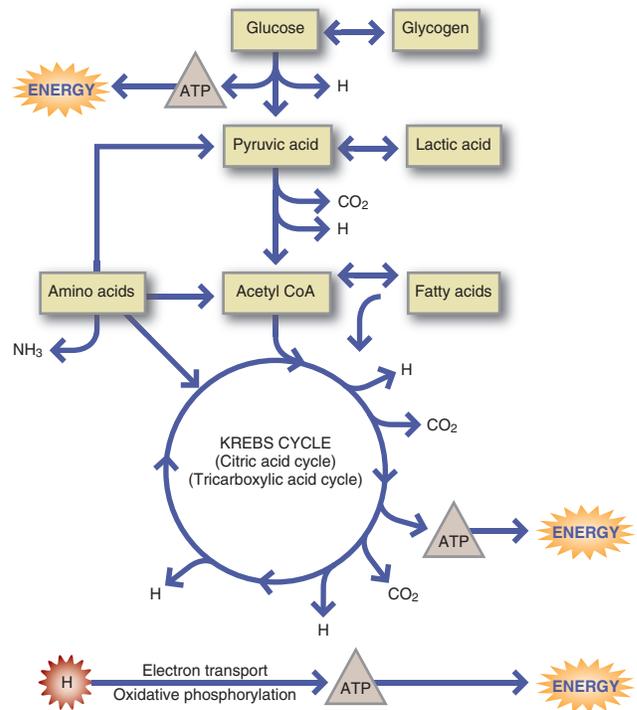

Fig. 22.1 Production of ATP for exercise.

ATP for exercise. If the person continues to exercise and does so at a moderate intensity for a prolonged period, the aerobic pathway will become the dominant pathway for fuel. On the other hand, the anaerobic pathway provides most of the energy for short-duration, high-intensity exercise such as sprinting; the 200-meter swim; or high-power, high-intensity moves in basketball, football, or soccer. However, all of the ATP-generating pathways are turned on at the onset of exercise (Powers et al, 2018).

Other factors that influence oxygen capabilities and thus energy pathways are the capacity for intense exercise and its duration. These two factors are inversely related. For example, an athlete cannot perform high-power, high-intensity moves over a prolonged period. To do this, the athlete would have to decrease the intensity of the exercise to increase its duration (Fig. 22.2).

The aerobic pathway cannot tolerate the same level of intensity as duration increases because of the decreased availability of oxygen and accumulation of lactic acid. As the duration of exercise increases, power output decreases. The contribution of energy-yielding nutrients must be considered also. As the duration of exercise lengthens, fats contribute more as an energy source. The opposite is true for high-intensity exercise; when intensity increases, the body relies increasingly on carbohydrates as substrate (Powers et al, 2018).

FUELS FOR CONTRACTING MUSCLES

Protein, fat, and carbohydrate are possible sources of fuel for ATP generation and therefore muscle contraction. The glycolytic pathway is restricted to glucose, which can originate in dietary carbohydrates or stored glycogen, or it can be synthesized from certain amino acids through the process of gluconeogenesis. The Krebs cycle is fueled by three-carbon fragments of glucose; two-carbon fragments of fatty acids; and carbon skeletons of specific amino acids, primarily alanine and the branched-chain amino acids. All these

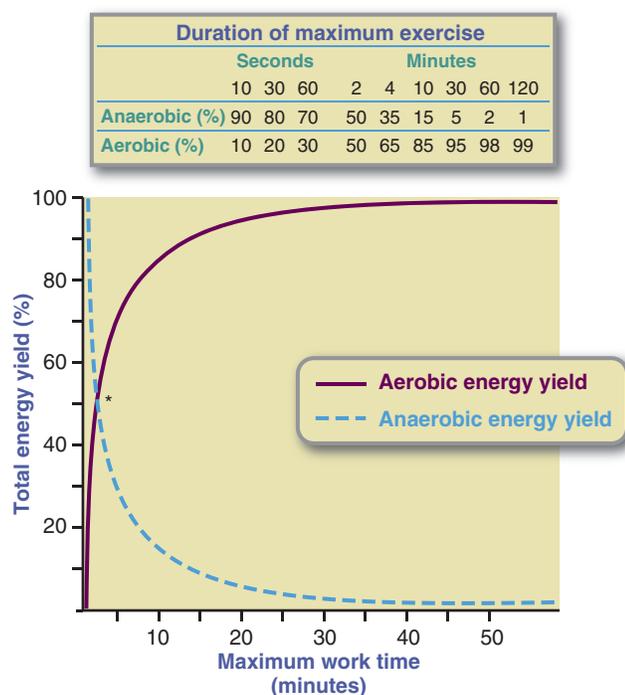

Fig. 22.2 Relative contribution of aerobic and anaerobic energy during maximum physical activity of various durations. Note that 90 to 120 seconds of maximum effort requires 50% of the energy from each of the aerobic and anaerobic processes. This is also the point at which the lactic acid pathway for energy production is at its maximum.

substrates can be used during exercise; however, the intensity and duration of the exercise determine the relative rates of substrate use (Powers et al, 2018).

Intensity

The intensity of the exercise is important in determining what fuel will be used by contracting muscles. High-intensity, short-duration exercise has to rely on anaerobic production of ATP. Because oxygen is not available for anaerobic pathways, only glucose and glycogen can be broken down anaerobically for fuel. When glycogen is broken down anaerobically, it is used 18 to 19 times faster than when broken down aerobically. Persons who are performing high-intensity workouts or competitive races may run the risk of running out of muscle glycogen before the event or exercise is done as a result of its high rate of use (Powers et al, 2018).

Sports that use the anaerobic and aerobic pathways also have a higher glycogen-use rate and, like anaerobic athletes, athletes in these sports also run the risk of running out of fuel before the race or exercise is finished. Sports such as basketball, football, soccer, tennis, and swimming are good examples; glycogen usage is high because of the intermittent bursts of high-intensity sprints and running drills. In moderate-intensity sports or exercise such as jogging, hiking, aerobic dance, gymnastics, cycling, and recreational swimming, approximately half of the energy for these activities comes from the aerobic breakdown of muscle glycogen, whereas the other half comes from circulating blood glucose and fatty acids.

Moderate- to low-intensity exercise such as walking is fueled primarily by the aerobic pathway; thus a greater proportion of fat can be used to create ATP for energy. Fatty acids cannot supply all the ATP during high-intensity exercise because fat cannot be broken down fast enough to provide the energy. Also, fat provides less energy per

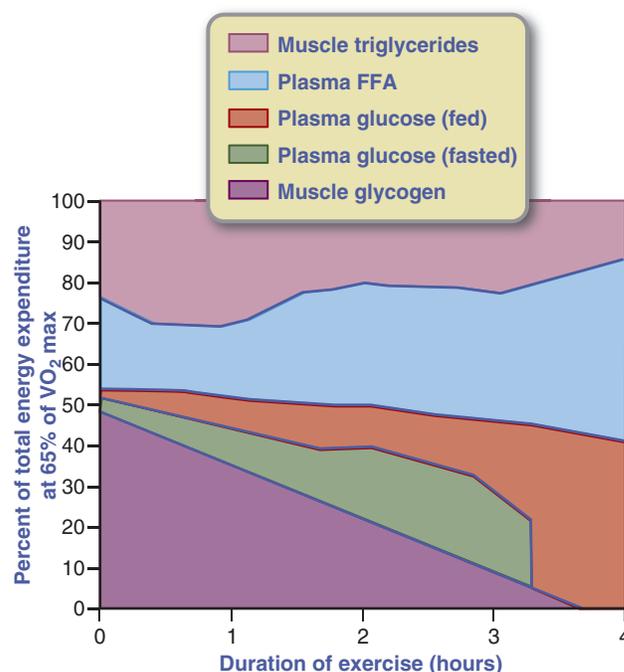

Fig. 22.3 Principle Energy Source and Exercise Duration.

liter of oxygen consumed than does glucose (4.65 kcal/L of O_2 versus 5.01 kcal/L of O_2). Therefore when less oxygen is available in high-intensity activities, there is a definite advantage for the muscles to be able to use glycogen because less oxygen is required.

In general, glucose and fatty acids provide fuel for exercise in proportions depending on the intensity and duration of the exercise and the fitness of the athlete. Exertion of extremely high intensity and short duration draws primarily on reserves of ATP and CP. High-intensity exercise that continues for more than a few seconds depends on anaerobic glycolysis (Powers et al, 2018). During exercise of low-to-moderate intensity (60% of maximum oxygen uptake [VO_{2max}]), energy is derived mainly from fatty acids. Carbohydrate becomes a larger fraction of the energy source as intensity increases until, at an intensity level of 85% to 90% VO_{2max} , carbohydrates from glycogen are the principal energy source, and the duration of activity is limited (Fig. 22.3) (Powers et al, 2018).

Duration

The duration of a training session determines the substrate used during the exercise bout. For example, the longer the time spent exercising, the greater the contribution of fat as the fuel. Fat can supply up to 60% to 70% of the energy needed for ultraendurance events lasting 6 to 10 hours. As the duration of exercise increases, the reliance on aerobic metabolism becomes greater, and a greater amount of ATP can be produced from fatty acids. However, fat cannot be metabolized unless a continuous stream of some carbohydrates is also available through the energy pathways. Therefore muscle glycogen and blood glucose are the limiting factors in human performance of any type of intensity or duration (Powers et al, 2018).

Effect of Training

The length of time an athlete can oxidize fatty acids as a fuel source is related to the athlete's conditioning, as well as the exercise intensity. In addition to improving cardiovascular systems involved in oxygen delivery, training increases the number of mitochondria and the levels of enzymes involved in the aerobic synthesis of ATP, thus increasing the

capacity for fatty acid metabolism. Increases in mitochondria with aerobic training are seen mainly in the type IIA (intermediate fast-twitch) muscle fibers. However, these fibers quickly lose their aerobic capacity with the cessation of aerobic training, reverting to the genetic baseline.

These changes from training result in a lower **respiratory exchange ratio (RER)**, also called respiratory quotient, which is CO₂ eliminated/O₂ consumed; lower blood lactate and catecholamine levels, and a lower net muscle glycogen breakdown at a specific power output. These metabolic adaptations enhance the ability of muscle to oxidize all fuels, especially fat (Powers et al, 2018).

AN INTEGRATIVE APPROACH TO WORKING WITH ATHLETES

Performance nutrition is not limited to exercise physiology or diet alone but integrates six core areas of study: the role of optimal overall health and longevity, optimal growth, peak physiologic function, energy balance and body composition, nutrition enhancement, and safety.

Genetics and individualized differences, exercise environments, and life stress also can affect the athlete's microbiome and tolerance of specific nutrients. It appears that exercise is linked with modifying the brain-gut-microbe axis, diet microbe host metabolic interactions, neuroendocrine and neuroimmune interactions. There is evidence to suggest that stress, both physiologic and emotional, can modulate the composition of gut microbiota and vice versa; the microbiota can act like an endocrine organ secreting serotonin, dopamine, or other neurotransmitters and control the hypothalamic-pituitary-adrenal (HPA) axis in athletes (Clark and Mach, 2017). See Chapter 30 for more information about the HPA axis.

Although a direct relationship between exercise and gut microbial composition or function has not been established, there are several mechanisms by which physical activity might modify the microbiota and impact immune status, gut function, the incidence of upper respiratory infections (URI), mood, and sports performance (Clark and Mach, 2017; Foster et al, 2017; Hart, 2018; O'Sullivan et al, 2015). It is estimated that 20% to 60% of athletes are impacted by the stress of excessive exercise, especially endurance training and inadequate recovery and 20% to 50% of athletes suffer from gastrointestinal symptoms, which have been shown to increase with exercise intensity (Clark and Mach, 2017; Lamprecht et al, 2012). (see *Clinical Insight*.)

Training and dietary programs that aim to balance the systematic stressors that athletes experience, together with personalized diet plans to improve performance, can reduce exercise-related stress symptoms and improve gut microbiota, inflammation, and performance. One study demonstrated this with the Irish international rugby football team during World Cup training camp. The study found that when monitoring diet and exercise under extreme training condition and comparing to controls, professional athletes had lower levels of inflammatory cytokines and increased fecal microbial diversity suggesting that exercise plays a protective and positive role in nourishing the microbiota (O'Sullivan et al, 2015).

In order to find solutions for potential nutrient deficiencies, dietitians must integrate anthropometric, biochemical, and dietary data and feedback from athletes to determine how additional factors such as alterations in gut microbiota, food allergies or intolerances, dietary preferences or aversions, and/or disease processes may affect the overall absorption, assimilation, digestion, metabolism, and transport of specific macronutrients, micronutrients, or fluids, and ultimately affect performance potential.

A sports dietitian also needs to be able to critically evaluate health claims, advise on special dietary modifications, and recommend evidence informed nutritional supplements to enhance physical performance and exercise training responses.

NUTRITIONAL REQUIREMENTS OF EXERCISE

Energy

The most important component of successful sports training and performance is to ensure adequate calorie intake to support energy expenditure and maintain strength, endurance, muscle mass, and overall health. Energy and nutrient requirements vary with age, gender, weight, height, training/sport type, frequency, intensity, and duration. Other influencing factors include typical diet, history of restrictive and disordered eating; and endocrine and environmental conditions such as heat, cold, and altitude. Data suggests that a negative energy balance is common in endurance athletes, weight making and esthetic sports (wrestling, gymnastics, skating, dancing), and athletes with a larger body size, especially during high-volume training (Rogerson, 2017). Estimating energy intake is also challenging to accomplish, especially in sports that are less well studied (Powers et al, 2018).

Individuals who participate in an overall fitness program (i.e., 30 to 40 min/day, three times per week) can generally meet their daily nutritional needs by following a normal diet providing 25 to 35 kcal/kg/day or roughly 1800 to 2400 calories a day. However, energy requirements for athletes training 90 minutes a day may require 45 to 50 kcal/kg/day, and in certain sports even more (Thomas et al, 2016).

For example, the 50-kg athlete engaging in more intense training of 2 to 3 hours/day five to six times a week or high-volume training of 3 to 6 hours in one to two workouts per day 5 to 6 days a week may expend up to an additional 600 to 1200 calories a day above and beyond resting energy expenditure, thus requiring 50 to 80 kcal/kg/day or roughly 2500 to 4000 kcal/day. For elite athletes or athletes with larger bodies, daily calorie needs can reach 150 to 200 kcal/kg, or roughly 7500 to 10,000 calories a day, depending on the volume and intensity of different training phases.

Estimation of Energy Requirements

Resting metabolic rate (RMR) or resting energy expenditure (REE) can be measured using indirect calorimetry or estimated by using predictive equations. Indirect calorimetry involves using a handheld device such as the MedGem calorimeter or metabolic cart typically used in exercise physiology or research settings to measure a person's oxygen consumption to determine RMR or basal metabolic rate (BMR). Measuring RMR or BMR is more accurate than using prediction equations.

Predictive equations are used to estimate RMR/BMR when technical equipment, such as a metabolic cart, is not available. The Cunningham equation has been shown to be the best predictor of RMR or REE for active men and women followed by the Harris-Benedict equation. DeLorenzo developed an equation that also has been shown to be accurate specifically with male strength and power athletes such as those in water polo, judo, and karate (Academy of Nutrition and Dietetics [AND], 2014; Jagim et al, 2018). If the sports dietitian has body composition data including percent body fat, the REE can be calculated as shown in Box 22.1.

Once REE has been calculated, the total energy expenditure (TEE) can be estimated using energy expenditure from physical activity. Because metabolic equipment is expensive, requires considerable training to use, and is not practical outside research settings, indirect methods can be employed and include heart rate monitors, pedometers, or accelerometers.

BOX 22.1 Calculating RMR from Body Composition Data

$$\text{RMR (calories/day)} = 500 + (22 \times \text{LBM in kilograms})$$

RMR = resting metabolic rate
LBM = lean body mass

Other indirect methods are to use a daily activity factor as a base to which is added calories expended in exercise, which are calculated by multiplying the calories expended per minute of exercise times the amount of time spent in that activity, known as **metabolic equivalents (METs)** of task (Powers et al, 2018). One MET is defined as the amount of oxygen consumed while sitting quietly in a chair at rest and equivalent to 3.5 mL O₂ per kg body weight x min, while the energy cost of an activity is (mL O₂/kg/min) x 3.5 (Jetté et al, 1990). A recent study, however, suggests that the standardized MET value overestimated observed resting oxygen consumption (VO₂) in 114 healthy men, resulting in underestimations of the maximal MET and energy cost of running (Ázara et al, 2017).

Heart rate monitoring to estimate energy expenditure is based on the assumption that there is a linear relationship between heart rate and VO₂. Using heart rate to calculate intensity is not necessarily accurate since increases may be due to not only energy demand but also factors such as stress, medications, caffeine, and dehydration. Pedometers measure ambulatory distance covered, which is a limitation of the method because it does not consider other types of physical activities such as weight lifting, cycling, or yoga. Accelerometers have the advantage of measuring all activities, are easy to wear, and can give feedback for long periods of time. Other personal fitness devices have been developed in recent years, although no method is as accurate as measuring directly with a metabolic cart. A method for calculating TEE using activity factors provided is shown in Box 22.2.

Meeting caloric needs for many fitness-minded or elite, intensely training individuals can be a challenge regardless of the accuracy of the formulas used to predict energy needs.

For high school and college athletes, disruptive sleep patterns and accommodating academic, social, and training schedules often lead to skipped meals, high frequency of unplanned snacking, use of sport shakes and bars in lieu of whole food meals, and late-night snacking while studying or socializing online or with friends. Adult athletes with family and work responsibilities and religious obligations such as fasting, Lent, or celebrating Ramadan may also have additional challenges when juggling daily training schedules with carpools, work deadlines, and accommodating family's eating schedules, which may ultimately compromise the quantity, quality, and timing of meals and greatly affect energy, strength levels, and overall health.

In elite athletes, consuming enough food at regular intervals without compromising performance is challenging, particularly when athletes are traveling abroad, or are at the mercy of airport food, foreign foods and schedules, unfamiliar training facilities, delays, and unforeseen events such as weather-postponed games and competition schedules. All athletes regardless of age and lifestyle demands can be better prepared by packing snacks and ready-to-eat meals, which are essential for keeping energy intakes adequate to support overall health and performance.

Meeting the daily energy needs and the appropriate macronutrient distribution for active individuals may necessitate the use of

BOX 22.2 Calculating Daily Energy Requirements for Athletes

Cunningham Equation

$$\text{RMR or REE (resting energy expenditure in kcalories/day)} = 500 + [22 \times \text{lean body mass (LBM) in kilograms (kg)}]$$

For example:

175-pound (79.5kg) athlete with 10% body fat

Kg of fat = fat weight = 79.5 kg x .10 = 7.9 kg fat.

LBM = total weight – fat weight = 79.5 – 7.9 = 71.6 kg of LBM

REE = 500 + (22 x 71.6kg LBM) = 2075 calories.

To Determine EEPA—Energy Expended for Physical Activity

Can use:

Calories expended in a day using: http://www.cdc.gov/nccdphp/dnpa/physical/pdf/PA_Intensity_table_2_1.pdf

Or

Can use:

Specific caloric expenditures for different weights using:

<http://www.nutribase.com/exercala.htm>.

Or

Can multiply REE by the activity factor using:

1.200 = sedentary (little or no exercise)

1.375 = lightly active (about 30 minutes of moderate training, 1-3 days/week)

1.550 = moderately active (45 minutes of moderate training, 3-5 days/week)

1.725 = very active (training for 1 hour, 6-7 days/week)

1.900 = extra active (very hard training, including weight lifting, 2-3 days/week)

Or METs (Metabolic Equivalents)

Example METs = 4.5. Weight of individual: 80 kg.

Amount of energy expended = 0.0175 kcal/kg/minute x 80 kg x 4.5 = 6.3 kcal/min.

Walking for 30 minutes at 4 mph for an 80 kg individual = 189 kcal.

METs Calculation source: http://www.globalrph.com/metabolic_equivalents.htm

To continue the example:

The EEPA for this 175-pound athlete who is training hard would be the following:

REE (2075 kcalories) x activity factor (1.9) = 3942 *total* kcalories for basal energy expenditure (BEE) and EEPA

To continue the example:

Thermic effect of food (TEF) = the total kcalories for REE and EEPA x 10% = 3942 x 0.1 = 394 kcalories

Total daily energy requirements = total kcalories (3942) + TEF (394 kcalories) = 4336 kcalories.

Total daily energy requirements = 4336 kcalories

Thompson J, Manore MM. Predicted and measured resting metabolic rate of male and female endurance athletes. *J Am Diet Assoc.* 1996 Jan; 96(1):30-4.

formulated sports bars, drinks, and convenience foods and snacks in addition to whole foods and meals. While whole foods are preferred over convenience or packaged foods, dietitian nutritionists need to be open minded and flexible in accommodating athletes' lifestyles and eating behaviors when designing meal plans for maximum sport performance.

WEIGHT MANAGEMENT

One goal of a performance-targeted diet is to help an athlete reach an optimum body size and weight/body fat distribution to achieve greater athletic success. Although exercise performance is influenced

by weight/body composition, these physical measures are not the only performance criteria for optimal sports outcomes. Optimal weight, BMI, and body composition measures for athletic performance have yet to be determined, therefore sports performance may be the best indicator to determine an athlete's optimal body composition and weight at their age for best performance (Carl et al, 2017).

Regardless of age, ultimately, an athlete's optimal competitive body weight and relative body fatness should be determined based on individual health and level of performance. For young athletes there are no established recommendations regarding body composition in children and adolescents. For master-level athletes older than 40 years, chronic training has been shown to preserve body fat levels similar to that of young, healthy individuals in an exercise mode-specific manner (McKendry et al, 2018).

In some sports, athletes may be pressured to lose weight and body fat to improve their power-to-weight ratio (as for running, distance cycling, and triathlons), achieve a desirable body composition for aesthetic sports (i.e., gymnastics, figure skating, dancing, cheerleading, and diving) or compete in a specific weight class (as for wrestling, lightweight rowing, sailing, martial arts, horse racing [jockeys], and boxing), in spite of having an appropriate weight for overall health (Larson-Meyer et al, 2018; Manore, 2015).

Athletes' body-fat percentages vary depending on sex and sport as assessed in one study of 898 male and female athletes from 21 sports (Schneider et al, 2014). When no standard exists, experts agree athletes should remain above a certain minimal body fat. While the estimated minimal level of body fat compatible with health is 5% for males and 12% for females, optimal body-fat percentages for an athlete may be much higher to achieve optimal success in their respective sports and need to be established on an individual basis. The highest optimal weight can be calculated using a value at the highest end of the range satisfactory for health: 10% to 22% body fat for males and 20% to 32% for females (Turocy et al, 2011).

Weight Loss

In efforts to maximize performance or meet weight criteria determined by specific sports—whether to “make a lower weight” in sports such as martial arts, sailing, rowing, or wrestling, or reach a higher weight for power lifting, football, or baseball—many athletes alter normal energy intake to either gain or lose weight (Carl et al, 2017). Although such efforts are sometimes appropriate, weight reduction or weight gain programs may involve elements of risk, especially when the pressure to lose or gain weight is expected in an unrealistically short amount of time. For some young athletes, achievement of an unrealistically low weight or conversely a high weight with the use of weight gainer or other supplements can jeopardize growth and development.

The goal weight of an athlete is based on optimizing health and performance and should be determined by the athlete's best previous performance weight and body composition. Adequate time should be allowed for a slow, steady weight loss of approximately 1 to 2 pounds each week over several weeks. Weight loss should be achieved during off-season or preseason when competition is not a priority. A weight loss planning guide can be found online at the *AND Sports Nutrition Care Manual*.

The National Athletic Trainers Association (NATA) suggests the lowest safe weight should be calculated at no lower than the weight determined by the low reference body fat composition delineated by sex and age. The lowest safe weight can be defined as the lowest weight

TABLE 22.1 Body Fat (%) Standards by Sex and Age

Body Fat Standard	Males	Females
Lowest reference body fat for adults	5	12
Lowest reference body fat for adolescents	7	14
Healthy body fat ranges	10-22	20-32

sanctioned by the governing body at which a competitor may compete (Turocy et al, 2011). When no standard exists, participants would be required to remain above a certain minimal body fat. (Turocy et al, 2011; Table 22.1).

In 1997 specific rules and guidelines were implemented by the National Collegiate Athletic Association (NCAA) to ensure safe weight control practices in wrestling, applied early in the competitive season and conducted on a regular basis to ensure prevention of dehydration and other weight-cutting behaviors. In 2006 the National Federation of State High School Associations adopted similar standards for determining body weights, although they are not accepted or enforced universally.

Weight Gain

Athletes are often motivated to gain lean muscle mass for power and team sports. An athlete's stage of development, genetic factors, and type of training, diet, and motivation are all factors that influence weight gain and muscle development (Carl et al, 2017). The healthiest strategy for weight gain is to increase muscle mass by consuming sufficient calories and macronutrients. The rate of weight gain will be dependent on the athlete's genetic makeup, degree of positive energy balance, number of rest and recovery sessions per week, and exercise type (Hall et al, 2012).

Weight gain should be gradual to avoid excess body fat deposition, which is not conducive to optimal performance. An excess of 2 pounds per week may result in increased body fat. Male athletes can target a reasonable gain of 0.5 lb to 1.0 lb of lean mass per week, whereas females can expect a gain 0.25 lb to 0.75 pounds of lean mass per week. Increased energy intake should always be combined with strength training to induce muscle growth.

Nutrient-dense, high-calorie foods such as nuts and nut butters and avocados are a great addition to meals and snacks. Smoothies and nut butter sandwiches can add healthy fats, protein, and vitamins and minerals. Other foods such as beans and lentils, lean meats, and dairy can also be incrementally added to daily calorie needs to achieve an additional 250 to 500 calories per day.

WEIGHT MANAGEMENT AND AESTHETICS

Disordered Eating

Although drive, perfection, and attention to detail are the hallmarks of talented athletes, they are also some of the personality traits associated with the development of eating disorders (see Chapter 21). Disordered eating behaviors among athletes can be difficult to detect given the tendencies of athletes to maintain rigid nutritional requirements, follow intense training schedules, and push through fatigue and pain.

Disordered eating behaviors specifically in athletes have been termed **anorexia athletica (AA)**, where the ultimate goal is to perform

at one's best as opposed to thinness in and of itself. Athletes who are more vulnerable to AA are those who participate in "lean-build" sports, such as cross country running, swimming, gymnastics, cheerleading, dance, yoga, and wrestling, who may think they need to be a certain weight or body type, often far less than what it is realistic to attain and maintain to be competitive. This desire to be unrealistically light or lean may lead to restrictive eating, bingeing and purging, and excessive training far beyond what is required for their sport.

Female Athlete Triad

Chronic dieting by female athletes can lead to the **female athlete triad (FAT)**, which consists of three interrelated health disorders: low energy availability with or without an eating disorder, osteoporosis, and amenorrhea. The prevalence of FAT for athletes participating in lean-requiring versus non-lean-requiring sports has been shown to range from 1.5% to 6.7% and from 0% to 2.0% respectively (Gibbs et al, 2013). For example, it has been shown that student and professional female dancers consume only 70% to 80% of the recommended dietary allowance (RDA) for total daily energy intake (Mountjoy et al, 2014).

The low energy intake of **athletic energy deficit (AED)**, also known as **relative energy deficit in sports (RED-S)**, can lead to an increase in bone fractures, lifelong consequences for bone and reproductive health, impaired judgment, decreased coordination, decreased concentration, irritability, depression, and decreased endurance performance in developing adolescent girls and even young men (Ackerman et al, 2018). Evidence suggests it is energy availability that regulates reproductive function in women, not exercise or body composition, and that ensuring adequate calorie intake is imperative to the overall health of the athletic woman (Ackerman et al, 2019; De Souza et al, 2014). Low energy intake paired with ovarian suppression or amenorrhea has been associated with poor athletic performance.

Muscle Dysmorphia

Although many studies suggest females are more susceptible to disordered eating behaviors than males, results from descriptive data from project EAT (Eating Among Teens) revealed that males in a weight-related sport are comparable to females in the same category. In fact, as the media's portrayal of the male physique has been increasingly muscular and unattainable, men have become more dissatisfied with their bodies and more vulnerable to **eating, exercise, and body image (EEBI) disorders**.

Muscle dysmorphia (MD), also known as "bigorexia" or reverse AN, is a disorder in which individuals are preoccupied with their bodies not being muscular enough or big enough. It is marked by symptoms that are similar to and the opposite of AN symptomatology.

AA and MD experience grossly distorted perceptions of their bodies, which in the case of MD, often leads to maladaptive eating, exercise, and substance use behaviors, including preoccupation with diet and excessively high protein intakes. In addition there is anabolic steroid, diet pill, caffeine, and over-the-counter supplement abuse, especially of those reputed for fat-burning, ergogenic, or thermogenic effects. Last, the athlete exercises excessively, especially weight lifting, in an attempt to increase body satisfaction and attain the "perfect" lean and muscular physique. As with other EEBI, MD can lead to social, occupational, and relationship impairments (Box 22.3).

Research suggests that this preference for a muscular physique is already evident in boys as young as 6 years old and may affect up to

BOX 22.3 Body Image and Eating Disorders in Athletes

Anorexia Athletica

Exercising beyond the requirements for good health
Obsessive dieting; fear of certain foods
Obsessive or compulsive exercising; overtraining
Won't eat with teammates, tries to hide dieting
Stealing time from work, school, and relationships to exercise
Focusing on challenge and forgetting that physical activity can be fun
Defining self-worth in terms of performance
Rarely or never being satisfied with athletic achievements
Always pushing on to the next challenge
Justifying excessive behavior by defining self as an athlete or insisting that the behavior is healthy
Desire to keep losing more pounds despite already low body weight
Mood swings; angry outbursts
Menstrual periods stop
<http://www.eatingdisorderonline.com/explain/anorexiathleticasigns.php>

Muscle Dysphoria

Primarily male eating disorder
Getting bigger is on the mind constantly. This includes thinking about diet, working out, or appearance
See themselves as looking small or "puny" even though they typically appear normal or very muscular to others
Constant concerns with body fat percentage
Hide physique with baggy clothing since never feel "good enough" and is source of shame
Workouts take precedence over other significant events or time spent with family and friends
Fear that missing one workout session will set them back or stymie progress
Workout even when injured
Common to abuse anabolic steroids to enhance their appearance
Missing workout or eating a "forbidden" food item can trigger extreme anxiety and crush self-esteem
Individual might add additional workout sessions, skip meals, or use some means to punish themselves for diet cheating
Frequently accompanying symptoms of depression
<http://www.eatingdisorderonline.com/lifestyle/general/recognizing-muscle-dysmorphia-bigorexia>

95% of college-age American men who are dissatisfied with some aspect of their body and up to 25% of college men engaging in negative body talk (Engeln et al, 2013; Murray et al, 2012). Many studies suggest that bodybuilders display higher MD prevalence rates and more MD features than other resistance training athletes, with prevalence rates ranging from 3.4% to 53.6% within this population (Cerea et al, 2018).

MACRONUTRIENTS

According to the position of the AND, Dietitians of Canada, and the American College of Sports Medicine (ACSM), most recreational athletes do not need to eat a diet that is substantially different than the U.S. Dietary Guidelines for Americans to attain and maintain optimal health (Kerksick et al, 2017). Individuals engaging in a general fitness

TABLE 22.2 A Nutrition Periodization Program

Cycle	Training Goal/Dietary Recommendation
Preseason training	Preparation load cycles followed by recovery cycles Higher or lower energy needs depending on weight goals Greater protein needs for lean muscle mass development
Competitive season	Peak cycles with recovery; energy needs depending on expenditure; higher carbohydrate needs to support high-intensity competition; protein and fat needs relative to weight maintenance, recovery and overall health
Postseason training	Active rest-transition cycle of conditioning and recovery; energy to support but not exceed needs; emphasis on more lax dietary guidelines for mental and emotional competitive break

program of moderate activity typically can meet their macronutrient needs by consuming a normal balanced diet of 45% to 55% of calories from carbohydrates (3 to 5 g/kg/day), 10% to 15% from protein (0.8 to 1 g/kg/day), and 25% to 35% from fat (0.5 to 1.5 g/kg/day).

Nutrition Periodization

The composition of the athlete's diet is dependent on training phase: preseason, season, off-season; sport type including intensity and duration of training; and weight and body composition goals. Competitive athletes involved in moderate- to high-volume training will however require greater amounts of carbohydrates, protein, and fat to meet macronutrient needs for training and seasonal requirements and goals, whether it is gaining mass, improving speed, and/or improving endurance. Specific macronutrient recommendations should be used when counseling a competitive or elite athlete to maximize performance, a concept known as nutrition periodization.

Nutrition periodization is a term to describe dietary modification to match specific training patterns during in and off seasons as well as pre- and postcompetition periods, which are marked by different nutritional needs. Periodization involves different training cycles, including load, recovery peak, and conditioning that are implemented according to the athlete's sports demands and competition schedules (Kerksick et al, 2017; Table 22.2).

Strategies and Tools for Eating Guides in Athletes

According to the United States Olympic Committee (USOC), sports dietitians, and other sports nutrition experts, keeping guidelines simple for athletes is imperative for compliance.

The USOC dietitians created the Athlete's Plate as a guide for eating for athletes based on easy, moderate, and hard training regimens (Fig. 22.4). This tool helps athletes who play a sport for more than 5 hours a week modify servings and portion sizes from each food group based on their training.

CARBOHYDRATE

Adequate glycogen stores are important, particularly for endurance athletes, for maintaining high work rate and preventing fatigue. Carbohydrates are one of two main fuels used for sport activity. The first source of glucose for the exercising muscle is its own glycogen store. When this is depleted, **glycogenolysis** and then gluconeogenesis (both in the liver) maintain the glucose supply. Glycogen depletion can result from inadequate carbohydrate intake after training sessions, especially

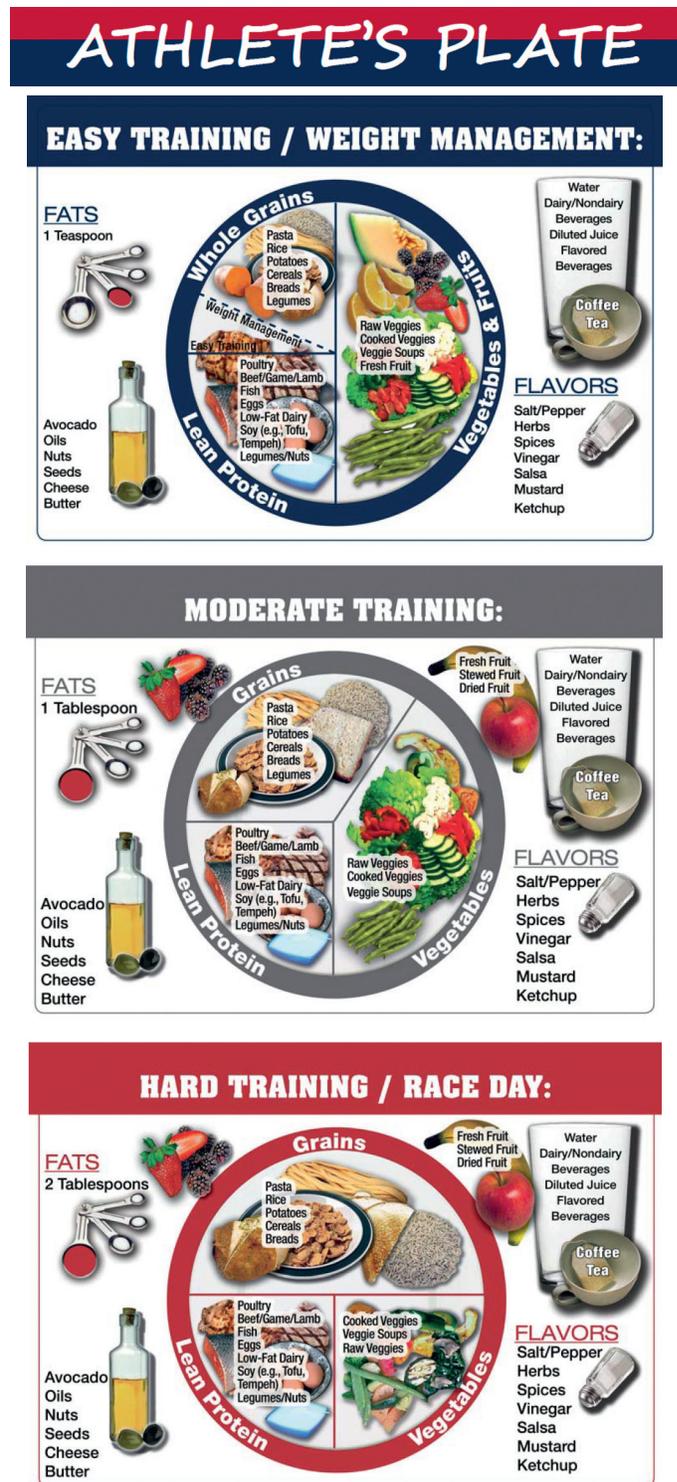

Fig. 22.4 The Athlete's Plate adjusted for training and competition. United States Olympic Committee Sport Dietitians and University of Colorado Sport Nutrition Graduate Program, My Plate for Athletes.

multiple training sessions, or may also be a gradual process, occurring over repeated days of heavy training in which muscle glycogen breakdown exceeds its replacement. Glycogen depletion can also occur during high-intensity exercise that is repeated several times during competition or training.

During endurance exercise that exceeds 90 minutes, such as marathon running, muscle glycogen stores become progressively smaller. When they drop to critically low levels, high-intensity exercise cannot be maintained. In practical terms the athlete is exhausted and must either stop exercising or drastically reduce the pace. Athletes often refer to this as “hitting the wall.”

Historically, a high-carbohydrate or **glycogen loading (glycogen supercompensation)** diet was used to guide athletes to enhance and maximize glycogen stores and be able to continue endurance performance, but this approach has its benefits and drawbacks (McArdle et al, 2014). The 7-day carbohydrate-loading approach combined muscle-specific depletion training with a low-carbohydrate diet for 4 days followed by a high-carbohydrate diet and little to no training for 3 days before competition. Normal muscle typically contains about 1.7 g glycogen per 100 g of muscle; supercompensation packs up to 5 g glycogen per 100 g of muscle. Although this may be beneficial for the endurance athlete training or competing over 60 minutes, it has not been shown to benefit those in higher-intensity, shorter-duration activities. The negative effects of the additional weight of 2.7 g of water for each gram of glycogen can be a hindrance to performance, making it a heavy fuel. A modified approach of gradual exercise tapering along with more modified increases in carbohydrate intake may minimize the negative outcomes associated with classical loading (McArdle et al, 2014).

Experts now agree that habitual carbohydrate regimens for competitive athletes are not advantageous, instead recommending periodizing carbohydrate intake depending on the intensity and duration of training sessions; training block goals; and glycogen supercompensation before competition (Casazza et al, 2018).

Effects of Training Low, Competing High

Numerous studies conducted over the past 40 to 50 years have consistently directed to carbohydrates as the primary macronutrient for sustaining and improving physical performance. In recent years, with the advent of techniques that better allow scientists to measure the metabolism of key nutrients such as proteins/amino acids and studies on alternative feeding regimens such as ketogenic diets, performance diets have become more personalized. Considering the athlete's preferences, genetic makeup, dietary history, and training regimen requires a periodization approach optimizing nutrient needs for performance (Kanter, 2018).

Research suggests that training low, competing high, and a nutritional periodization approach, can increase the rate of fat oxidation while attenuating the rate of muscle glycogenolysis during submaximal exercise.

Studies have investigated the impact of short-term, 1- to 2-week diet-training interventions that increase endogenous muscle glycogen and lipids and alter patterns of substrate utilization during exercise. Otherwise known as the **fat adaptation strategy** or “train low” approach, well-trained endurance athletes consume a high-fat, low-cholesterol diet for up to 2 weeks while undertaking their normal training and then immediately follow this by a high-carbohydrate diet and tapering of exercise 1 to 3 days before an endurance event.

Recent studies have also examined the proposal that adaptation to a low-carbohydrate (<25% energy), high-fat (>60% energy) (LCHF) diet to increase muscle fat utilization during exercise could enhance performance in trained individuals by reducing reliance on muscle glycogen. Studies suggest a LCHF for 5 days retools the muscle to enhance fat-burning capacity with changes that persist in spite of acute strategies to restore carbohydrate availability (i.e., glycogen supercompensation, carbohydrate intake during exercise). In

addition, a 2- to 3-week exposure to minimal carbohydrate (<20 g/day) intake achieves adaptation to high blood ketone concentrations (Burke, 2015). However, in one study with elite endurance racewalkers, in contrast to training with diets providing chronic or periodized high carbohydrate availability, adaptation to an LCHF diet impaired performance despite a significant improvement in peak aerobic capacity (Burke et al, 2017).

While recent research suggests an athlete's need for protein and some fats may be higher than once believed, and dietary protein and fat can provide necessary energy to perform physical activity, carbohydrate is the substrate most efficiently metabolized by the body and the only macronutrient that can be broken down rapidly enough to provide energy during periods of high-intensity exercise (Kanter, 2018).

Carbohydrate Recommendations

The amount of carbohydrate required depends on the athlete's total daily energy expenditure, type of sport, gender, and environmental conditions, with the ultimate goal of providing adequate energy for performance and recovery and a protein sparing effect.

Recommendations should provide for daily carbohydrate intake in grams relative to body mass and allow flexibility for the athlete to meet these targets within the context of energy needs and other dietary goals. Carbohydrate intake of 5 to 7 g/kg/day can meet general training needs, and 7 to 10 g/kg/day will likely suffice for endurance athletes, although elite athletes training 5 to 6 hours a day may need as much as 12 g/kg/day or a range of 420 to 720 g of carbohydrates a day for the 60-kg athlete (AND, 2014; Powers et al, 2018).

Carbohydrates are especially important not only as an overall contributor to meeting daily calorie needs but also as ergogenic aids in a more time-specific approach, also known as nutritional periodization, designed to enhance and maximize performance for competition, especially more than 90 minutes in length.

Food Timing

Pretraining Carbohydrates

The pretraining or preevent meal serves two purposes: (1) it keeps the athlete from feeling hungry before and during the exercise, and (2) it maintains optimal levels of blood glucose for the exercising muscles. A preexercise meal can improve performance compared with exercising in a fasted state. Athletes who train early in the morning before eating or drinking risk developing low liver glycogen stores, which can impair performance, particularly if the exercise regimen involves endurance training.

Carbohydrate meals before exercise can enhance liver glycogen stores. In addition to allowing for personal preferences and psychological factors, the preevent meal should be high in carbohydrate, nongreasy, and readily digested. Fat should be limited because it delays gastric emptying time and takes longer to digest. A meal eaten 3½ to 4 hours before competition should be limited to 25% of the kilocalories from fat. Closer to the event, the fat content should be less than 25% (Box 22.4).

Exercising with a full stomach may cause indigestion, nausea, and vomiting. Thus the pregame meal should be eaten 3 to 4 hours before an event and can provide up to 200 to 350 g of carbohydrates for athletes exercising more than 90 minutes, although each athlete has to make an individual determination based on personal tolerance as to the amount and source before exercise (≤ 4 g/kg) (Potgieter, 2013). Allowing time for partial digestion and absorption provides a final addition to muscle glycogen, additional blood sugar, and

BOX 22.4 Examples of Preevent Meals and Snacks

For athletes who compete in events such as track or swimming meets or soccer, basketball, volleyball, and wrestling tournaments all day, nutritious, easy-to-digest food and fluid choices may be a challenge. The athlete should consider the amount of time between eating and performance when choosing foods during all-day events. Suggested precompetition menus include the following:

1 Hour or Less Before Competition—About 100 to 150 kcal One of these choices:

Fresh fruit such as a banana or orange slices
Half of a sports or breakfast bar
Corn tortilla or small plain arepa
1 small naan, roti chapati, or makai
1 slice of bread, ½ plain bagel or ½ English muffin
1 small pita, lavash, or sangak
Crackers such as rice crackers, saltines, or Melba toast
Small box of plain rice or flake cereal or hot cereal packet-quinoa, oatmeal, rice.
8 to 12 oz of a sports drink

2 to 3 Hours Before Competition—About 300 to 400 kcal One of these choices:

½ of turkey or hummus sandwich on pita with ½ banana
½ bagel with low-sugar jelly and 1 banana
2 pancakes with light or sugar-free syrup and berries
32 fluid oz of a sports drink, endurance drink
1 low-sugar smoothie with berries, banana, and 1 scoop (< or = 20 g) of protein, which can be plant-based, whey, or egg whites
1 sports energy bar, 1 cup sports beverage, 1 cup water
1 clear broth soup, plain baked or sweet potato or yuca w/yogurt topping

3 to 4 Hours Before Competition—About 600 to 700 kcal One of these selections:

Scrambled eggs/egg whites with 2 waffles or toast and banana
1 pita pocket with hummus, pureed fruit or pea soup, crackers, fruit
1 to 6-in turkey sub with lettuce, tomato, and small bag baked chips
1 3-oz grilled chicken breast with small baked potato, roll, and water
1 to 2 cups pasta, 2 to 3 oz chicken breast, 1 small roll
Miso soup, 1 sushi roll or 4 to 5 pieces sashimi with rice
1 20-oz sport shake with protein scoop, 1 sports bar, 1 banana, water

also relatively complete emptying of the stomach. To avoid gastrointestinal (GI) distress, the carbohydrate content of the meal should be reduced when the meal is close to the exercise time. For example, 4 hours before the event, the athlete consume 4 g of carbohydrate per kilogram of body weight, whereas 1 hour before the competition the athlete would consume 1 g of carbohydrate per kilogram of body weight.

Commercial liquid formulas providing an easily digested high-carbohydrate fluid are popular with athletes and probably leave the stomach faster. Foods high in fiber, fat, and lactose cause GI distress for some (e.g., bloating, gas, or diarrhea) and should be avoided before competition. Athletes should always use what works best for them by experimenting with foods and beverages during practice sessions and planning ahead to ensure they have these foods available when they compete.

Types of Carbohydrate

Even though the effects of different sugars on performance, substrate use, and recovery have been studied extensively, the optimal type of carbohydrate for the athlete is still subject to debate by sports performance experts (Colombani et al, 2013). The **glycemic index** represents the ratio of the area under the blood glucose curve resulting from the ingestion of a given quantity of carbohydrate and the area under the glucose curve resulting from the ingestion of the same quantity of white bread or glucose (see Appendix 28).

While preexercise consumption of a low-glycemic-index (LGI) carbohydrate meal is generally recommended, the results from subsequent exercise performance has been inconsistent (Burdon et al, 2017). A recent meta-analysis indicated that while the endurance performance following an LGI meal was superior to that following a high-glycemic-index (HGI) meal, subgroup analyses demonstrated that the effect did not vary across outcome measures (exercise to exhaustion, time trial, and work output) or athletic status (trained or recreational participants) (Wang et al, 2017).

Pretraining Fasting

Some athletes either rise too early for workouts to consume a meal or snack or feel nauseous when consuming food before exercise. An overnight fast causes a drop in liver glycogen, causing glycogenolysis to maintain the supply of glucose to the brain. Although a modest fall in blood sugar may not affect the average individual, it may affect the physical and cognitive performance of athletes fasting longer than 12 to 24 hours. Although some evidence suggests a metabolic advantage of endurance training in a fasted state to increase fat oxidation in trained muscles, other evidence supports the intake of nutrients, primarily carbohydrates, before, during, and after training sessions (Pinckaers et al, 2017; Pons et al, 2018).

Personalizing the preexercise fuel prescription for athletes is critical, because the wrong food or fluid may impact a morning run or an elite competition.

Training Fuel During Exercise

Carbohydrates consumed during endurance exercise lasting longer than 1 hour ensure the availability of sufficient amounts of energy during the later stages of exercise, improve performance, and may delay fatigue. Carbohydrate ingestion for exercise duration less than 60 minutes does not appear to be warranted (Thomas et al, 2016).

The type of carbohydrates consumed may affect performance during exercise. Because glucose and fructose are absorbed by the intestine via different transporters (SGLT1 and GLUT5), their combination in sports products appears to allow for greater absorption of carbohydrate resulting in higher rates of oxidation (Rosset et al, 2017). Recent research suggests that compared with water, a solution containing fructose attenuates thermoregulatory responses compared with glucose (Suzuki et al, 2014). Glucose ingestion during exercise was shown to spare endogenous protein and carbohydrates in fed cyclists without glycogen depletion; thus consuming an exogenous carbohydrate during endurance exercise helped to maintain blood glucose and improve performance (McArdle et al, 2014). (See Fig. 22.5).

The form of carbohydrate consumed does not appear to be a factor physiologically, although some athletes prefer to use a sports drink, whereas others prefer to eat solid food or gel and drink water. Studies have also shown that frequent contact with carbohydrate-containing beverages with the mouth and oral cavity through a mouth rinse during short high-intensity workouts can stimulate parts of the brain and

Fig. 22.5 A triathlon is a high-intensity endurance sport during which both carbohydrates and fats are used as fuels, the amount depending on the speed and length of the event. (Photo©istock.com).

nervous system to reduce perceived exertion and increase work intensity (Peart, 2017).

If a sports drink with carbohydrates is consumed during exercise, the rate of carbohydrate ingestion recommended is approximately 25 to 30 g every 30 minutes, an amount equivalent to 1 cup of a 4% to 8% carbohydrate solution taken every 15 to 20 minutes. This ensures that 1 g of carbohydrate is delivered to the tissues per minute at the time fatigue sets in. It is unlikely that a carbohydrate concentration of less than 5% is enough to help performance, but solutions with a concentration greater than 10% often are associated with abdominal cramps, nausea, and diarrhea.

Combining protein and carbohydrates in a sport fluid or snack also may improve performance, muscle protein synthesis and net balance, and recovery. Amino acids ingested in small amounts, alone or in conjunction with carbohydrates before or after exercise, appear to improve net protein balance and may stimulate protein synthesis during exercise and postexercise recovery (Australian Institute of Sport [AIS], 2014). Adding protein to carbohydrate beverages/gel during exhaustive endurance exercise has been shown to suppress markers of muscle damage 12 to 24 hours postexercise and decreases muscle soreness (Jäger et al, 2017).

Postworkout and Recovery Fuel

Dietary strategies that can enhance recovery from the negative effects of exercise can help promote effective physiologic adaptation, muscle conditioning after exercise, and enable a faster return to training. The resulting improvement in training efficiency may lead to significant performance benefits and sport career longevity by supporting repetitive training and competition and helping to maintain immune status and long-term health (Lynch, 2013).

Identifying the precise optimal quantity of carbohydrate to maximize glycogen repletion has been shown to be challenging due to the number of confounding variables, including the type and timing of the ingested carbohydrate, the training status of the participants, and the duration of the postexercise recovery period (Alghannam et al, 2018). It has been demonstrated that carbohydrate ingestion at a rate of 1.2 g/kg body weight/hour during the postexercise recovery period results in a 150% greater glycogen response relative to lower

amounts. In addition, because 1.6 g/kg bodyweight/hour does not further stimulate muscle glycogen resynthesis, it is considered the optimal amount to maximize muscle glycogen repletion (Alghannam et al, 2018).

The consumption of carbohydrates with a high glycemic index appears to result in higher muscle glycogen levels 24 hours after exercise compared with the same amount of carbohydrates provided as foods with an LGI (Cermak and van Loon, 2013). Adding approximately 5 to 9 g of protein with every 100 g of carbohydrate eaten after exercise may further increase glycogen resynthesis rate, provide amino acids for muscle repair, and promote a more anabolic hormonal profile (Sousa et al, 2014).

Many athletes find it difficult to consume food immediately after exercise. Usually when body or core temperature is elevated, appetite is depressed, and it is difficult to consume carbohydrate-rich foods. Many athletes find it easier and simpler to drink their carbohydrates and ingest easy-to-eat, carbohydrate-rich foods such as fruit pops, bananas, oranges, melon, or apple slices, or consume a sports recovery shake or bar.

Supplemental sport shakes, drinks, and energy bars may offer an easy-to-carry, easy-to-consume, and easy-to-digest meal-replacement. These products are often fortified with 33% to 100% of the dietary reference intakes (DRIs) for vitamins and minerals; provide varying amounts and types of carbohydrates, protein, and fat; and are ideal for athletes on the run. They can be used peripherally, while traveling, at work, in the car, or throughout the day at multievent meets such as track and field, swimming, diving, or gymnastics.

Many fitness-minded and athletic individuals use these products, generally recognized as safe, as a convenient way to enhance their diets. However, if they are substituted in the place of whole foods on a regular basis, they can deprive the athlete of a well-balanced diet. They also may contain excesses of sugars, fats, and protein and banned substances such as stimulants and other botanicals prohibited by United States Anti-Doping Agency (USADA) in and out of competition.

PROTEIN

The current RDA is 0.8 g/kg bodyweight, and the acceptable macronutrient distribution range for protein for people 18 years and older is 10% to 35% of total calories. Reports of food intake in athletes and nonathletes consistently indicate that protein represents from 12% to 20% of total energy intake or 1.2 to 2 g/kg/day. The exception to the rule is small, active women who may consume a low-energy intake in conjunction with their exercise or training program.

Recent studies suggest and support higher protein requirements than the RDA and increase with high training volumes in order to maintain energy balance, protein balance, and muscle mass (Jäger et al, 2017). Factors affecting the protein needs of athletes include age, gender, lean body mass, fitness level, training regimen, and phase of competition.

Protein for Muscle Hypertrophy

Resistance training (RT) and diet consistently appear to play a role in postworkout muscle protein synthesis. The metabolic basis for muscle growth appears to be a balance between muscle protein synthesis (MPS) and prevention of catabolism, especially the balance of myofibrillar protein or contractile protein synthesis, in which dietary protein plus exercise plays an important role. RT enhances the anabolism by 40% to 100% over and above resting levels and dietary protein

response for up to 24 hours when protein is consumed immediately before and at least within 24 hours after (Tipton and Phillips, 2013). Studies have also suggested that preexercise feedings of amino acids in combination with carbohydrates can achieve maximal rates of MPS, but proteins and amino acids during this time have not been shown to improve performance (Jäger et al, 2017).

For athletes interested in muscle hypertrophy, protein consumed within the recommended range for resistance-training athletes of 1.2 to 2 g of protein per kilogram of body weight is recommended. Research shows that a minimum of 30 g of high-quality protein at each meal that contains 2.5 g leucine per meal will optimally stimulate protein synthesis. Research suggests the anabolic response to resistance exercise and protein ingestion works just as well with whole food proteins as with nutritional supplement proteins, although convenience often makes the difference because taking a high-protein shake or bar to training is more practical than carrying a chicken breast. After resistance exercise, between 20 and 25 g of a high-quality protein maximizes the response of MPS, whereas no difference appears to occur between the ingestion of 20 g of protein and 40 g, suggesting that more is not better, at least in young, resistance-trained males. Better responses have been reported from spreading protein intake throughout the day 0.3g/kg every 3 to 5 hours (Jäger et al, 2017).

Several studies in people engaged in RT show that consuming some protein before sleep can increase the rate of protein synthesis during the night and/or augment muscle mass and strength. Participants in these studies consumed a bedtime drink containing 27.5 or 40 g of the milk protein casein, which increased circulating amino acid levels throughout the night. Some studies show increased MPS when plasma levels of amino acids are raised (Jäger et al, 2017; National Institutes of Health [NIH] Office of Dietary Supplements [ODS], 2017). Preworkout ingestion of essential amino acids also appears to enhance the MPS response.

Although the inclusion of carbohydrates does not seem to have an impact on protein synthesis, it may have an impact on the prevention of breakdown. Fat content of postworkout fuel also may have a positive impact. Whole milk may increase utilization of available amino acids for protein synthesis (Elliot et al, 2006).

FAT

Fat is an essential component of an athlete's diet as a concentrated source of food energy, supplying 9 kcal/g. Essential fatty acids are necessary for cell membranes, skin health, hormones, and transport of fat-soluble vitamins. The body has total glycogen stores (muscle and liver) equaling approximately 2600 calories, whereas each pound of body fat supplies about 3500 calories. This means that an athlete weighing 74 kg (163 lb) with 10% body fat has 16.3 lb of fat and thus carries energy worth about 57,000 calories depending on the individual's metabolic rate.

The greater use of fat as an energy source to spare muscle glycogen has been shown to improve performance in ultraendurance events. Improved fat oxidation can be achieved through long slow duration exercise, fasting, acute preexercise intake of fat/ketones, and high-fat low-carbohydrate diets (Bytomski, 2018). Exercise intensity and duration are important determinants of fat oxidation.

Fat oxidation rates decrease when exercise intensity becomes high. A high-fat diet has been shown to compromise high-intensity performance even when a high-fat diet regimen is followed by carbohydrate loading before high-intensity performance (McArdle et al, 2014). The mode and duration of exercise also can affect fat

oxidation; running increases fat oxidation more than cycling (Rosenkilde et al, 2015).

Recently very high-fat ketogenic diets have become popular in athlete communities, with mixed performance results. In one study, researchers examined the impact of adaptation to a ketogenic, low-carbohydrate diet during 3 weeks of intensified training in world-class endurance athletes. All groups consumed identical calories and protein (40 cal/kg and 2.2 g/kg) and constant high-carbohydrate, periodized high-carbohydrate, or low-carbohydrate diets. Both high-carbohydrate groups improved performance after intensified training but showed no improvement for the low-carbohydrate high-fat group (Burke et al, 2017).

While ketone bodies have also been suggested to have positive effects on exercise metabolism and performance as an alternative fuel source, sparing muscle glycogen, there is limited information in recreational and/or elite athletes.

Fats, Inflammation, and Sports Injury

When athletes are injured, they want to heal and get back to training as soon as possible. Specific foods at the right time can help to provide energy for rehabilitation, rebuild strength, and ensure a complete, healthy, and faster recovery.

Increased oxidative stress and inflammatory responses among individuals performing strenuous exercise, elite athletes, or military personnel have been consistently reported. Stress to muscle leads to inflammation, bruising, and tissue breakdown. Failure to decrease inflammation can lead to scar tissue, poor mobility, and delayed recovery times. The inflammatory stage is affected by foods, especially by the types of dietary fat consumed. A diet high in trans fats, saturated fats, and some omega-6 vegetable oils has been shown to promote inflammation and impact the gut microbiota, whereas a diet high in monounsaturated fat and essential omega-3 fats has been shown to be antiinflammatory (see Chapter 7 and Appendix 26).

Omega-3 polyunsaturated fatty acids have been shown to decrease the production of inflammatory eicosanoids, cytokines, and reactive oxygen species; to possess immunomodulatory effects; and to attenuate inflammatory diseases. While human data is inconclusive as to whether supplementation is effective in attenuating the inflammatory, immunomodulatory response to exercise, animal studies assessing the effectiveness of supplementation on exercise metabolism and endurance exercise performance have produced very promising findings (Shei et al, 2014).

Diets supplemented with omega-3 fats have been shown to reduce postexercise delayed-onset muscle soreness and inflammation and promote healing (Jouris et al, 2011). There is also evidence to suggest a strong connection between omega-3 status and neuroprotection and supplementation to accelerate recovery from traumatic brain injury, including concussion (Michael-Titus and Priestley, 2014; Rawson et al, 2018).

Supplemental omega-3 fat has been recommended during the inflammation stage after injury, especially when the diet is deficient. However, some concern exists regarding the sources of omega-3 fat supplements and fish oils, because some have been found to be contaminated with mercury and polychlorinated biphenyls (PCBs), toxins dangerous to humans (see *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation* in Chapter 14).

Plant-based foods are also good sources of alpha linolenic acid (ALA), an omega-3 fatty acid. However, the conversion in the body of ALA to the more active forms of omega-3 fatty acids, docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), is very low. Plant-based foods rich in ALA include spinach, broccoli, tomatoes, green peas,

flaxseeds, chia seeds, walnuts, almonds, and tofu. Wheat germ, free-range beef, poultry, and some eggs are also good sources of omega-3 fats when the animals are fed omega-3-rich food (see Appendix 26).

Monounsaturated fats such as olive, peanut, canola, and sesame oils, as well as avocado oil, also inhibit and reduce inflammation by interfering with proinflammatory compounds such as leukotrienes, which are produced naturally by the body.

FLUID

Maintaining fluid balance requires the constant integration of input from hypothalamic osmoreceptors and vascular baroreceptors so that fluid intake matches or modestly exceeds fluid loss (McArdle et al, 2014). Proper fluid balance maintains blood volume, which in turn supplies blood to the skin for body temperature regulation. Because exercise produces heat, which must be eliminated from the body to maintain appropriate temperatures, regular fluid intake is essential. Any fluid deficit that is incurred during an exercise session can potentially compromise the subsequent exercise bout.

The body maintains appropriate temperatures by **thermoregulation**. As heat is generated in the muscles during exercise, it is transferred via the blood to the body's core. Increased core temperature results in increased blood flow to the skin; in cool-to-moderate ambient temperatures, heat is then transferred to the environment by convection, radiation, and evaporation.

Environmental conditions have a large effect on thermoregulation. When ambient temperatures range from warm to hot, the body must dissipate the heat generated from exercise, as well as the heat absorbed from the environment. When this occurs, the body relies solely on the evaporation of sweat to maintain appropriate body temperatures. Thus maintaining hydration becomes crucial when ambient temperatures reach or exceed 36° C (96.8° F). The hotter the temperature, the more important sweating is for body-heat dissipation. Exercise in the heat also affects blood flow and alters the stress response, with modest changes in circulating leukocytes and cytokines. A critical threshold for elevation of body temperature is 3.5° C (6° F), above which the systemic inflammatory response leads to heatstroke (Tyler et al, 2016).

Humidity affects the body's ability to dissipate heat to a greater extent than air temperatures. As humidity increases, the rate at which sweat evaporates decreases, which means more sweat drips off the body without transferring heat from the body to the environment. Combining the effects of a hot, humid environment with a large metabolic heat load produced during exercise taxes the thermoregulatory system to its maximum. Ensuring proper and adequate fluid intake is key to reducing the risk of heat stress.

Fluid Balance

Body fluid balance is regulated by mechanisms that reduce urinary water and sodium excretion, stimulate thirst, and control the intake and output of water and electrolytes. In response to dehydration, antidiuretic hormone (ADH or vasopressin) and the renin-angiotensin II-aldosterone system increase water and sodium retention by the kidneys and provoke an increase in thirst. These hormones maintain the osmolality, sodium content, and volume of extracellular fluids, and play a major role in the regulation of fluid balance (see Chapter 3).

Water losses throughout the course of the day include those from sweat and the respiratory tract, plus losses from the kidneys and GI

tract. When fluid is lost from the body in the form of sweat, plasma volume decreases and plasma osmolality increases. The kidneys, under hormonal control, regulate water and solute excretion in excess of the obligatory urine loss. However, when the body is subjected to hot environments, hormonal adjustments occur to maintain body function. Some of these adjustments include the body's conservation of water and sodium and the release of ADH by the pituitary gland to increase water absorption from the kidneys. These changes cause the urine to become more concentrated, thus conserving fluid and making the urine a dark gold color. This feedback process helps to conserve body water and blood volume.

At the same time, aldosterone is released from the adrenal cortex and acts on the renal tubules to increase the resorption of sodium, which helps maintain the correct osmotic pressure. These reactions also activate thirst mechanisms in the body. However, in situations in which water losses are increased acutely, such as in athletic workouts or competition, the thirst response can be delayed, making it difficult for athletes to trust their thirst to ingest enough fluid to offset the volume of fluid lost during training and competition. A loss of 1.5 to 2 L of fluid is necessary before the thirst mechanism kicks in, and this level of water loss already has a serious effect on temperature control. Athletes need to rehydrate on a timed basis rather than as a reaction to thirst, enough to maintain the preexercise weight.

Imbalance between fluid intake and fluid loss during prolonged exercise may increase the risk for **dehydration**. It is estimated that more than 50% to 55% of athletes in professional sports, collegiate sports, high school sports, and youth sports arrive at workouts dehydrated (McDermott et al, 2017; Hew-Butler et al, 2018). Dehydration may enhance the development of hyperthermia, heat exhaustion, and heat stroke. The reasons for dehydration vary. In one study, approximately 66% of collegiate athletes, more men than women, were found to be dehydrated pretraining, due to individual hydration habits, lack of hydration before early morning practices, or lack of knowledge regarding proper hydration before and after training (Volpe et al, 2009). **Hypohydration** is particularly common in weight class sports. One study found the prevalence of elite wrestlers, judokas, boxers, and taekwondo athletes on competition day was 89% (Pettersson et al, 2013).

Urine specific gravity is a noninvasive test that assesses the hydration level of athletes. It measures the concentration of all chemical particles in the urine and looks at the ratio of the density of urine compared with the density of water. The specific density of water would be 1.000. Ideally, urine specific gravity results will fall between 1.002 and 1.030 when the kidneys are functioning normally and the athlete is hydrated. Specific gravity results above 1.010 can indicate mild dehydration. The higher the number, the more dehydrated the athlete is. The best sample for a urine specific gravity test contains 1 to 2 ounces of urine first thing in the morning, when the urine is the most concentrated.

Men appear to have higher sweat rates that may lead to more fluid loss during exercise compared with women. Studies also have shown that men have higher plasma sodium levels and a higher prevalence of hypernatremia than women after prolonged exercise, which suggests larger fluid losses in men. In contrast, it also is reported that women have an increased risk for overdrinking, which could lead to exercise-associated hyponatremia. This was demonstrated in a recent endurance study that compared female and male walkers. The study demonstrated a significantly larger change in body mass in men than in women, a higher incidence of dehydration in the men (27% of the men vs. 0% of the women showed postexercise hypernatremia), and a

significantly lower fluid intake and higher fluid loss in the men compared with females (Eijssvogels et al, 2013).

Body water is lost as a consequence of thermoregulatory sweating, and when fluid intake is insufficient to replace sweat losses, hypohydration occurs. It is well established that a 2% body mass loss can impair endurance performance, especially in hot/humid environments, however, the impact of hypohydration on an athlete's performance during team sport competition is less clear (Nuccio et al, 2017). The effect of hydration status on team sport performance has been studied mostly in soccer, basketball, cricket, and baseball, with mixed results (Nuccio et al, 2017). Hypohydration typically impaired performance at higher levels (3% to 4%) and when the method of dehydration involved heat stress. Increased subjective ratings of fatigue and perceived exertion consistently accompanied hypohydration.

Sweat losses in team sports can be significant due to repeated bursts of high-intensity activity, as well as the large body size of athletes, equipment and uniform requirements, and environmental heat stress often present during training and competition. Significant hypohydration of >2% has been reported most consistently in soccer. Mean sweating rates from 1.0 to 2.9 L/h have been reported for college and professional American football players, with several studies reporting 3.0 L/h or more in some larger players (Davis et al, 2016). Although American football, rugby, basketball, tennis, and ice hockey have reported high sweating rates, fluid balance disturbances have generally been mild, with a mean <2%, probably due to ample drinking opportunities.

Although, for years, studies have shown that substantial fluid and body mass losses greater than 2% of total body weight were related to an impaired exercise performance, one study shows otherwise (Wall et al, 2013). High-intensity prolonged exercise may increase the discrepancy between fluid intake and losses. In one study, increased body temperature and dehydration up to 3% in well-trained male cyclists had no effect on a 25-km cycling time-trial performance in hot conditions in well-trained men who were blinded to their hydration status (Wall et al, 2013).

Daily Fluid Needs

Fluid intake recommendations for sedentary individuals vary greatly because of the wide disparity in daily fluid needs created by body size, physical activity, and environmental conditions. The DRI for water and electrolytes identifies the adequate intake for water to be 3.7 L/day for men (130 oz/day, 16 cups of fluid/day) and 2.7 L/day for women (95 oz/day, approximately 12 cups/day) (Institute of Medicine [IOM], 2005). Approximately 20% of the daily water need comes from water found in fruits and vegetables; the remaining 80% is provided by beverages, including water, juice, milk, coffee, tea, soup, sports drinks, and soft drinks. When individuals work, train, and compete in warm environments, their fluid needs can increase greatly (McArdle et al, 2014).

Fluid Replacement

Controversy exists among experts as to how to assess fluid needs because there is no scientific consensus regarding the best method to assess hydration status. Recreational sports typically result in hypotonic fluid losses, which increase relative concentrations of blood and urine. Field measures to assess body hydration status include body mass measurements, urine specific gravity and color, and taste sensation. Each has its limitations (McArdle et al, 2014).

Several position statements and recommendations are published by a variety of professional organizations that address fluid and

electrolyte replacement before, during, and after exercise. A summary of these recommendations can be found in Box 22.5.

Although specific recommendations differ slightly, the intent is to keep athletes well hydrated. These strategies will help prevent hypohydration, maximize safety during exercise, and optimize physical performance (McDermott et al, 2017).

Fluid Absorption

The speed at which fluid is absorbed depends on a number of different factors, including the amount, type, temperature, and osmolality of the fluid consumed and the rate of gastric emptying. Because glucose is absorbed actively in the intestines, it can markedly increase sodium and water absorption. A carbohydrate-electrolyte solution potentially enhances exercise capacity, especially in endurance athletes, by elevating blood sugar, maintaining high rates of carbohydrate oxidation, preventing central fatigue, and reducing perceived exertion (McDermott et al, 2017).

Early studies indicate that water absorption is maximized when luminal glucose concentrations range from 1% to 3% (55 to 140 mM); however, most sports drinks contain two to three times this quantity without causing adverse GI symptoms for most athletes. To determine the concentration of carbohydrate in a sports drink, the grams of

BOX 22.5 Summary of Guidelines for Proper Hydration

General Guidelines

- Monitor fluid losses: Weigh in before and after practice, especially during hot weather and the conditioning phase of the season.
- Do not restrict fluids before, during, or after the event.
- Do not rely on thirst as an indicator of fluid losses.
- Drink early and at regular intervals throughout the activity.
- Avoid alcohol before, during, or after exercise because it may act as a diuretic and prevent adequate fluid replenishment.
- Discourage caffeinated beverages a few hours before and after physical activity because of their diuretic effect.

Before Exercise

- Drink approximately 400 to 600 mL (14 to 22 oz) of water or sports drink 2 to 3 hours before the start of exercise.

During Exercise

- Drink 150 to 350 mL (6 to 12 oz) of fluid every 15 to 20 min, depending on race speed, environmental conditions, and tolerance; no more than 1 C (8 to 10 oz) every 15 to 20 min, although individualized recommendations must be followed.

After Exercise

- Drink 25% to 50% more than post workout weight loss to ensure hydration 4 to 6 hours after exercise.
- Drink 450 to 675 mL (16 to 24 oz) of fluid for every pound of body weight lost during exercise.
- If an athlete is participating in multiple workouts in 1 day, then 80% of fluid loss must be replaced before the next workout.

Electrolyte Replacement

- Sodium: 0.5 to 0.7 g/L in activity longer than 1 hour to enhance palatability and the drive to drink, to reduce the risk of hyponatremia, and to minimize risk of muscle cramps.

carbohydrate or sugar in a serving are divided by the weight of a serving of the drink, which is usually 240 g, the approximate weight of 1 cup of water. A 6% carbohydrate drink contains 14 to 16 g of carbohydrate per 8 oz (1 cup).

Cold water is preferable to warm water because it attenuates changes in core temperature and peripheral blood flow, decreases sweat rate, speeds up gastric emptying, and is absorbed more quickly. In one recent study, sweating response was influenced by water temperature and voluntary intake volume. Cool tap water at 60° F appeared to replace fluids better in dehydrated individuals compared with warmer fluids (Hosseini et al, 2013).

Burdon et al. (2013) showed that, although ingestion of cold beverages is preferable, an ergogenic benefit was also seen from the effect of ice slush ingestion and mouthwash on thermoregulation and endurance performance in the heat. Another study compared ice slush to cold water in moderately active males while running and showed prolonged time to exhaustion and reduced rectal temperature, supporting possible sensory and psychological effects of ice slush beverages either consumed or used as a mouthwash. Precooling with an ice slushy solution also may have more beneficial effects over cold fluid ingestion during exercise and performance (Dugas, 2011).

Children

Children differ from adults in that, for any given level of dehydration, their core temperatures rise faster than those of adults, probably because of a greater number of heat-activated sweat glands per unit skin area than in adolescents or adults. Children sweat less even though they achieve higher core temperatures. Sweat composition also differs between children and adults: adults have higher sodium and chloride concentrations but lower lactate, hydrogen, and potassium concentrations. Children also take longer to acclimate to heat than adolescents and adults (McArdle et al, 2014).

Because young children often do not drink enough when offered fluids freely during exercise in hot and humid climates, and because they participate in physical activities less than 60 minutes in duration, often little attention is paid to their hydration. Children who participate in sports activities must be taught to prevent dehydration by drinking above and beyond thirst and at frequent intervals, such as every 20 minutes. As a general rule, a child 10 years of age or younger should drink until thirst is satiated and then should drink an additional half a glass (3 to 4 oz or ½ to ½ cup) of fluid.

Older children and adolescents should follow the same guidelines; however, they should consume an additional cup of fluid (8 oz). When relevant, regulations for competition should be modified to allow children to leave the playing field periodically to drink. One of the hurdles to getting children to consume fluids is to provide fluids they like. Providing a sports drink or slushy ice drink as described in the previous section that will maintain the drive to drink may be the key to keeping child athletes hydrated.

Older Athletes

Hydration is especially important for masters athletes (older than 40 years), especially during the first 5 days of heat acclimatization. Hypohydration (water loss exceeding water intake with a body water deficit) in older individuals can affect circulatory and thermoregulatory function to a greater extent and may be caused by the lower skin blood flow, causing core temperature to rise. Because the thirst drive is reduced in older adults, they need to drink adequately before exercise, well before they become thirsty (McDermott et al, 2017). Although older adults can restore fluid losses, this occurs at a slower rate than younger adults.

Hydration at High Altitudes

Unacclimated individuals undergo a plasma volume contraction when acutely exposed to moderately high altitude. This is the result of increased renal sodium and water excretion and decreased voluntary sodium and water intake. Respiratory losses are increased by high ventilatory rates and typically dry air. The result is an increase in serum hematocrit and hemoglobin, which increases the oxygen-carrying capacity of the blood, but at the cost of reduced blood volume, stroke volume, and cardiac output. Fluid requirements increase as a result. With acclimation, red blood cell production increases and plasma and blood volumes return to pre-high altitude levels.

Electrolytes

The replacement of electrolytes as well as water is essential for complete rehydration (Table 22.3).

Sodium

It is important to include sodium in fluid-replacement solutions, especially with excessive intake of plain water (McArdle et al, 2014) for events lasting more than 2 hours; sodium should be added to the fluid to replace losses and to prevent hyponatremia. Rehydration with water alone dilutes the blood rapidly, increases its volume, and stimulates urine output. Blood dilution lowers sodium and the volume-dependent part of the thirst drive, thus removing much of the drive to drink and replace fluid losses.

Water-soluble electrolytes such as sodium can move rapidly across the proximal intestines. During prolonged exercise lasting more than 4 to 5 hours, including sodium in replacement fluids increases palatability and facilitates fluid uptake from the intestines. Sodium and carbohydrate are actively transported from the lumen to the bloodstream.

Water replacement in the absence of supplemental sodium can lead to decreased plasma sodium concentrations. As plasma sodium levels fall below 130 mEq/L, symptoms can include lethargy, confusion, seizures, or loss of consciousness. Exercise-induced hyponatremia may

TABLE 22.3 Comparison of the Sweat Electrolyte Losses and Sports Drink Content

Electrolyte	Sweat Loss mg/L	Standard Sport Drink mg/L	Endurance Specific Sport Drink mg/L
Sodium	900-2600	230-1700	800-1110
Potassium	150	80-125	390-650
Magnesium	8.3-14.2	0	10-815
Chloride	900-1900	0	390-1550
Calcium	28	0-100	24-275
Iron	0.1-0.4	0	0
Phosphorus	40	0	0
Zinc	0.36-0.48	0	0-5

*Dependent on exercise duration, intensity, ambient temperature, hydration status before and during exercise

Kenefick RV, Chevront SN: Hydration for recreational sport and physical activity, *Nutr Rev* 70 (Suppl 2):S137, 2012.

result from fluid overloading during prolonged exercise over 4 hours. Hyponatremia is associated with individuals who drink plain water in excess of their sweat losses or who are less physically conditioned and produce a saltier sweat.

Guidelines recommend the consumption of sodium during exercise to replace losses in sweat; however, the effects of sodium on thermoregulation are less clear. In one double-blind, randomized-sequence, crossover study, 11 endurance athletes underwent 2 hours of endurance exercise at 60% heart rate reserve with 1800 mg of sodium supplementation during one trial and placebo during the other trial. A progressive intensity time-to-exhaustion test was performed after the 2-hour steady state exercise as an assessment of exercise performance. High-dose sodium supplementation did not appear to impact thermoregulation, cardiovascular drift, or physical performance in trained, endurance athletes (Earhart et al, 2015).

Potassium

As the major electrolyte inside the body's cells, potassium works in close association with sodium and chloride in maintaining body fluids, as well as generating electrical impulses in the nerves, muscles, and heart. Potassium balance is regulated by aldosterone and its regulation is precise. Although aldosterone acts on sweat glands to increase the resorption of sodium, potassium secretion is unaffected. Loss of potassium from skeletal muscle has been implicated in fatigue during athletic events. There is little loss of potassium through sweat, and in a recent study exercise intensity has been shown to have a minimal impact on sweat potassium losses in practice and can be easily replaced by diet (Baker et al, 2019).

VITAMINS AND MINERALS

Many micronutrients play an important role in the regulation of processes that support sports performance, ranging from energy production to the manufacture of new cells and protein. A deficiency in one or more of these nutrients may lead to impairment either directly or by reducing the athlete's ability to train effectively (i.e., iron deficiency, anemia) or stay away from illness or injury (i.e., calcium and vitamin D) and bone health. Suboptimal nutrient intakes and deficiencies may also have a profound impact on performance (Maughan et al, 2018).

While all athletes are encouraged to follow sports nutrition strategies that optimize dietary intake to support optimal health and performance, many fall short of meeting 100% of the recommended dietary allowance (RDA) for micronutrients. In one study of Dutch elite and sub elite athletes, micronutrient intakes of 553 athletes showed that nonusers of supplements were at risk for low intakes of vitamins B₁, B₂, B₃ and vitamins A, C, and selenium (Wardenaar et al, 2017).

High training volume, exercise performed in stressful conditions including hot conditions and altitude, or training with substandard diets may promote excessive losses of micronutrients because of increased catabolism or excretion (Lukaski, 2004). Para athletes (athletes with disabilities) are a high-risk group for inadequate dietary intake leading to deficiencies in energy, carbohydrate, protein, iron, and vitamin D, which can impair sports performance (Scaramella et al, 2018).

Training and work schedules, low-nutrient snacks, infrequent nutrient-dense meals, and overall low calorie intakes may cause inadequate intakes of vitamins and minerals. Athletes who adopt popular diets that eliminate whole food groups such as meat, dairy,

grains, or fruits, as in the case of vegans, or those following a Paleo or ketogenic diet, run the risk of poor micronutrient intake. Micronutrients such as calcium, zinc, iron, vitamin B₁₂, and others will be of concern.

Description of vitamin metabolism and resulting physical performance is very limited. Assessments of vitamin intake, biochemical measures of vitamin status, and determination of resulting physical performance involves systematic protocols that obtain, verify, and interpret evidence of nutrition related problems, as well as their causes and significance. A complete assessment is required; however, very few studies have provided this information.

In 2010 numerous dietary vitamin and mineral deficiencies were reported in elite female athletes, including folate (48%), calcium (24%), magnesium (19%), and iron (4%) (Heaney et al, 2010). A 2014 report also highlighted the risk of injury in female athletes with iron, vitamin D, and calcium deficiencies (McClung et al, 2014). A 2013 study of male athletes showed significant deficiencies in vitamin A (44% of group), vitamin C (80% of group), vitamin D (92% of group), folate (84% of group), calcium (52% of group), and magnesium (60% of group) (Wierniuk and Włodarek, 2013).

Without a doubt, impaired micronutrient status affects exercise and work performance. Some of the deficiency signs and symptoms associated with exercise have been summarized in this section (Table 22.4).

B Vitamins

Increased energy metabolism creates a need for more of the B vitamins, including thiamin, riboflavin, niacin, pyridoxine, folate, biotin, pantothenic acid, and choline, which serve as part of coenzymes involved in regulating energy metabolism by modulating the synthesis and degradation of carbohydrates, protein, fat, and bioactive compounds.

Some athletes who have poor diets, and athletes such as wrestlers, jockeys, figure skaters, gymnasts, or rowers who consume low-calorie diets for long periods of time may be prone to deficiencies. A B-complex vitamin supplement to meet the RDA may be appropriate (Thomas et al, 2016). However, there is no evidence that supplementing the well-nourished athlete with more B vitamins increases performance.

The intake of folate could potentially be low in athletes whose consumption of whole grains, whole fruits, and vegetables is low. Likewise a deficiency of vitamin B₁₂ could develop in a vegetarian athlete after several years of a strict vegan intake; thus a vitamin B₁₂ supplement may be warranted. However, while correcting folate and vitamin B₁₂ deficiencies with a supplement may be warranted for a safeguard for health, supplementation for either vitamin has not been shown to improve performance.

Antioxidants

Antioxidants have been studied individually and collectively for their potential to enhance exercise performance or to prevent exercise-induced muscle tissue damage. Cells continuously produce free radicals and **reactive oxygen species (ROS)** as a part of metabolic processes. The rate of VO₂ during exercise may increase 10- to 15-fold, or as much as 100-fold in active peripheral skeletal muscles. This oxidative stress increases the generation of lipid peroxides and free radicals, and the magnitude of stress depends on the ability of the body's tissues to neutralize ROS (see Chapter 7).

Free radicals are neutralized by antioxidant defense systems that protect cell membranes from oxidative damage. These systems include catalase; superoxide dismutase; glutathione peroxidase; antioxidant

TABLE 22.4 Ergogenic Aids

Ergogenic Aid	Reported Action/Claim	Research on Ergogenic Effects	Side Effects
Antioxidants	Minimize free radical damage to muscle, reducing fatigue inflammation soreness	Small clinical trials; does not directly improve performance	May hinder some physiologic and physical exercise induced adaptations
Arginine	Increases blood flow and O ₂ delivery to muscle; increases HGH secretion	Limited clinical trials with conflicting results; little or no effect on vasodilation, blood flow, or exercise metabolites.	Diarrhea and nausea
Beetroot or beet juice	Enhances NO bioavailability; dilates blood vessels in exercising muscle, reduces O ₂ use, improves energy production	Acute performance benefits seen 2-3 hours following ingestion of 310-560 mg; prolonged periods also may benefit performance; 4%-25% improvement in exercise time to exhaustion; enhances type II muscle fiber function resulting in 3%-5% improvement of HIIT team sport 12-40 min duration. Performance gains harder to obtain in highly trained athletes	GI upset in some athletes
Beta alanine	Increases carnosine synthesis, augments buffering capacity in muscle reducing muscle fatigue and loss of force in high intensity exercise	Daily consumption of approx. 65 mg/kg BM ingested in split dose, 0.8-1.6 every 3-4 hours over 10-12 weeks may have small performance benefits during continuous and intermittent exercise of 30 s-10 min	Skin rash, transient paresthesia
Betaine	Increases creatine production, blood nitric acid levels or water retention in cells	Limited clinical trials in men with conflicting results; potential but modest strength and power improvements with bodybuilders and cyclists	No safety concerns reported for 2-5 g/day up to 15 days
Citrulline	Dilates blood vessels to increase delivery of O ₂ and nutrients to skeletal muscle	Few clinical trials with conflicting results	Few safety concerns reported for up to 9 g for 1 day or 6 g/day for up to 16 days
HMB (beta-hydroxy-beta-methylbutyrate)	Metabolite of EAA leucine; anticatabolic; enhances recovery by stimulating protein and glycogen synthesis	3 g in 2 divided doses shown to improve performance; may increase upper-body strength and lean body mass and minimize muscle damage; decreases muscle catabolism	No safety concerns reported for dose of 3 g/day for up to 2 months
Collagen hydrolysate/gelatin and vitamin C	Increased collagen production, thickened cartilage, decreased joint pain	Gelatin and collagen supplements are low risk; increased collagen production, decreased pain recovery from injury reported; dose 5-15 g gelatin with 50 g vitamin C; collagen hydrolysate dose is 10 g/day	
Curcumin	Antiinflammatory, decrease muscle damage, DOMS	Conflicting results—reductions in DOMS, CK, and inflammatory cytokines (TNF- α , IL-8) following eccentric contraction, however not seen following endurance exercise	Up to 5 g/day dose, none reported
Chondroitin sulfate	Builds and grows cartilage	No studies that it is effective in treating arthritis or joint damage or helps torn ligaments or cartilage	None
Glucosamine	Serves as nonsteroidal antiinflammatory drug alternative	Readily absorbed; benefit in reducing pain and need for medication	None reported
Creatine	Increases lean mass and strength, enhances recovery from intense exercise; enhances adaptive response to exercise; increases intracellular water; enhances recovery from DOMS; decreased risk/enhanced recovery from TBI	Well studied, shows benefit for high-intensity intermittent activity, variation in response, greater impact with those with low stores (i.e., vegan, vegetarian, or low meat eaters); recommended dose of creatine monohydrate is 20 g/day for 5 days followed by 3-5 g/day to increase and maintain levels	No negative effect up to 4 years; weight gain due to water retention not suitable for weight dependent sports; anecdotal reports of nausea, diarrhea, stiffness, heat intolerance
Omega 3 fatty acids	Improved cognitive processing, decreased risk, enhanced recovery from TBI; reduced symptoms or enhanced recovery from DOMS	Few data on TBI, animal studies show structural damage and cognitive decline reduced; benefits to muscle damage inconsistent; may increase protein synthesis in muscle	Low risk but possible bleeding GI problems or increased LDL
Probiotics	Decrease severity or duration of GI distress; decreased incidence duration and severity of URTI	Modest benefits to athletes w/GI issues or traveling to regions which GI issues more likely; most studies report reduced incidence of URTI but specific recommendations/strains difficult to ascertain	Dosing regimens of 10 (9) to 4 x 10 (10) for 4-21 weeks

Continued

TABLE 22.4 Ergogenic Aids—cont'd

Ergogenic Aid	Reported Action/Claim	Research on Ergogenic Effects	Side Effects
COQ ₁₀	Cofactor for ATP production; electron transport in mitochondria; reduces fatigue	Mixed: double-blinded, placebo, crossover trial, 100 mg/d for 2 months, lift loads of 75 g/kg of body weight 5x/30 s improved mean power; may improve in those with mitochondrial disorders or CoQ deficiency	
Sodium bicarbonate/sodium citrate	Buffers lactic acid production; delays fatigue	High level of intraindividual variability in performance; increases body's ability to buffer lactic acid during sub max exercise for events lasting 1-7 min	Stomach distress: bloating, diarrhea; dangerous in high doses; alkalosis; dosing with small carbohydrate meal may reduce GI upset
Sodium phosphate	Buffer	Some; increases VO ₂ max and anaerobic threshold by 5%-10%; improves endurance	Stomach distress
Creatine	Improves strength, power, and intermittent sprint performance; accelerates training recovery	Increases muscle free creatine, phosphocreatine; performance effect seen in sprint/power through endurance by enhancing muscle glycogen storage; stimulates muscle anabolism, muscle relaxation; effects may fade after 2 months supplementation; consume with CHO to increase levels to greater extent	Weight gain 0.8%-2.9%; watch with weight-sensitive sports; unknown long term

ALA, α -Lipoic acid; ATP, adenosine triphosphate; BM, body mass; CF, cardiorespiratory fitness; CHO, cholesterol; CK, creatine kinase; DOMS, delayed onset muscle soreness; EAA, essential amino acid; GH, growth hormone; GI, gastrointestinal; HIIT, high-intensity interval training; HGH, human growth hormone; HMB, β -hydroxy- β -methylbutyrate; IL-8, interleukin-8; LDL, low-density lipoprotein; NO, nitric oxide; TBI, traumatic brain injury; TNF- α : tumor necrosis factor alpha; URTI, upper respiratory tract infection.

vitamins A, E, and C; selenium; and phytonutrients such as carotenoids (see Chapter 7). Susceptibility to oxidative stress varies from person to person, and the effect is influenced by diet, lifestyle, environmental factors, and training. Antioxidant nutrients may enhance recovery from exercise by maintaining optimal immune response and lowering lipid peroxidation.

Although large-dose antioxidant supplementation attenuates exercise-induced ROS production and consequential oxidative damage, studies suggest oversupplementation may block necessary cellular adaptations to exercise (Sureda et al, 2013). Further research is needed to assess the response to supplementation with varying degrees of exercise duration and intensity (Sureda et al, 2013).

A diet rich in fruits and vegetables can ensure an adequate intake of antioxidants, and prudent use of an antioxidant supplement may provide insurance against a suboptimal diet and the increased stress from exercise. Research has also shown the positive benefits of phytonutrients with antiinflammatory and antioxidant effects, which may help with posttraining inflammation. Examples include anthocyanins in purple and red fruits and vegetables, and quercetin found in red onions, blueberries, tomatoes, apples, black tea, and purple grapes. Compounds found in tart cherry juice help to reduce inflammation, muscle damage, and oxidative stress (Rawson et al, 2018).

Vitamin D

Over the past few years, vitamin D has been shown to play an increasingly important role in sports performance beyond its role in calcium absorption and use in bone formation (Todd et al, 2015). As a secosteroid hormone, upon activation to 1,25-hydroxy vitamin D₃, vitamin D responsive gene expression is altered with more than 1000 responsive genes affecting MPS, muscle strength, muscle size, reaction time, balance coordination, endurance, inflammation,

and immunity, all of which are important to athletic performance (Box 22.6).

Vitamin D deficiency may be more common in athletes than previously thought, especially in specific groups (Shuler et al, 2012). The prevalence appears to vary by sport, training location, time of year, and skin color (Rawson et al, 2018). Research has shown that more than 75% of Caucasians and 90% of African Americans and Latinos are possibly vitamin D deficient according to set values. It is possible that up to 77% of athletes who live in northern climates with little winter sunlight and who are indoor athletes (94% of basketball players and 83% of gymnasts) may be affected by deficiencies of vitamin D (Sikora-Klak et al, 2018). One recent study showed vitamin D deficiency is quite common among National Basketball Association (NBA) Draft Combine participants, affecting 73.5% (Grieshober et al, 2018). Outdoor athletes may not have an advantage over indoor athletes; in a National Football League (NFL) study, 81% of Caucasian and African

BOX 22.6 Vitamin D and Athletic Performance

Vitamin D Potential Impact on Athletic Performance

Positive effect on muscle strength, power, and mass
Increased force and power output of skeletal muscle tissue
May influence maximal oxygen uptake (VO₂max)
Improved skeletal muscle function and bone strength
Potentially increased size and number of type II muscle fibers
Decreased recovery time from training
Increase testosterone production

From Dahlquist DT et al: Plausible ergogenic effects of vitamin D on athletic performance and recovery, *J Int Soc Sports Nutr*, 12:33, 2015.

American players may be at risk for deficiency. Blood tests can better determine deficiency states.

Although the specific amount of vitamin D needed to reverse deficiency states has not been determined, partly because it depends on the extent of deficiency, athletes should be tested and guided by a health professional if diagnosed with a deficiency (see Chapter 5 and Appendices 12 and 38).

After a detailed assessment, recommendations for attaining and maintaining optimal vitamin D levels can be individualized to the athlete's current 25(OH)D concentration, dietary intake, lifestyle habits and clinical symptoms. The recommendation for fair-skinned individuals is to obtain 5 minutes and for dark-skinned individuals, 30 minutes of sunlight exposure to arms, legs, and back several times a week without sunscreen (see Appendix 38). Short-term, high-dose "loading" regimens for rapid repletion under the care of a physician also may be beneficial (Todd et al, 2015).

MINERALS

Although 12 minerals have been shown to be designated as essential nutrients, iron, calcium, magnesium, and copper have biochemical functions with the potential to affect athletic performance.

Iron

Iron is critical for sport performance because, as a component of hemoglobin, it is instrumental in transporting oxygen from the lungs to the tissues. It performs a similar role in **myoglobin**, which acts within the muscle as an oxygen acceptor to hold a supply of oxygen readily available for use by the mitochondria. Iron is also a vital component of the cytochrome enzymes involved in the production of ATP. Iron adequacy can be a limiting factor in performance because deficiency limits aerobic endurance and the capacity for work. Even partial depletion of iron stores in the liver, spleen, and bone marrow, as evidenced by low serum ferritin levels, may have a detrimental effect on exercise performance, even when anemia is not present (see Chapter 31).

Sports anemia is a term applied to at least three different conditions: hemodilution, iron deficiency anemia, and foot-strike anemia. Athletes at risk are the rapidly growing male adolescent; the female athlete with heavy menstrual losses; the athlete with an energy-restricted diet; distance runners who may have increased GI iron loss, hematuria, hemolysis caused by foot impact, and myoglobin leakage; and those training with heavy sweating in hot climates. Recent research suggests that anemia may be common in female athletes, especially adolescent and premenopausal females, long-distance runners, and vegetarians, who should be screened periodically to assess their iron status. One retrospective analysis of routine blood test data taken from 2009 to 2015 from elite level runners and triathletes 21 to 36 years old showed a higher incidence of at least 1 episode of iron deficiency in 60% of female triathletes, 55.6% of female runners, 37.5% of male triathletes, and 31.3% of male runners compared with values reported for endurance athletes (20% to 50% females, 0% to 17% males) (Coates et al, 2017). In another study of 2749 collegiate athletes, 2.2% of females indicated iron deficiency anemia and 30.9% indicated iron deficiency without anemia. For male athletes, 1.2% indicated iron deficiency anemia and 2.9% indicated iron deficiency without anemia (Parks et al, 2017).

Heavy endurance training also can cause a transient decrease in serum ferritin and hemoglobin. This condition, known as **pseudoanemia**, is characterized by reduced hemoglobin levels resulting from

expanding blood volumes that are almost those of clinical anemia but return to pretraining normal levels. Performance does not appear to deteriorate and the pseudoanemia may in fact improve aerobic capacity and performance (McArdle et al, 2014).

Some athletes, especially long-distance runners, experience GI bleeding that is related to the intensity and duration of the exercise, the athlete's ability to stay hydrated, how well the athlete is trained, and whether they have taken ibuprofen before the competition. Iron loss from GI bleeding can be detected by fecal hemoglobin assays.

It is possible that using serum hemoglobin as the determining factor for identifying anemic athletes who may benefit from iron supplementation with performance improvement is not the best biomarker. Nonanemic athletes (with normal serum hemoglobin) who are supplemented with iron have shown improved performance. Optimal levels of serum ferritin, which is the most common index of body iron status associated with performance, and thus a better marker, may also be inadequate, because athletes supplemented with iron to achieve higher than "normal" serum ferritin levels have also shown improved performance (DellaValle, 2013). Some athletes experience iron deficiency without anemia and have normal hemoglobin levels but reduced levels of serum ferritin (20 to 30 ng/mL; see Chapter 5).

Athletes should be assessed for their iron status using serum hemoglobin and serum ferritin at the beginning of and during the training season. This is especially important in those suspected to have sickle cell trait (SCT) because their rate of sudden death is 10 to 30 times higher than in non-SCT athletes. Typically deaths have occurred early in the season, during exhaustive drills in hot weather without adequate warmup time (Harris et al, 2012). In 2010 the NCAA instituted a universal screening program to test for SCT in all Division I athletes; however, in athletes at the high school level, and in the NBA, NFL, Navy, Marines, and Air Force, testing is not required (Jung et al, 2011).

Although male athletes have been reported to consume at least the RDA for iron, female athletes tend to consume somewhat less for a variety of reasons, including low energy intake, lower intake of animal products, or adherence to a vegetarian or vegan diet (Rogerson, 2017). Increasing dietary intake of iron or supplementation is the only way to replace iron losses and improve status (Farrokhyyar, 2015).

Who should be supplemented and with how much iron remains to be answered. Given the evidence suggesting iron's role in overall health and physical performance, there is no debate that athletes with clinical deficiency should be identified and treated. Whether those with subclinical deficiency should be treated with iron supplementation remains controversial. Individuals with normal status typically do not benefit from supplementation, and concerns regarding unregulated doses and overload should be considered.

Calcium

Suboptimal levels of dietary calcium intake are seen in athletes. Because low levels of calcium intake have been shown to be a contributing factor in osteoporosis, young female athletes, especially those who have had interrupted menstrual function, may be at risk for decreased bone mass. Strategies to promote the resumption of menses include estrogen replacement therapy, promotion of optimal weight status, and reduced training. Regardless of menstrual history, most female athletes need to increase their calcium, vitamin D₃, and magnesium intake. Dairy and nondairy options such as fortified

almond, flax, and soy beverages, yogurts and cheeses, calcium-fortified fruit juices, and tofu made with calcium sulfate are good sources (see Appendix 39).

Magnesium

Magnesium is an essential mineral that supports more than 300 enzymatic reactions including glycolysis, fat and protein metabolism, and ATP hydrolysis, and is a regulator of neuromuscular, immune, and hormonal functions. Although hypomagnesemia has been seen in athletes, possibly caused by excessive sweating while training and transient redistribution of magnesium indicating a release from one storage area to an active site, levels return to normal within 24 hours after exercise (Malliaropoulos et al, 2013).

True magnesium deficiency has been shown to impair athletic performance, causing muscle spasms and increased heart rate and VO_2 during submaximal exercise. For deficient athletes, supplemental magnesium has been shown to improve performance by improving cellular function, although in athletes with adequate status, performance

outcomes are mixed (Kass et al, 2013). In one recent study with female volleyball players, magnesium supplementation improved alactic (does not produce any lactic acid) anaerobic metabolism, even though the players were not magnesium deficient (Setaro et al, 2014). In another study with young men participating in a strength training program for 7 weeks, daily magnesium intake of 8 mg/kg of body weight resulted in increases in muscle strength and power, whereas marathon runners with adequate stores did not seem to benefit (Moslehi et al, 2013). As with most nutrients, supplementation does not seem to improve performance in those who are not deficient. Food sources of magnesium include whole grains, nuts, beans, and leafy greens. See Appendix 43 for sources of magnesium.

In a 2017 meta-analysis, no significant improvements in the supplementation group were observed regarding isokinetic peak torque extension, muscle, or muscle power, nor does the evidence support a beneficial effect of supplementation on muscle fitness in most athletes and physically active individuals who have a relatively high Mg status (Wang et al, 2017).

CLINICAL INSIGHT

Gastrointestinal Issues in Athletes

Gut issues are a common problem, affecting about 45% to 85% of athletes, 30% to 50% on a regular basis and in 70% of runners (Jeukendrup, 2017a; Koon et al, 2017; ter Steege et al, 2012). Issues can affect the upper GI tract, such as reflux, heart burn, chest pain, nausea, vomiting, gastritis, peptic ulcers, bleeding, or **exercise related transient abdominal pain (ETAP)**, also known as “stitches,” or the lower GI tract, such as gas, bloating, excessive urge to defecate, diarrhea, hemorrhoids, and colitis.

Genetic and individualized differences, exercise environments, and life stressors can affect the athlete’s gut function, **microbiome**, and tolerance of specific foods. Although a direct relationship between exercise and gut microbial composition or function has not been established, there are several mechanisms by which physical activity might modify the microbiota and impact immune status, gut function, the incidence of upper respiratory infections (URI), mood, and sports performance (Clark and Mach, 2017; Foster et al, 2017; Hart, 2018; O’Sullivan et al, 2015).

It appears that exercise impacts the brain-gut-microbe axis, diet microbe host metabolic interactions, neuroendocrine and neuroimmune interactions; and an individual athlete’s response to physical stress. It is thought that the microbiota can act like an endocrine organ secreting serotonin, dopamine, or other neurotransmitters that can modify the stress response in athletes. There is also evidence to suggest that exercise-induced stress, both physiologic and emotional, can modulate the composition of gut microbiota and vice versa (Clark and Mach, 2017).

Additionally, changes in mechanical forces seen with endurance sports, (i.e., long-distance running and triathlon) include altered GI blood flow and GI motility, along with neuroendocrine changes from training. ETAP may be possibly due to irritation of the peritoneum although gastric or diaphragm ischemia, muscular cramping, and stretching of the visceral ligaments of the solid organs have also been proposed (Koon et al, 2017).

Other factors such as the athlete’s pretraining and/or precompetition diet, climate changes, cool to very hot/humid conditions, emotional stress due to competition, dehydration, nonsteroidal antiinflammatory drug (NSAID) use, and whether or not the athlete has evacuated before exercise (bowel movement) may also add to GI distress.

It is estimated that 20% to 60% of athletes are impacted by the stress of excessive training, especially endurance training along with inadequate recovery,

and the impacts have also been shown to increase with exercise intensity (Clark and Mach, 2017; Lamprecht et al, 2012). Educating athletes on best pretraining and precompetition fueling; applying a periodization trial and error with simple plain, low fiber, low fat, spice free solid or liquid, whole or sport food with varying amounts and types of carbohydrate sources and blends is one strategy for eliminating potential GI issues.

Assessment tools used to rule out food-related issues include (1) a thorough dietary analysis including an analysis of foods, fluids, alcohol use, and supplements consumed before, during, and after training; (2) food sensitivity or allergy testing to determine whether food intolerances to gluten, lactose, or other foods or herbals exist; (3) a bowel function and chronic GI disease history and functional comprehensive stool test; (4) a history of overall fluid intake and possible dehydration because of changes in training climate; and (5) a history of infections and antibiotic use.

Training and dietary programs that aim to balance the systematic stressors that athletes experience together with personalized diet plans to improve performance can reduce exercise-related stress symptoms and improve gut function and athletic performance. One study that supports this is with an Irish rugby football team during World Cup training camp. Compared with controls, monitoring diet and exercise while training under extreme training conditions was found to lower levels of inflammatory cytokines and increase fecal microbial diversity. This suggests that exercise can play a protective and positive role in nourishing the microbiota when athletes are nutritionally well fed and training incorporates adequate recovery (O’Sullivan et al, 2015). This supports a body of research that suggests that the GI system is highly adaptable. The rate of gastric emptying and perceptions of fullness can be decreased or “trained,” and the diet can play an important role (Jeukendrup, 2017a).

Nutritional strategies for overcoming GI issues include an elimination diet or low FODMAP diet, and/or a competition-day diet that is individualized to the athlete based on their tolerance of foods. Another strategy is to offer a high-carbohydrate diet, as this can increase the activity of glucose-1 transporters (SGLT1) in the intestine allowing greater carbohydrate uptake and oxidation during exercise (Jeukendrup, 2017b; Koon et al, 2017).

ERGOGENIC AIDS

Athletes are always looking for an edge, such as a new technique, a training regimen, or gear that might help them improve athletic performance, increase strength and speed, or hasten recovery after training. Many athletes test the latest trendy diet or supplement to achieve sports success in spite of whether it supports optimal health or, at worst, leads to the risk of illness, injury, or a failing drug doping blood test. Unfortunately, many athletes are misinformed about the best way to achieve sports performance with diet alone (Kanter, 2018).

Ergogenic aids include any training technique, mechanical device, nutrition practice, pharmacologic method, or physiologic technique that can improve exercise performance capacity and training adaptations. Many athletes devote substantial time and energy striving for optimal performance and training and turn to ergogenic aids, especially dietary supplements (Larson-Meyer et al, 2018).

The Food and Drug Administration (FDA) regulates dietary supplement products and ingredients in addition to labeling, product claims, package inserts, and accompanying literature. The Federal Trade Commission (FTC) regulates dietary supplement advertising. (See Chapter 11 for a definition of a dietary supplement as defined by the Dietary Supplement Health and Education Act [DSHEA] of 1994.)

According to the law, dietary supplement manufacturers are allowed to publish information about the benefits of dietary supplements in the form of advertisements, including structure and function claims. This results in a great deal of printed material that can be confusing to athletes at the point of sale of nutritional products. In

addition, athletes are bombarded with advertisements and testimonials from other athletes and coaches about the effects of dietary supplements on performance.

The use of ergogenic aids in the form of dietary supplements is widespread in all sports (Garthe and Maughan, 2018). Many athletes, whether recreational or professional, use some form of dietary supplementation to improve athletic performance or to assist with weight loss (Knapik et al, 2016; Larson-Meyer et al, 2018).

According to one survey, 88% of collegiate athletes report using one or more nutritional supplements (Buell et al, 2013). A recent meta-analysis of 159 studies suggested that it is difficult to generalize about dietary supplement use by athletes because of the lack of homogeneity among studies (Knapik et al, 2016). Data has suggested that elite athletes use dietary supplements more than nonelite athletes, use is similar for men and women, and appears to change little over time. Additionally, a larger proportion of athletes use dietary supplements compared with the general U.S. population.

Surveys show reasons for supplement use are varied and differ between genders. Women athletes often take supplements for their health, or to overcome an inadequate diet, whereas men may take supplements to improve speed, agility, strength, and power, and also use them to help build body mass and reduce weight or excess body fat. In one study, 75% of adolescent athletes reported taking supplements, males for sports performance enhancement and better muscle development and function, whereas females reported taking supplements for immune system improvement (Zdešar Kotnik et al, 2017). See Table 22.5 for discussion of ergogenic aids commonly used by athletes.

TABLE 22.5 Commonly Used Banned and Recreational Drugs Used by Athletes

Ergogenic Drug	Goals of Use	Athletic Effect	Adverse Effects
Alcohol	Reduce stress and inhibition; most widespread used drug in sport (88% of intercollegiate athletes)	No benefits	Dependence producing; twofold higher risk of injury; cardiovascular/liver disease; worsens left ventricular dysfunction; decreases amino acid, glucose utilization; decreases energy, hypoglycemia; dehydration; decreases skeletal muscle capillary density, cross-sectional area; inhibits sarcolemmal calcium channel actions, impairs excitation-contraction coupling and diminishes performance; decreases muscle oxidative capability; compromises blood coagulation/fibrinolysis/postexercise perturbations in clotting factors; positive energy balance, obesity; increases HR and VO ₂ , reductions in power output
Nicotine	CNS psychostimulant	Mixed: Enhances brain norepinephrine and dopamine; higher doses enhance serotonin and opiate exerting calming and depressing effect, increases pain tolerance; increases muscle blood flow, lipolysis; may improve cognitive function, learning memory, and reaction time and fine motor abilities; delays central fatigue	Addictive; may lead to development of respiratory, cardio, and skin diseases and tobacco-related cancers if smoked; increases heart rate and blood pressure, cardiac stroke volume and output, and coronary blood flow; increases skin temperature
Tetrahydrocannabinol (marijuana, cannabis)	Diminish nerves/pre competition stress, and anxiety; relax/decrease inhibition; improve sleep	No positive effect	Increases HR and BP at rest; physical work capacity decreases by 25%; decrease in standing steadiness, reaction time, psychomotor performance
Anabolic androgenic steroids	Gain muscle mass and strength	Increase muscle mass and strength, especially when combined with strength training and high-protein diets	Multiple organ systems including infertility, gynecomastia, female virilization, hypertension, atherosclerosis, physeal closure, aggression, depression, suicidal ideation

Continued

TABLE 22.5 Commonly Used Banned and Recreational Drugs Used by Athletes—cont'd

Ergogenic Drug	Goals of Use	Athletic Effect	Adverse Effects
Androstenedione	Increases testosterone to gain muscle mass and strength	Increase muscle strength and size	Tendopathy, rhabdomyolysis; tendon rupture
DHEA	Increases testosterone to gain muscle mass and strength	No measurable effect	Increases estrogens in men; impurities in preparation
Human growth hormone	Increase muscle mass, strength, and definition	Decreases subcutaneous fat and increases lipolysis; increases muscle mass and strength; improves wound healing; stimulates testosterone production	Acromegaly, glucose intolerance, physeal closure, increased lipids, myopathy
Stimulants (ephedrine alkaloids, amphetamines, cocaine)	Increases weight loss; fatigue delay	Increases metabolism, no clear performance benefit, although may benefit power, endurance, strength, or speed; reduces tiredness; increases alertness and aggression	Muscle and joint pain; misjudgment in time orientation; tremors; cerebral vascular accident, arrhythmia, myocardial infarction, seizure, psychosis, hypertension, death
Arimidex, (anastrozole); selective estrogen receptor modulators (SERMs) like tamoxifen	Cancer drug used to decrease estrogen levels associated with testosterone use	None; increase testosterone, luteinizing hormone secretion; increase muscle strength and size; prevent bone loss	Side effects associated with taking these agents; early fatigue; increased bone resorption and decreased BMD (hip, lumbar spine)
Ghrelin mimetics (GHRP6 and GHRP2)	Increase GH secretion	Increase muscle mass; stimulate glycogenesis; anabolic effects on muscle mass	GH-associated side effects (see above)
Glucocorticoids	Alleviate pain; reduce tiredness	No improvement	Growth suppression, osteoporosis, avascular necrosis of femoral head; tendon or facial rupture (by local injections) osteoarthritis

BMD, Bone mineral density, *BP*, blood pressure; *CNS*, central nervous system; *DHEA*, dehydroepiandrosterone; *GH*, growth hormone; *HR*, heart rate. Refs: Pesta, D et al 2013; Nikolopoulos, D et al 2011, Rogol A 2010; Hoffman J et al 2009.

The biggest concern for athletes is the use of drugs prohibited in sport and the possibility that a supplement may contain something that will result in a positive drug test, which may also apply to supplemental sport food products such as drinks, shakes, and bars. In fact a wide range of stimulants, steroids, and other agents that are included in the World Anti-Doping Agency's (WADA) prohibited list have been identified in supplements. This may occur either intentionally or unintentionally by the manufacturers in the preparation of the raw ingredients or in the formulation of the finished product. In some cases, the amount of product may be exceptionally higher or lower than the therapeutic dose (Table 22.6). The FDA has identified sports supplements and ergogenic aids among the highest risk for adulteration with drugs and banned substances (see Chapter 11).

TABLE 22.6 Foods High in Branched-Chain Amino Acids

Branched-Chain Amino Acid	Food Sources
Leucine	Meat, dairy, nuts, beans, brown rice, soy, and whole wheat
Isoleucine	Meat, chicken, eggs, fish, almonds, chickpeas, soy protein, and most seeds
Valine	Meat, dairy, soy protein, grains, peanuts, and mushrooms

Research suggests that all too often, physically active individuals, including high-level athletes, obtain nutrition information from coaches, fellow athletes, trainers, advertisements, and the Internet rather than well-informed and educated sports dietitians, physicians, and accredited exercise professionals (Morente-Sánchez and Zabala, 2013).

Information on the efficacy and safety of many of these products used by athletes is limited or completely lacking. Sports nutritionists need to be on the forefront of information; know how to evaluate the scientific merit of articles and advertisements about exercise and nutrition products so that they can separate marketing hype from scientifically based training and nutrition practices (see Chapter 11). Certification programs such as National Sanitation Foundation (NSF) for Sport and Informed Choice can help guide dietitians and athletes to selecting certified safe sport supplements.

NSF for Sport is a program that focuses primarily on the sports supplement manufacturing and sourcing process, provides preventive measures to protect against adulteration of products, verifies label claims against product contents, and identifies athletic banned substances in the finished product or ingredients. The program, designed for manufacturers and their products, includes product testing for more than 180 banned substances, label content confirmation, formulation and label review, and production facility and supplier inspections, as well as ongoing monitoring in line with substance prohibitive lists. The program is recognized by the NFL, National Football League Players Association (NFLPA), Major League Baseball (MLB), Major League Baseball Players Association

(MLBPA), Professional Golfers Association (PGA), Ladies Professional Golf Association (LPGA), and Canadian Centre for Ethics in Sports (CCES).

Informed Choice is also a quality assurance program for sports nutrition products, suppliers to the sports nutrition industry, and supplement manufacturing facilities. Its testing capability for supplements/ingredients includes the analysis of over 146 substances that are considered prohibited in sport and substances that pose a threat with respect to product contamination. These substances include drugs of abuse, anabolic agents, stimulants, beta-2-agonists, masking agents, and so on. Testing methods used for a range of substances from these categories have been validated and accredited to the ISO 17025 standard in supplements/ingredients in each of the relevant matrices: powders, bars, liquids, capsules, tablets, and so on, with defined method capabilities/reporting limits.

POPULAR ERGOGENIC AIDS

Creatine

As an amino acid, creatine is produced normally in the body from arginine, glycine, and methionine. Most dietary creatine comes from meat, but half is manufactured in the liver and kidneys. For meat eaters, dietary intake of creatine is approximately 1 g daily (Kreider et al, 2017). The body also synthesizes approximately 1 g of creatine per day, for a total production of approximately 2 g daily (Kreider et al, 2017).

In normal, healthy persons approximately 40% of muscle creatine exists as free creatine; the remainder combines with phosphate to form creatine phosphate (CP). Approximately 2% of the body's creatine is broken down daily to creatinine before excretion by the kidneys. The normal daily excretion of creatinine is approximately 2 g for most persons. Those with lower levels of intramuscular creatine, such as vegetarians, may benefit from creatine supplementation (McArdle et al, 2014).

Creatine monohydrate is one of the most popular supplements used by strength and power athletes. Supplementation elevates muscle creatine levels and facilitates the regeneration of CP, which helps to regenerate ATP. A variety of synthetic creatine supplements have been developed, including creatine malate, pyruvate, citrate, and many more with marketing claims of greater performance enhancement and absorption. Creatine monohydrate is not only the most extensively studied but the most clinically effective form of creatine for use in nutritional supplements in terms of muscle uptake and ability to increase high-intensity exercise capacity (Kreider et al, 2017).

Numerous reviews identify performance benefits with repeated bouts of high-intensity exercise less than 150 s in duration with the greatest impact in less than 30 s (Lanthers et al, 2017). Classical loading consists of an initial loading phase of 15 to 20 g per day for 4 to 7 days, followed by a maintenance dose of 2 to 5 g per day. However, alternative dosing methods also have been shown to effectively increase creatine stores and result in strength gains. Regimens without the loading include a dose of 0.3 g/kg body weight for 5 to 7 days, followed by maintenance dose of 0.03 g/kg body weight for 4 to 6 weeks. However, with this regimen creatine stores increase more slowly, and it may take longer to see the strength training effects (Hall and Trojian, 2013).

As creatine is one of the most researched supplements, numerous studies support the use and effectiveness of creatine for short-term, maximum output exercise such as weight lifting, running a 100-m sprint, swinging a bat, or punting a football. When creatine stores in the

muscles are depleted, ATP synthesis is prevented and energy can no longer be supplied at the rate required by the working muscle. Improved athletic performance has been attributed to this ATP resynthesis.

Creatine supplementation increases body mass or muscle mass during training. It may improve submaximal exercise performance for high-intensity interval training (HIIT), which promotes fitness similar to endurance training. A 2013 study on swimmers showed creatine supplementation improved swimming performance and reduced blood lactate levels after intermittent sprint swimming bouts (Dabidi Roshan et al, 2013).

Studies are conflicting on creatinine's effect on aerobic performance. In a double-blind, placebo-controlled study 16 male amateur soccer players, consuming 20 g of creatine per day, or a placebo, for 7 days, experienced no beneficial effect on physical measures obtained during a 90-minute soccer test (Williams et al, 2014).

Creatine absorption appears to be stimulated by insulin. Therefore ingesting creatine supplements in combination with carbohydrate, amino acids, or protein can increase muscle creatine concentrations. Once creatine is taken up by the muscles, it is trapped within the muscle tissue. It is estimated that once creatine stores in the muscle are elevated, it generally takes 4 to 6 weeks for creatine stores to return to baseline (Kreider et al, 2017).

Few data exist on the long-term benefits and risks of creatine supplementation. Because of the long-term risks, the American Orthopedic Society for Sports Medicine, the ACSM, and the American Academy of Pediatrics (AAP) advise children and adolescents younger than 18 years and pregnant or nursing women to never take creatine supplements. While a few case studies have reported that individuals purportedly taking creatine with or without other supplements presented with high creatinine levels and/or renal dysfunction, there appears to be no compelling evidence that supplementation negatively affects renal function in healthy or clinical populations (Kreider et al, 2017; Williamson and New, 2014).

Beta-Alanine

Intermittent bouts of **high-intensity interval training (HIIT)** deplete energy substrates and allow for metabolite accumulation. Studies suggest that supplementation with beta-alanine may improve endurance performance as well as lean body mass (Kern and Robinson, 2011). Because of its relationship with carnosine, beta-alanine appears to have ergogenic potential. Carnosine is believed to be one of the primary acid buffering substances in muscle. Although carnosine is synthesized from two amino acids, beta-alanine and histidine, its synthesis appears to be limited by the availability of beta-alanine, thus taking supplemental beta-alanine can increase carnosine levels and reduce lactic acid build up in the muscles (Trexler et al, 2015; Peeling et al, 2018).

This proposed benefit would help increase an athlete's capacity for training and increase time to fatigue. Supplementing with beta-alanine has been associated with improved strength, anaerobic endurance, body composition, and performance on various measures of anaerobic power output.

Daily supplementation with 3.2 to 6.4 g (approx. 65mg/kg body mass) for a minimum of 2 to 4 weeks can increase muscle carnosine content about 65% above resting levels; extended to 10 to 12 weeks, 80% above resting levels and improving tolerance for exercise bouts lasting 30 seconds to 10 minutes. However, the correlation between muscle changes and magnitude of performance benefits are yet to be determined. The only reported side effect is paresthesia (tingling), but studies indicate this can be attenuated by using divided lower doses (1.6 g) or using a sustained-release formula (Trexler et al, 2015).

Caffeine

Research on the physiologic benefits of caffeine on performance is extensive in areas of strength, endurance, rates of perceived effort, hydration, and recovery. The ergogenic benefits include:

- (1) affecting the central nervous system (CNS) and cognitive performance
- (2) mobilizing fat and sparing glycogen during exercise
- (3) increasing intestinal absorption and oxidation of carbohydrates
- (4) speeding up resynthesis of muscle glycogen in recovery
- (5) reducing perceived exertion and pain of training.

Caffeine contributes to endurance performance, apparently because of its ability to enhance mobilization of fatty acids and thus conserve glycogen stores. Caffeine also may directly affect muscle contractility, possibly by facilitating calcium transport. It could reduce fatigue as well by reducing plasma potassium accumulation, which contributes to fatigue. An energy-enhancing effect is seen with up to 3 mg/kg body mass or about 200 mg caffeine for the 150-lb athlete (Spriet, 2014). Unwanted side effects of overconsuming caffeine that may limit performance are headaches, insomnia, GI irritation, reflux, shakiness, heart palpitations, and increased urination. Previous reports showed that caffeine combined with ephedra resulted in serious illness and death, and the combination was banned from use in dietary supplements by the FDA in 2004. Safety data from 50 trials determined that the use of ephedra or ephedrine combined with caffeine has been associated with a 2.2- to 3.6-fold increases in odds of psychiatric, autonomic, or GI symptoms, and heart palpitations (Shekelle et al, 2003).

Consumer demand for caffeine has resulted in greater accessibility and acceptance of a variety of beverages beyond coffee and tea. An emerging trend in sports nutrition is the intake of caffeine-containing energy drinks and drink shots for performance.

The growing availability and consumption of energy drinks with caffeine among all age groups is of concern, especially among young athletes because excessive amounts of caffeine have been shown to disrupt adolescent sleep patterns, exacerbate psychiatric disease, cause physiologic dependence, increase the risk of subsequent addiction and risk-taking behaviors, raise blood pressure, and cause dehydration, vomiting, irregular and rapid heartbeat, convulsions, coma, and death. Altered sleep patterns from excessive caffeine use can lead to poor performance, delayed reaction times, and increased risk for injuries.

Energy drinks consumed with alcohol are another growing concern among health experts, and in 2010 the FDA declared caffeine an “unsafe food additive” to alcoholic beverages, effectively banning pre-mixed alcoholic energy drinks.

There are concerns and safety issues regarding another similar supplement, citrus aurantium L. (bitter orange) extracts, which are also used for weight loss/weight management, sports performance, appetite control, energy, and mental focus and cognition, and which contain p-synephrine as the primary protoalkaloid, as they have similar structural aspects as ephedrine (Stohs, 2017).

Nitrates and Beet Juice

Several studies suggest that inorganic nitrates may alter the physiologic responses to exercise and enhance performance by increasing vasodilation and glucose uptake and reducing blood pressure and the O₂ cost of submaximal exercise (Peeling et al, 2018). Because the consumption of nitrate salts may result in the production of harmful nitrogenous compounds, researchers have explored using natural nitrate-rich foods such as beetroot juice and powders. A dose of dietary nitrate, approximately 0.5 L of beetroot juice, has been shown to increase plasma nitrite, which peaks within 3 hours and remains elevated for 6 to 9 hours before returning to baseline (Wylie et al, 2013).

In one study, supplementing the diet with 0.5 L of beetroot juice per day for 4 to 6 days reduced the steady state cost of submaximal exercise by 5% and extended the time to exhaustion during high-intensity cycling by 16%, which has been confirmed in other exercise populations, including rowers and team sports. Although the mechanistic bases for the effects are unclear, evidence suggests mitochondrial efficiency and contractile function may be enhanced (Wylie et al, 2013). Other positive effects include increased NO₂ and vasodilation and reduced VO₂ at less than or equal to VO₂max intensity while improving the relationship between watts required and VO₂ level, increasing time-to-exhaustion at less than or equal to VO₂max intensity (Domínguez et al, 2017; Mills et al, 2017).

It has been recommended to consume nitrate immediately before, during, and after long-duration endurance exercise because of peak and maintenance level times. A daily dose of the supplement has been shown to keep plasma nitrite elevated (Jones et al, 2013). Although there is a possibility that uncontrolled high doses of nitrate salts may be harmful to health, natural sources found in beetroot, spinach, lettuce, and celery are likely to promote health.

PERFORMANCE ENHANCEMENT SUBSTANCES AND DRUGS: DOPING IN SPORT

The use of performance enhancement substances is not a new phenomenon in sports. As early as 776 bc the Greek Olympians were reported to use substances such as dried figs, mushrooms, and strychnine to perform better. Their use is prevalent in amateur and professional athletes, receiving even greater attention with use by high-profile accomplished athletes such as Lance Armstrong, disqualification of some professional athletes for failed drug tests, and the seizure of companies caught with tainted supplements (Pope et al, 2014).

Since 2004, the WADA has had a list of banned drugs for athletes who compete and a strategy to detect drugs such as anabolic steroids, erythropoietin (EPO), human growth hormone (HGH), and insulin-like growth factor (IGF-1). WADA annually updates its prohibited list of supplements suspected of (1) illegally enhancing athletic performance, (2) representing an actual or potential health risk to the athlete, or (3) violating the spirit of the sport.

As the number of individuals participating in different sports increases, so does the variety of doping agents. According to WADA, the rate of use has been fairly consistent, suggesting a prevalence of approximately 2% of elite athletes. Rates derived from self-reports have ranged from 1.2% to 26%. Between 10% and 24% of male athletes have reported they would use doping if it would help them achieve better results without the risk of consequences, with an additional 5% to 10% indicating potential doping behavior regardless of health hazards.

Reasons given for using banned substances include achievement of athletic success by improving performance, financial gain, improving recovery, prevention of nutritional deficiencies, and the idea that others use them or the “false consensus effect.”

Steroids

Androgenic-anabolic steroids (AASs) categorize all male sex steroid hormones, their synthetic derivatives, and their active metabolites used to enhance athletic performance and appearance. AAS use was reported in the 1950 Olympics and was banned in 1976. Steroids may be used as oral or intramuscular preparations.

The legal and illegal use of these drugs is increasing as a result of society’s preoccupation with increasing muscle strength, size, and libido. Originally designed for therapeutic uses to provide enhanced anabolic potency, nontherapeutic use of AAS is increasing among

adolescents and females. Anecdotal evidence suggests widespread use of anabolic steroids among athletes (20% to 90%), especially at the professional and elite amateur levels. Use among high school boys is approximately 5% to 10%; rates among college athletes are slightly higher.

Anabolic effects of AAS include increased muscle mass; increased bone mineral density; increased blood cell production; decreased body fat; increased heart, liver, and kidney size; vocal cord changes; and increased libido. Anabolic steroids increase protein synthesis in skeletal muscles and reverse catabolic processes; however, increased muscle mass and strength are observed only in athletes who maintain a high-protein, high-calorie diet during steroid administration. **Androgenic effects** are the development of secondary sexual characteristics in men, changes in genital size and function, and growth of auxiliary pubic and facial hair. Some adverse effects associated with steroid use are irreversible, especially in women.

Although steroid use has some valid medical uses (e.g., the treatment of delayed puberty, or body wasting resulting from disease), it also has adverse physical and emotional consequences in adolescents, such as arrested bone growth, internal organ damage, feminization in males, and masculinization in females. It also is associated with other high-risk behaviors, such as the use of other illicit drugs, reduced involvement in school, poor academic performance, engaging in unprotected sex, aggressive and criminal behavior, and suicidal ideation and attempted suicide.

Erythropoietin

EPO is used commonly to promote the body's production of red blood cells in patients with bone marrow suppression, such as patients with leukemia, those who are receiving chemotherapy, or those with renal failure (see Chapters 34 and 35). In athletes, injections increase the serum hematocrit and oxygen-carrying capacity of the blood, and thus enhance Vo_2max and endurance. EPO use as an ergogenic aid is difficult to detect because it is a hormone produced by the kidneys, although newer blood tests can detect its use. Typically, athletes with elevated hematocrit have been banned from endurance sports for suspected EPO misuse; however, despite its ban by the IOC, it is still commonly abused. Drastically high hematocrit combined with exercise-induced dehydration can lead to thick or viscous blood, which can lead to coronary or cerebral vascular occlusions, heart attack, or stroke. EPO also can cause elevated blood pressure or elevated potassium levels.

Human growth hormone (HGH) has many functions in the body, and it is produced naturally throughout life. It stimulates protein synthesis, enhances carbohydrate and fat metabolism, helps to maintain sodium balance, and stimulates bone and connective tissue turnover. HGH production decreases with age after the peak growth years. The amount secreted is affected by diet, stress, exercise, nutrition, and medications. HGH is banned by the IOC; however, it continues to be used by athletes. Potential side effects include skin changes, darkening of moles, adverse effects on glucose and lipid metabolism, and the growth of bones as evidenced by development of a protruding jaw and boxy forehead.

Prohormones and Steroids

Prohormones are popular among bodybuilders, many of whom believe that these prohormones are natural boosters of anabolic hormones. Androstenedione, 4-androstenediol, 19-nor-4-androstenedione, 19-nor-4-androstenediol, 7-keto dehydroepiandrosterone (DHEA), and 7-keto DHEA are naturally derived precursors to testosterone and other anabolic steroids.

Androstenedione

Androstenedione is a prohormone, an inactive precursor to female estrogen and male testosterone. It has about one-seventh of the activity of testosterone and is a precursor that directly converts to testosterone by a single reaction. It is produced naturally in the body from either DHEA or 17-alpha-hydroxyprogesterone. Some researchers have found that taking androstenedione elevates testosterone more than DHEA does; however, the induced increase lasts only several hours and remains at peak levels for just a few minutes. Acute or long-term administration of testosterone precursors does not effectively increase serum testosterone levels and fails to produce any significant changes in lean body mass, muscle strength, or performance improvement (Smurawa and Congeni, 2007).

Adverse reactions occur in male and female athletes, including muscle tightness and cramps, increased body weight, acne, GI problems, changes in libido, amenorrhea, liver damage, and stunted growth in adolescents. Consumption of a prohormone supplement can alter a patient's hypothalamic-pituitary-gonadal axis. Andro-related hormones may elevate abnormally estrogen-related hormones and alter elevations of serum estrogen, which is thought to increase the risk for developing prostate or pancreatic cancers. A significant decline in high-density lipoprotein (HDL) occurs, leading to an increased cardiovascular disease risk. Therefore taking androstenedione may be irresponsible because of the potential risks associated with long-term use. Until there is scientific support for its use, androstenedione should not be sold under the assumption that it is either an effective or a safe athletic ergogenic aid. Clearly, adolescents and women of childbearing age should not use it. In 1998 androstenedione was added to the list of banned substances by the IOC and several amateur and professional organizations, including the NFL and the NCAA.

Dehydroepiandrosterone (DHEA) is a weak androgen and product of dehydroandrosterone-3-sulfate (DHEA-S) and is used to elevate testosterone levels. It is a precursor to more potent testosterone and dihydrotestosterone. Although DHEA-S is the most abundant circulating adrenal hormone in humans, its physiologic role is poorly understood. DHEA has been labeled the "fountain of youth" hormone because its levels peak during early adulthood. The decline with aging has been associated with increased fat accumulation and risk of heart disease. Several studies have suggested a positive correlation between increased plasma levels of DHEA and improved vigor, health, and well-being in persons who range in age from 40 to 80 years. By decreasing cortisol output from the liver by 50%, DHEA could have an anabolic effect.

DHEA supplementation does not increase testosterone levels or increase strength in men, but it may increase testosterone levels in women with a virilizing effect. Because DHEA can take several different hormonal pathways, the one that it follows depends on several factors, including existing levels of other hormones. It can take several routes in the body and interact with certain enzymes along the sex-steroid pathway. Thus it can turn into less desirable byproducts of testosterone, including dihydrotestosterone, which is associated with male-pattern baldness, prostate enlargement, and acne.

The benefits of taking DHEA for sports performance have not been clearly established, and the effects of chronic DHEA ingestion are not known. Long-term safety has not been established, and there are concerns that chronic use in men may worsen prostate hyperplasia or even promote prostate cancer. DHEA is not recommended for athletic use because it can alter the testosterone-epitestosterone ratio so that it exceeds the 6:1 limit set by the IOC, the USOC, the NFL, and the NCAA.

CLINICAL CASE STUDY

Jose is a 32-year-old Hispanic male and former college athlete who has been competing in long-distance triathlon and marathon events for the past year. He complains of low energy as training and racing duration increases and is plagued by gut issues—gas and bloating after meals, nausea, and vomiting during races. He also suffers from sleep issues, waking up frequently during the night. He works full time at a stressful job as manager of an electrical contracting firm and trains in swimming, cycling, and running 10 to 12 hours/week.

Assessment

His height is 5 ft, 9 in and his weight is 174 lb. His body composition analysis as measured using the International Society for the Advancement of Kinanthropometry (ISAK) method was 6.8% (10.4 lb. body fat, 164 lb. [74kg] fat free mass [FFM]). He is satisfied with his body fat percentage but would like to reduce his weight, if possible, to lighten up for the running portion of his events.

A urine specific gravity test determined hydration status on three visits: 1.035, 1.025, and 1.030

Cholesterol levels were 250 mg/dL, high-density lipoprotein (HDL) 50 mg/dL, low-density lipoprotein (LDL) 170 mg/dL, triglycerides 160 mg/dL; all other values were within normal limits.

Using the Cunningham equation to calculate resting energy expenditure (REE):

$$500 + (22 \times \text{FFM [kg]}) \quad 500 + (22 \times 74) = 2128 \text{ REE}$$

Day off training: Activity factor 1.2 = approximately 2553 calories

1-2 hours steady state training: Activity factor 1.4 = approx. 2979 calories

3-4 hours steady state training: Using Activity factor 1.6 = approx. 3404 calories

4-6 hours training steady state: Using 1.73 Activity factor = approx. 4581 calories

Current Diet

Breakfast 1 hour before workout

12 oz coffee with 1 oz coffee creamer

3 eggs, fried with onions, 2 slices bacon, 2 slices ham

1 corn tortilla with cheese

Analysis: 570 calories, 30 grams fat (49%), 40 grams carbs (28%) 570 mg cholesterol

Workout: 2000-yard swim, 2-hour bicycle ride, 4-mile run

During swim portion of workout (less than 1 hour): nothing

During cycle portion of workout: 2 hours

2 electrolyte pills every 20 minutes on bike—total 12 pills

Each pill contains: 40 mg Na—480 mg sodium

3 16 oz bottles fluid:

- 1 × 170 calories, 32 g cholesterol, 10 g protein
- 1 bottle high carbohydrate, hypertonic sports drink with maltodextrin—270 cal, 54 g carb, 7 g sugar and protein, 220 mg Na, 25 mg caffeine
- Water

1 gel pack every 30 minutes = 6 packs

Double latte with caffeine 110 cal, 27g carbs, 200 mg Na

During run portion of workout (less than 1 hour): nothing

Total workout fuel: 1100 calories, 248 g carbohydrates (124 g/hr cycling, 900 mg Na)

Immediately after workout: nothing

Breakfast

Coffee with half-and-half

1 plain bagel, cream cheese, jelly

Banana

12 ounces milk

Snack: none

Lunch

2-6 oz chicken breasts grilled with skin, 2 cups black beans and white rice, ½ cup fried plantains

Snack: high-protein sports bar

Dinner

1 onion soup with melted cheese

12 oz grilled steak

1 c yellow rice

Sautéed mushrooms

Dietary Analysis

3041 calories, 216 g protein (2.77 g/kg) (28%), 249 g carbohydrates (3.15 g/kg) (33%), 13.5% saturated fat, 1172 mg cholesterol, 5634 mg Na (recommended dietary allowance (RDA): 64% potassium, 85% Ca and folate, 26% vitamin C, 30% vitamin E, 13% vitamin K, dietary fluid intake = 9 cups

Nutrition Diagnostic Statements

- Inadequate energy intake (NI-1.2) related to knowledge deficit about kcal needs for exercise performance as evidenced by diet low in calories (3041 calories [4141 with sport fuel] vs. 4581 calories required).
- Inadequate carbohydrate intake (NI-5.8.1) related to knowledge deficit about carbohydrate needs for sports performance as evidenced by intake of 249 g carbohydrates (3.15 g/kg) (33%) (497 g sport fuel), vs. a minimum of 5 to 7 g/kg = 395-553 g
- Excess fat intake (NI-5.5.2) related to knowledge deficit about fat needs for exercise performance as evidenced by total fat intake of 38% total calories, saturated fat and cholesterol 1172 mg
- Other assessments:
 - Low in antioxidants
 - Excessive fat in preworkout breakfast
 - Excessive in sport fuel carbohydrates and sodium for 2-hour bike portion of ride
 - Excessive in mealtime calories and protein
 - Questionable whether athlete can tolerate fructo-, oligo-, di-, and monosaccharides and polyols (FODMAPs) foods (i.e., onions, beans, mushrooms, cream cheese, dairy [lactose], sport fuel sources of high fructose corn syrup [HFCS], and gluten). See Chapter 27 for more information about FODMAPs.

Interventions

- Increase meal frequency and calories while modifying fat, saturated fat, and cholesterol
- Increase plant-based tolerable sources of protein and complex carbohydrates
- Modify amounts of animal protein at mealtime to 4 to 5 oz. (30 to 35 g)
- Improve leafy green vegetable intake via juicing or cooked versions if whole food vegetables not desired or tolerated
- Improve intake of antioxidant rich fruits and fruit juices without added sugar since fruits and fruit juices have ample amounts of sugar and excess fructose can cause gastrointestinal (GI) distress in some athletes.

Recommendations

Prebiotic/probiotic rich foods to support gut health; Some RDN's recommend enzymes before meals but the use is controversial in traditional medicine as evidence is based on expert opinion vs. clinical trials.

Adjust amount of sport fuel intake to decrease amount of sugar consumed during training/competition. Decrease electrolyte supplementation as excess amounts can cause GI distress in some athletes and is typically unnecessary since sports drinks already contain sodium and other electrolytes.

CLINICAL CASE STUDY—cont'd

Consider reducing carbohydrate-fortified liquids and/or changing carbohydrate source (i.e., as different beverages offer different simple and complex sugar sources and tolerability is individualized).

Include meditation or yoga on day off from training and/or prayer or meditation 5 to 10 minutes a day for relaxation

Laboratory and Integrative Approaches

Follow-up lipid profile after 9 to 12 weeks on modified fat, saturated fat, and cholesterol diet

Nutrition Care Questions

1. Calculate calorie and macronutrient needs using Cunningham equation and guidelines provided in chapter.
2. Assess what eating/lifestyle behaviors may be affecting this athlete's energy levels (i.e., sleep, stress, portion sizes at meal time).
3. Calculate training/race day/recovery fuel formulas for preworkout, workout calories, carbohydrates, and sodium.
4. List issues that appear to be a valid reason to initiate FODMAPs and elimination diet.

Nutrition and Bone Health

Karen Chapman-Novakofski, PhD, RDN, LDN
Rickelle Richards, PhD, MPH, RDN

KEY TERMS

7-dehydrocholesterol	cancellous bone	osteomalacia
25-hydroxy vitamin D (calcidiol)	collagen	osteopenia
1,25-dihydroxy vitamin D ₃ (calcitriol)	cortical bone	osteoporosis
bisphosphonates	estrogen agonists	parathyroid hormone (PTH)
bone densitometry	estrogen receptor (ER)	peak bone mass (PBM)
bone mineral content (BMC)	hydroxyapatite	primary osteoporosis
bone mineral density (BMD)	hyponatremia	sarcopenia
bone modeling	osteoblast	secondary osteoporosis
bone remodeling	osteocalcin	selective estrogen receptor modulator (SERM)
bone resorption	osteoclast	trabecular bone
calcium homeostasis	osteocytes	
calcitonin	osteoid	

INTRODUCTION

Adequate nutrition is essential for the development and maintenance of the skeleton. Although diseases of the bone such as osteoporosis and **osteomalacia** (a condition of impaired mineralization caused by vitamin D and calcium deficiency) have complex causes, the development of these diseases can be minimized by providing adequate nutrients throughout the life cycle. Of these diseases, osteoporosis is the most common and destructive of productivity and quality of life. As true of many chronic diseases, signs and symptoms of osteoporosis become more evident in older age.

As more adults reach older ages, osteoporosis with resulting hip, wrist, and vertebral fractures has become more significant in cost, morbidity, and mortality in the United States. Prevention and treatment are equally important to the quality of life.

BONE STRUCTURE AND BONE PHYSIOLOGY

Bone is a term used to mean both an organ, such as the femur, and a tissue, such as trabecular bone tissue. Each bone contains bone tissues of two major types, trabecular and cortical. These tissues undergo bone modeling during growth (height gain) and bone remodeling after growth ceases.

Bone mass is a generic term that refers to **bone mineral content (BMC)**. **Bone mineral density (BMD)** describes the mineral content of bone per unit of bone. Neither BMC nor BMD provides information on the microarchitectural (three-dimensional) structural quality of bone tissue (i.e., index of risk of fracture).

Composition of Bone

Bone consists of an organic matrix or **osteoid**, primarily collagen fibers, in which salts of calcium and phosphate are deposited in

combination with hydroxyl ions in crystals of **hydroxyapatite**. The cable-like tensile strength of collagen and the hardness of hydroxyapatite combine to give bone its great strength. Other components of the bone matrix include osteocalcin, osteopontin, and several other matrix proteins.

Types of Bone Tissue

Approximately 80% of the skeleton consists of compact or cortical bone tissue. Shafts of the long bones contain primarily **cortical bone**, which consists of osteons or Haversian systems that undergo continuous but slow remodeling, and both contain an outer periosteal layer of compact circumferential lamellae and an inner endosteal layer of trabecular tissue. The remaining 20% of the skeleton is **trabecular** or **cancellous bone** tissue, which exists in the knobby ends of the long bones, the iliac crest of the pelvis, the wrists, scapulas, vertebrae, and the regions of bones that line the marrow. Trabecular bone is less dense than cortical bone as a result of an open structure of interconnecting bony spicules that resemble a sponge in appearance.

The elaborate interconnecting components (columns and struts) of trabecular bone add support to the cortical bone shell of the long bones and provide a large surface area that is exposed to circulating fluids from the marrow and is lined by a disproportionately larger number of cells than cortical bone tissue. Therefore trabecular bone tissue is much more responsive to estrogens or the lack of estrogens than cortical bone tissue (Fig. 23.1). The loss of trabecular bone tissue late in life is largely responsible for the occurrence of fractures, especially those of the spine (vertebral fractures).

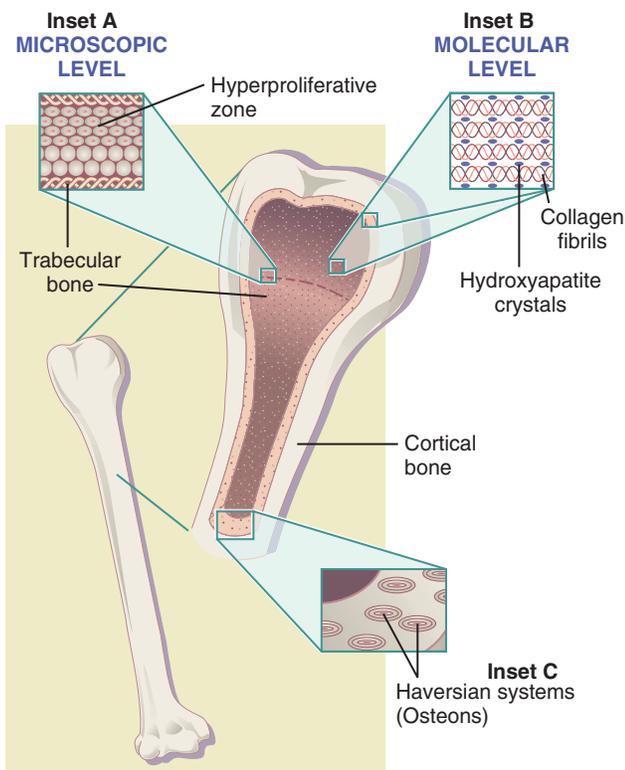

Fig. 23.1 Schematic diagram of the structure of a long bone (hemisection of a long bone, such as the tibia). The ends of the long bones contain high percentages of trabecular (cancellous) bone tissue, whereas the shaft contains predominately cortical bone tissue. *Inset A* includes an enlarged section (approximately 100-fold) of the growth plate (epiphysis) and the subjacent hyperproliferative zone containing cartilage cells stacked like coins. *Inset B* includes a section of collagen molecules (triple helices) surrounded by mineralized deposits (dark spheroids) at a magnification of approximately 1,000,000-fold. These collagen-mineral complexes exist in both trabecular and cortical bone tissues. *Inset C* shows the cross-section of half of the midshaft of a long bone (magnification 10-fold). This section of cortical bone tissue contains vertical Haversian systems (osteons) that run parallel with the shaft axis; many are required to extend this system from one end of the shaft to the other. At the center of each osteon is a canal that contains an artery that supplies bone tissues with nutrients and oxygen, a vein for removing wastes, and a nerve for returning afferent relays to the brain. (Copyright John J. B. Anderson and Sanford C. Garner.)

Bone Cells

Osteoblasts are responsible for the formation or production of bone tissue, and **osteoclasts** govern the resorption or breakdown of bone (also see Bone Modeling and Bone Remodeling later in this chapter). The functions of these two cell types are listed in Table 23.1.

Two other important cell types also exist in bone tissue, **osteocytes** and bone-lining cells (inactive osteoblasts), both of which are derived from osteoblasts. The origin of the osteoblasts and osteoclasts is from primitive precursor cells found in bone marrow, stimulated by hormones and growth factors as part of their differentiation to become mature, functional bone cells.

Cartilage

In the embryo, cartilage forms the first temporary skeleton, until it develops into a mature bone matrix. In the adult, cartilage is found as flexible supports in areas such as the nose and ear. Cartilage is not bone, and it is neither vascularized nor calcified.

TABLE 23.1 Functions of Osteoblasts and Osteoclasts

Osteoblasts	Osteoclasts

Mineralization Communication: Secretion of cytokines that act on osteoblasts	Communication: Secretion of enzymes that act on osteoclasts

Calcium Homeostasis

Bone tissue serves as a reservoir of calcium and other minerals. **Calcium homeostasis** refers to the process of maintaining a constant serum calcium concentration. The serum calcium is regulated by complex mechanisms that balance calcium intake and excretion with bodily needs. When calcium intake is not adequate, homeostasis is maintained by drawing on mineral from the bone to keep the serum calcium ion concentration at its set level (approximately 8.5 to 10 mg/dL). Homeostasis can be accomplished by drawing from two major skeletal sources: readily mobilizable calcium ions in the bone fluid or osteoclastic resorption from the bone tissue itself. The daily turnover of skeletal calcium ions (transfers in and out of bone) supports the dynamic activity of bone tissue in calcium homeostasis.

Serum calcium concentration is regulated by two calcium-regulating hormones—**parathyroid hormone (PTH)** and **1,25 dihydroxy vitamin D3 (calcitriol)**. If serum calcium levels fall, PTH will increase reabsorption from the kidney and bone, and calcitriol will increase gut absorption and initiate osteoclastic activity for bone breakdown. Increased serum calcium, hypercalcemia, occurs primarily due to hyperparathyroidism. Serum calcium includes free calcium (formerly called ionized calcium) and albumin-bound calcium.

Bone Modeling

Bone modeling is the term applied to the growth of the skeleton. Bone formation and resorption are not linked as they are in remodeling. In long bones, growth occurs both at terminal epiphyses (growth plates that undergo hyperproliferation) and circumferentially in lamellae; at each location, cells undergo division and contribute to the formation of new bone tissue (see Fig. 23.1). Although we typically consider bone modeling complete by the time mature height is achieved, bone modeling can occur later in life, especially in response to physical activity. Bone modeling results in the formation of new bone, but it does not remove or repair old bone as is seen in bone remodeling (Langdahl et al, 2016).

During the growth period, formation exceeds the resorption of bone. **Peak bone mass (PBM)** is reached by 30 years of age or so (Fig. 23.2). The long bones stop growing in length by approximately age 18 in females and age 20 in males, but bone mass continues to accumulate for a few more years by a process known as consolidation (i.e., filling-in of osteons in the shafts of long bones). The age when BMD acquisition ceases is variable and depends on diet and on physical activity, genetics, and hormonal influences.

PBM is greater in men than in women because of men's larger frame sizes. The greater height of most males accounts for the greater PBM. The variation in BMD within an ethnicity is greater than among ethnicities. Genetics, skeletal size, and presence or absence of chronic

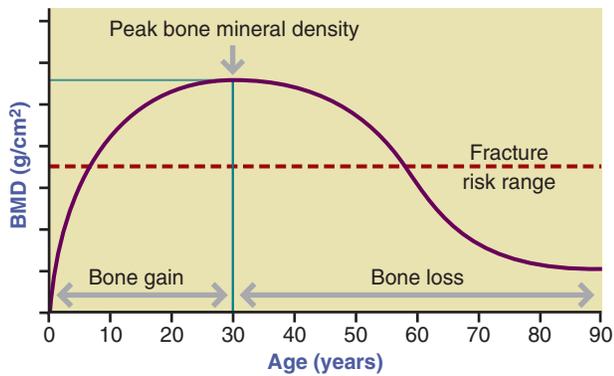

Fig. 23.2 The early gain and later loss of bone in females. Peak bone mineral density (BMD) is typically achieved by age 30. Menopause occurs at approximately age 50 or within a few years. Postmenopausal women typically enter the fracture risk range after age 60. Men have a more gradual decline in BMD, which starts at 50 years. (Copyright John J. B. Anderson and Sanford C. Garner.)

disease influence BMD, and social, environmental, and personal factors also influence probability of fracture risk (Leslie, 2012).

Bone Remodeling

Bone is a dynamic organ both during growth and maintenance. **Bone remodeling** is a process in which bone is continuously resorbed through the action of the osteoclasts and reformed through the action of the osteoblasts. The remodeling process is initiated by the *activation* of preosteoclastic cells in the bone marrow. Interleukin (IL)-1 and other cytokines released from bone-lining cells act as the triggers in the activation of precursor stem cells in bone marrow. The preosteoclast cells from the bone marrow migrate to the surfaces of bone while differentiating into mature osteoclasts. The osteoclasts then cover a specific area of trabecular or cortical bone tissue. Acids and proteolytic enzymes released by the osteoclasts form small cavities on bone surfaces and *resorb* both bone mineral and matrix on the surface of trabecular bone or cortical bone. The resorptive process is rapid, and it is

completed within a few days, whereas the refilling of these cavities by osteoblasts is slow (i.e., on the order of 3 to 6 months or even as long as 1 year or more in older adults).

The *rebuilding* or *formation* stage involves secretion of **collagen** and other matrix proteins by the osteoblasts, also derived from precursor stem cells in bone marrow. Collagen polymerizes to form mature triple-stranded fibers, and other matrix proteins are secreted. Within a few days, salts of calcium and phosphate begin to precipitate on the collagen fibers, developing into crystals of hydroxyapatite. Approximately 4% of the total bone surface is involved in remodeling at any given time as new bone is renewed continually throughout the skeleton. Even in the mature skeleton, bone remains a dynamic tissue. Normal bone turnover is illustrated in Fig. 23.3.

When the resorption and formation phases are in balance, the same amount of bone tissue exists at the completion of the formation phase as at the beginning of the resorption phase. The benefit to the skeleton of this remodeling is the renewal of bone without any microfractures. With aging, osteoclastic resorption becomes relatively greater than formation by osteoblasts. This imbalance between formation and resorption is referred to as “uncoupling” of the osteoblastic and osteoclastic activity.

Because of the uncoupling of cell activity, age is an important determinant of BMD. Cortical bone tissue and trabecular bone tissue undergo different patterns of aging. Loss of cortical bone occurs around age 50, with an increase in cortical porosity in both genders. Trabecular bone loss may begin much earlier. In men trabecular bone loss reflects thinning of the trabecula. In women, the trabecular bone loss appears to be because of trabecula loss entirely (Farr and Khosla, 2015).

OSTEOPENIA AND OSTEOPOROSIS

This loss of bone can continue throughout aging, eventually leading to osteopenia or osteoporosis. However, it is important to remember that not all older persons have poor bone health, and that bone disease can occur in younger people, although rarely. Differences between normal and osteoporotic bone—both trabecular and cortical tissues—are shown in Fig. 23.4.

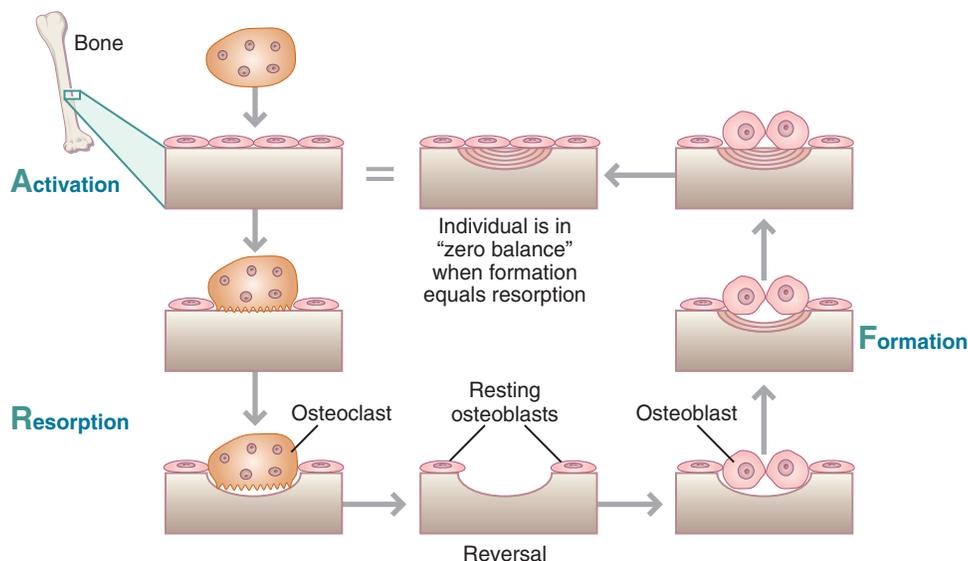

Fig. 23.3 Normal bone turnover in healthy adults. (Copyright John J. B. Anderson and Sanford C. Garner.)

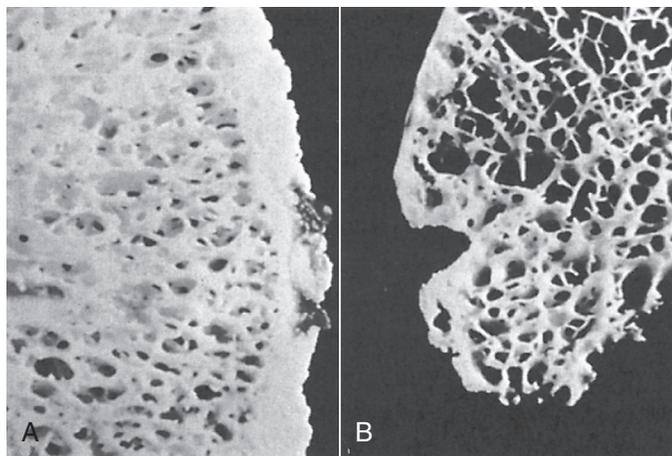

Fig. 23.4 Difference between normal bone (A) and osteoporotic bone (B). (From Maher AB et al: *Orthopedic nursing*, Philadelphia, 1994, Saunders.)

Prevalence

The prevalence of osteoporosis depends on the diagnostic criteria. Prevalence estimates using BMD T-scores of <2.5 at the femur neck and/or spine suggest that 10.3% of adults over 50 years in the United States have osteoporosis (Wright et al, 2014). When the Fracture Risk Assessment Tool (FRAX) calculations are used as the diagnostic criteria, 11.6% of men and 13.0% of women over age 50 were predicted to have osteoporosis. When identified low trauma fracture is a diagnosis, with or instead of the low T-score or FRAX score, the osteoporosis prevalence estimates increase to 16% of men and 29.9% of women over 50 years (Wright et al, 2017).

Types of Osteoporosis

Osteoporosis is considered to have a broad spectrum of variant forms. **Primary osteoporosis** occurs as a result of the natural aging process. BMD declines both with age and with the loss of estrogen after menopause. For women, primary osteoporosis is more likely 10 to 15 years after menopause, and in men, around age 65 to 80 (Ji and Yu, 2015). However, lifestyle factors and genetics also influence if and when osteoporosis may occur. **Secondary osteoporosis** results when an identifiable drug or disease process causes loss of bone tissue (Box 23.1).

Causes and Risk Factors

Osteoporosis is a complex, heterogeneous disorder and many risk factors contribute during a lifetime. Low BMD is common to all types of

BOX 23.1 Medical Conditions that Deplete Calcium and Promote Risk of Osteoporosis

- Chronic diarrhea or intestinal malabsorption
- Chronic obstructive lung disease
- Chronic renal disease
- Diabetes
- Hemiplegia
- Hyperparathyroid disease
- Hyperthyroidism
- Scurvy
- Subtotal gastrectomy

BOX 23.2 Risk Factors for Developing Osteoporosis

- Age, especially older than age 60
- Amenorrhea in women as a result of excessive exercise
- Androgen depletion with hypogonadism in men
- Cigarette smoking
- Estrogen depletion from menopause or early oophorectomy
- Ethnicity: white or Asian
- Excessive intake of alcohol, caffeine, fiber
- Female gender
- Family history of osteoporosis
- Inadequate calcium or vitamin D intake
- Lack of exercise
- Prolonged use of certain medications (see Box 23.3)
- Sarcopenia
- Underweight, low body mass index, low body fatness

osteoporosis, but an imbalance between **bone resorption** and formation results from an array of factors characteristic of each form of this disease. Risk factors for osteoporosis include age, race, gender, and factors noted in Box 23.2.

Alcohol

Excessive alcohol consumption is a risk factor for developing osteoporosis, probably because of toxic effects on osteoblasts. Moderate alcohol intake seems to have no detrimental effect on bone, and some studies show a modest positive effect. Three or more drinks per day is associated with increased risk of falling and may pose other threats to bone health (Abrahamsen et al, 2014).

Body Weight

There is a strong correlation between BMD and BMI suggesting that a BMI of $<21 \text{ kg/m}^2$ is associated with low BMD and greater fracture risk in women.

Cigarette Smoking

There are direct and indirect cellular effects on bone caused by smoking, as well as possible hormonal changes and lower dietary calcium absorption. Smoking may also be associated with lower body weight, decreased physical activity, and poor diet (Abrahamsen et al, 2014).

Ethnicity

Osteoporosis is a multifactorial disease, and determining the role of ethnicity in osteoporosis, BMD, bone strength, bone quality, and fracture incidence is difficult. While genetics have made strides in determining the role of ethnicity or race in these outcomes, the blending of ethnicities and races also makes definitive statements elusive. In addition, ethnicity has an influence on many lifestyle factors that could also affect these outcomes, such as diet and physical activity. A related issue is body frame size, often associated with an ethnic group (Rivadeneira and Uitterlinden, 2017).

Limited Weight-Bearing Exercise

Accrual and maintenance of healthy bone requires exposure to weight-bearing pressures throughout the lifespan. Immobility in varying degrees is well recognized as a cause of bone loss. Invalids confined to bed or persons unable to move freely are commonly affected. Astronauts

living in conditions of zero gravity for only a few days experience bone loss, especially in the lower extremities; appropriate exercise is a feature of their daily routines.

Loss of Menses

Acceleration of bone loss coincides with menopause, either natural or surgical, at which time the ovaries stop producing estrogen. In association with the decline in estrogen, more bone sites are undergoing resorption and for a longer time, with bone formation diminished. Compensatory mechanisms for the efflux of calcium from bone during this period of enhanced resorption include decreased renal calcium reabsorption, decreased intestinal calcium absorption, and reduced PTH secretion (Drake et al, 2015).

Any interruption of menstruation for an extended period results in bone loss. The amenorrhea that accompanies excessive weight loss seen in patients with anorexia nervosa or in hypothalamic amenorrhea, which occurs in individuals who participate in high-intensity sports or dance, is often associated with lifetime low bone density, compromised bone architecture, and increased fracture risk (Chou and Mantzoros, 2018).

Nutrients

Many nutrients and several nonnutrients have been implicated as causal risk factors for osteoporosis. Poor calcium and vitamin D intake have been linked to poor bone health, osteoporosis, and fracture risk. Vitamin C assists in the formation of collagen, which is necessary for healthy bones. Other nutrients that may play a role include protein (when it is too high or too low), vitamins A, B₆, B₁₂, E, and K, as well as thiamin (Abrahamsen et al, 2014).

Medications

A number of medications contribute adversely to osteoporosis, either by interfering with calcium absorption or by actively promoting calcium loss from bone (Box 23.3). For example, corticosteroids affect vitamin D metabolism and can lead to bone loss. Excessive amounts of exogenous thyroid hormone can promote loss of bone mass over time.

Sarcopenia

Sarcopenia is defined as a loss of skeletal muscle, with associated decline in muscle function. This results in increased risk for falls and disability. Sarcopenia is associated with low bone mass, osteoporosis, and hip fractures in most studies (Oliveira and Vaz, 2015).

BOX 23.3 Medications that Increase Calcium Loss and Promote Risk of Osteoporosis

- Aluminum-containing antacids
- Corticosteroids
- Cyclosporine
- Heparin
- Lasix and thiazide diuretics
- Lithium
- Medroxyprogesterone acetate
- Methotrexate
- Phenobarbital
- Phenothiazine derivatives
- Phenytoin (Dilantin)
- Thyroid hormone
- Tetracycline

Diagnosis and Monitoring

Bone densitometry measures bone mass on the basis of tissue absorption of photons produced by x-ray tubes. Dual-energy x-ray absorptiometry (DEXA) (see Chapter 5) is available in most hospitals and many clinics for the measurement of the total body and regional skeletal sites such as the lumbar vertebrae and the proximal femur (hip). Results of DEXA measurements are commonly expressed as T-scores. When the BMD T-score is 2.5 standard deviations (SDs) below the mean, a diagnosis of osteoporosis is made; between 1 and 2.5 SD is considered low bone mass or osteopenia; and within 1 SD of the adult mean is considered normal.

Definitions

When BMD falls sufficiently below healthy values (1 SD according to World Health Organization [WHO] standards) low bone mass or **osteopenia** exists. **Osteoporosis** occurs when the BMD becomes so low (greater than 2.5 SDs below healthy values) that the skeleton is unable to sustain ordinary strains. However, the National Osteoporosis Foundation (NOF) states that the WHO BMD diagnostic classification should not be applied to premenopausal women, men younger than 50 years of age, or children. Clinical assessment and ethnically adjusted Z-scores are thought to be more reflective of the norms in other groups.

Ultrasound Measurements of Bone

Ultrasound instruments measure the velocity of sound waves transmitted through bone and broadband ultrasound attenuation (BUA). Measurements at the calcaneus (heel) correlate fairly well with BMD measurements at this same skeletal site. However, ultrasound measurements are considered screening tools, whereas DEXA measurements are considered diagnostic.

Fracture Risk Assessment

The WHO Collaborating Centre for Metabolic Bone Disease, housed at the University of Sheffield, United Kingdom, developed an algorithm to predict fracture by using femoral head BMD and clinical indicators of low bone mass (Kanis et al, 2011). This uses economic modeling to guide the most cost-effective instances to begin medications (Borgström et al, 2011). Vertebral fractures that are confirmed by x-rays are a strong predictor of future vertebral fractures, as well as fractures at other sites (Kanis et al, 2011).

In the United States the National Bone Health Alliance recognizes FRAX as a means to diagnose osteoporosis risk; however, experiencing previous fractures and BMD testing are other tools that can be used (Siris et al, 2014). Several additional screening measures have been developed and suggested by the U.S. Preventative Services Task Force as being moderately accurate at predicting osteoporosis (Curry, 2018). See Table 23.2.

Bone Markers

Enzymes or degradation products in serum or urine have been used for research and are beginning to be used more often to monitor drug treatment effectiveness. For bone formation, serum osteocalcin, serum bone alkaline phosphatase, and serum procollagen type I N-terminal propeptide (PINP) are often used. For bone resorption, serum and urine C-telopeptide of type 1 collagen and urine N-telopeptide of type 1 collagen are used. Formation markers are useful in monitoring the effectiveness of anabolic medications, whereas resorptive markers are useful for monitoring antiresorptive medications (Chapurlat and Confavreux, 2016).

TABLE 23.2 Screening Tools for Osteoporosis

Tool Name Abbreviation	Full Name	Authors	Variables Used
FRAX	Fracture Risk Assessment Tool	Kanis et al, 2011	Gender, age, BMI, parental history of hip fracture, tobacco smoking, use of oral glucocorticoids, causes of secondary osteoporosis, alcohol
ORAI	Osteoporosis Risk Assessment Instrument	Cadarette et al, 2000	Age, weight, estrogen
OSIRIS	Osteoporosis Index of Risk	Sedrine et al, 2002	Age, weight, estrogen, previous fracture
OST	Osteoporosis Self-Assessment Tool	Richy et al, 2004	Age, weight
SCORE	Simplified Calculated Risk Estimation Score	Von Mühlen, et al, 1999	Age, weight, previous fracture, rheumatoid arthritis, estrogen, race

BMI, Body mass index

CLINICAL INSIGHT

Postmenopausal Women at High Risk for Hip Fracture

It is important to identify women who are at risk of developing osteoporosis as early as possible so that measures can be taken to monitor bone status and to prevent further bone loss. Because low bone mineral density (BMD) is a major risk factor for osteoporosis, its assessment is clinically useful. Assessment of bone status based on the existence of one or more risk factors such as age, height, weight, smoking status, alcohol consumption, drug use, calcium intake, exercise, frame size, and selected bone markers is not sufficiently accurate. BMD as measured by bone densitometry is more clinically useful. Typically, total body BMD and the regional sites such as the proximal femur and lumbar vertebrae are measured by dual-energy x-ray absorptiometry.

A BMD measurement of an at-risk woman entering menopause (before becoming estrogen deficient) serves as a baseline for subsequent measurements as the individual becomes increasingly estrogen deficient and loses bone mass. This information helps physicians and patients make decisions about the need for and use of drug therapy such as bisphosphonates, parathyroid hormone drugs, and estrogen agonist or antagonists. For men or women on long-term glucocorticosteroid therapy, a BMD measurement may indicate the need for treatment with a bone-preserving medication or calcitonin.

NUTRITION AND BONE

Energy

Calories do not have a direct effect on bone; rather, inadequate calories leading to low body weight or too many calories leading to overweight both have effects on bone. Being underweight is considered a risk factor for osteoporosis, while being overweight may be protective. While BMI and BMD are positively correlated, and fracture risk for hip and spine is lower in obese versus nonobese, fracture risk is higher in obese individuals at the proximal humerus, upper leg, and ankle (Fassio et al, 2018).

Protein

Both protein and calcium are important components of PBM, especially before puberty. Adequate protein intake, with adequate calcium intake, is needed for optimal bone health. Protein intakes greater than the recommended dietary allowance (RDA) may be beneficial in older adults to slow the loss of BMD, reduce the risk of hip fracture, and promote bone health, providing that calcium intakes are also adequate (Rizzoli et al, 2018). However, very-high-protein diets used specifically for weight loss have been linked to decreased BMD (Campbell and Tang, 2010).

Minerals

Calcium

Calcium intake in the primary prevention of osteoporosis has received much attention. The Institute of Medicine (IOM) dietary reference intakes (DRIs) for calcium and vitamin D are given as RDAs. The RDA for calcium from preadolescence (age 9 years) through adolescence (up to 19 years) was increased to 1300 mg/day for both genders (IOM, 2011). The RDAs for calcium in adults, pregnant and lactating women, and children are listed on the inside cover.

The Dietary Guidelines for Americans identified calcium as an underconsumed nutrient (U.S. Department of Health and Human Services and U.S. Department of Agriculture, 2015). Food sources are recommended first for supplying calcium needs because of the co-ingestion of other essential nutrients that aid in absorption. In the United States the primary source of calcium is dairy foods. However, calcium fortification of nondairy foods such as nondairy milks and other beverages, juices, breakfast cereals, bread, and some crackers is common.

Calcium bioavailability from foods is generally good, and the amount of calcium in the food is more important than its bioavailability. However, the order of concern relative to calcium absorption efficiency is first the individual's need for calcium, second the amount consumed because absorption efficiency is inversely related to amount consumed, and third the intake of absorption enhancers or inhibitors. For example, absorption from foods high in oxalic and phytic acid (certain vegetables and legumes) is lower than from dairy products.

The amount of calcium in foods varies with the brand, serving size, and fortification. Read the Nutrition Facts label to determine the amount of calcium per serving. Multiply the daily value (DV) percentage by 10 to determine the milligrams of calcium. For example, a 20% DV equals 200 mg of calcium (see Chapter 12). Labeling for "excellent" (>200 mg/serving) and "good" (100 to 200 mg/serving) sources of calcium are regulated by the Food and Drug Administration (FDA) (FDA, 2013).

Reaching RDA levels of calcium from foods should be the first goal, but if insufficient amounts of calcium from foods are consumed, supplements of calcium are recommended to reach the age-specific RDA. An increasing percentage of the population is taking calcium supplements. Persons who should take supplements include those not meeting the RDA on most days, those taking corticosteroids, those with low bone mass or osteoporosis, women who are perimenopausal or postmenopausal (see *Clinical Insight*, Postmenopausal Women at High Risk for Hip Fracture), and those who are lactose intolerant. Calcium carbonate is the most common form of calcium supplement. It should be taken with food because an acidic environment enhances absorption. For those with achlorhydria, which is a growing concern due to the increase in use of acid-blocking drugs, calcium citrate may

TABLE 23.3 Upper Limit for Calcium Intake

Age	Amount, mg
Birth to 6 months	1000
7-12 months	1500
1-8 years	2500
9-18 years	3000
19-50 years	2500
Over 50 years	2000

be more appropriate because it does not require an acidic environment for absorption and does not further reduce the acidity of the stomach.

Calcium supplementation absorption is optimal when taken as individual doses of 500 mg or less. Many formulations include vitamin D, because the likelihood of needing vitamin D is high if calcium supplementation is needed. Choosing a supplement that has the United States Pharmacopeia designation increases the likelihood that the supplement quantity is consistent with the label, and that good manufacturing practices are used.

Calcium supplementation increases the risk of reaching the upper limit of safety (UL). Other sources of calcium include water and medications, especially antacids. The UL for each age group is listed in [Table 23.3](#).

Phosphate

The body's reserve of phosphorus is found in the bone as hydroxyapatite. Phosphate salts are available in practically all foods either naturally or because of processing. In healthy adults, the urinary phosphorus excretion approximately equals intake.

The impact of higher dietary phosphorus or a low calcium: phosphorus ratio on bone health is unresolved. Researchers have found both a negative effect and no effect, with limitations in the ability to determine dietary phosphorus noted as a complicating issue ([Anderson et al, 2017](#); [Calvo and Tucker, 2013](#)).

Trace Minerals

Many trace elements are beneficial for bone health, such as boron, copper, manganese, magnesium, selenium, and zinc. However, cadmium, cobalt, and lead are detrimental. The role of fluoride in bone health is unclear ([Zofkova et al, 2017](#)).

Vitamins

Vitamin A

Vitamin A consumption consists of both retinol (animal sources) and carotenoids (plant sources). Some research has linked high dietary intake of retinol to greater risk of osteoporosis and hip fracture. In contrast, carotenoids, the precursors to vitamin A found only in plants, has shown beneficial effects. Although the research is not definitive, generally carotenoids are thought to be safe and beneficial ([Tanumihardjo, 2013](#)).

Vitamin D

In 2008 the FDA amended the label health claim regulations concerning calcium and osteoporosis so that they could also include vitamin D because of increasing recognition that vitamin D plays a pivotal role in calcium uptake and therefore bone homeostasis ([FDA, 2013](#)). While the main function of vitamin D is to maintain serum calcium and phosphorus levels within a constant range, vitamin D is important in stimulating intestinal calcium transport. Vitamin D also stimulates activity of osteoclasts in bone. In both these areas the net desired effect is to increase calcium availability.

An individual's vitamin D status depends mostly on sunlight exposure, and secondarily on dietary intake of vitamin D. The synthesis of vitamin D by skin exposed to sunlight varies considerably as a result of many factors, including skin color, sunscreen use, environmental latitude, season of the year, time of day, and age ([Holick, 2014](#)). The skin of older individuals is less efficient at producing vitamin D following exposure to ultraviolet (UV) light because lower amounts of **7-dehydrocholesterol** are present in the skin ([Gallagher, 2013](#)). In addition, older adults typically have little exposure to the outdoors and therefore less sunlight. Those who live at northern latitudes in the United States and Canada are at increased risk of osteoporosis because of limited UV light during winter months ([Holick, 2014](#)).

The few foods that naturally contain vitamin D are egg yolks; fatty fish such as salmon, mackerel, catfish, tuna, and sardines; cod liver oil; and some mushrooms (see Appendix 38). The vitamin D content of fish varies, as does the content in UV-exposed mushrooms. Fluid milk in the United States is fortified with vitamin D at a standardized level of 400 IU per quart, whereas other foods, including juices, cereals, yogurt, and margarines, may be fortified in varying amounts. The RDAs for vitamin D across the life cycle are shown inside the cover. The UL is 100 µg (4000 IU) for everyone older than 8 years, and lower levels for younger children (see inside cover). From any source, vitamin D must be hydroxylated in the kidney before becoming the physiologically active calcitriol.

To prevent rickets, the American Academy of Pediatrics and other global health professionals recommend that all infants who are exclusively breastfed be supplemented with 400 IU of vitamin D. Infants who are both formula and breastfed should also be supplemented until they are consistently taking 1 liter (1 quart) of formula a day. Experts further recommend continuing the supplementation until 1 year of age, when children begin drinking vitamin D–fortified milk ([Munns et al, 2016](#); [Wagner and Greer, 2008](#)).

The older adult is at increased risk for vitamin D deficiency because of the decreased synthesis of vitamin D by the skin and decreased exposure to sunlight, increased body fat, and decreased renal function that decreases the hydroxylation of vitamin D to its active form ([Gallagher, 2013](#); [Pourshahidi, 2015](#)). In general, daily vitamin D intake of 20 mcg (800 IU) is recommended for seniors to reach serum **25-hydroxy vitamin D (calcidiol)** levels higher than 20 ng/mL, thus preventing vitamin D insufficiency ([Gallagher, 2013](#)). The most common blood test for vitamin D status is serum 25-hydroxy vitamin D level, and the normal range is considered to be 20 to 50 ng/mL ([Wisse, 2016](#)).

Vitamin K

Vitamin K is an essential micronutrient for bone health. Its role in posttranslational modification of several matrix proteins, including **osteocalcin**, is well established ([Hamidi et al, 2013](#)). Vitamin K may also contribute to favorable bone health through decreasing bone resorption and increasing collagen content in bone cells ([Hamidi et al, 2013](#)). Following bone resorption, osteocalcin is released and enters the blood. In this way, osteocalcin serves as a serum bone marker for predicting the risk of a fracture (see Appendix 37).

Most of the vitamin K intake in the United States is from green leafy vegetables, with about one third from fats and oils. Although menaquinones, a form of vitamin K, are formed in the gut by bacteria, the influence of this source on vitamin K status appears to be weak. Many older adults have inadequate intakes of vitamin K, primarily because their consumption of dark-green leafy vegetables is so low. It is important to consider the vitamin K intake in older persons who may also be taking blood-thinning medications (vitamin K antagonists). Rather than having these patients avoid vitamin K in foods and thus jeopardize their bone status, it is better to have the vitamin K daily

intake be consistent and regulate the vitamin K antagonist medication. Because it is difficult for older adults to consume a consistent amount of vitamin K in their diet each day, a supplemental form of vitamin K is recommended for those on blood-thinning medications (Mahtani et al, 2014). In fact, it has been shown that therapeutic international normalized ratio (INR) ranges from blood-thinning medication can be achieved with vitamin K in low-dose supplementation and when fluctuations are few (Mahtani et al, 2014).

Other Dietary Components

Several other dietary factors have been associated with bone health, but their relative quantitative importance is not clear.

Alcohol

Although previously mentioned as a risk factor, low to moderate consumption of wine and beer may be beneficial to bone health. High alcohol intake is associated with lower bone density, higher prevalence of osteoporosis, and increased risk of fracture, although associated poor lifestyle factors and comorbid conditions increase the difficulty of interpreting results (Gaddini et al, 2016).

Caffeine

The relationship of consumption of caffeine to osteoporosis has not been clearly established. Whereas coffee intake was associated with a modestly increased risk of bone fracture in women, the opposite was true for men, where higher coffee intake was associated with a decreased risk in a meta-analysis of nine cohort and six case-control studies (Lee et al, 2014). However, a systematic review concluded that up to 400 mg/day of caffeine in healthy adults is not associated with adverse health effects, including bone (Wikoff et al, 2017). Interpretation of the caffeine content of coffee or other beverages is difficult because of variation due to brewing, portion size, and other beverage additions.

Dietary Fiber

Fiber includes a variety of different compounds, and so intake of “fiber” as a category can produce different effects on bone. Prebiotics are a form of fiber that has beneficial effects on calcium absorption and may have beneficial effects on bone health in humans (Wallace et al, 2017). The bioavailability of calcium in plant foods high in oxalates or phytates may be low. The overall impact on BMD, osteoporosis, and fracture risk has not been well studied.

Soy and Isoflavones

Epidemiologic studies have reported the prevalence of hip fracture to be lower in older Asian women who have a diet high in soy and isoflavones compared with older Caucasian women. Human studies have been inconclusive concerning the role of isoflavones on bone health, possibly because of differing study designs, doses, lengths of study, differences in participants, and other dietary or exercise components (Zheng et al, 2016). Soy protein has not been shown to be more beneficial to bone health than other protein sources (Shams-White et al, 2018).

High Acid or Alkaline Diets

Higher acid diets include those high in protein, dairy, and grains. It is theorized that these higher acid diets might increase calcium excretion and have a detrimental effect on bone. The theory also supports a converse beneficial effect of an alkaline diet (high in fruits and vegetables) on bone. Several meta-analyses, experimental studies, observational studies, and reviews have not supported either the negative effect of higher acid diets on bone or the positive effects of an alkaline diet on bone. Higher protein intake may, in fact, have a positive effect on bone (Cuenca-Sánchez et al, 2015; Hanley and Whiting, 2013; Remer et al, 2014).

Sodium

In a recent meta-analysis study, a high-sodium diet was found to increase osteoporosis risk (Fatahi et al, 2018). This association may be attributable to increased calcium excretion (Fatahi et al, 2018). Although the calciuric effect of sodium has been speculated, there seem to be no adverse effects with adequate calcium and vitamin D intake (Ilich et al, 2010). On the opposite end of the spectrum, because sodium is found abundantly in bone, hyponatremia, or low serum sodium, may increase an older adult's osteoporosis risk (Hannon and Verbalis, 2014).

Vegetarian Diets

Research has shown lower BMD among vegetarians compared with omnivores; however, the potential impact on osteoporosis risk is relatively small (Ho-Pham et al, 2009). Vegans and some vegetarians may consume less protein, vitamin D, vitamin B₁₂, and calcium compared with omnivores, thus increasing osteoporosis risk; however, vegan and vegetarian diets also typically include higher levels of other nutrients that may have positive effects on bone (Tucker, 2014). A study done in children concluded that a well-planned vegetarian diet that included dairy and egg intake did not lead to significantly lower bone mass and found some evidence that the lacto-ovo-vegetarian diet was protective against bone abnormalities (Ambroszkiewicz et al, 2018).

Prevention of Osteoporosis and Fractures

The increasing longevity of the population emphasizes the need for prevention of osteoporosis. Universal guidelines apply to everyone. Consuming adequate amounts of calcium and vitamin D, lifelong muscle strengthening and weight-bearing exercise, avoidance of tobacco, moderate or no intake of alcohol, and steps to avoid falls are all part of the holistic approach to a lifestyle that promotes bone health (North American Menopause Society [NAMS], 2010).

Exercise

To preserve bone health through adulthood, the American College of Sports Medicine recommends weight-bearing aerobic activity with high bone-loading force (such as intensive walking, jogging, or ascending/descending stairs) three to five times per week, resistance training two to three times per week, and balance exercises (Chodzko-Zajko et al, 2009; Garber et al, 2011). Regular walking and swimming appear to have minor benefits on BMD in older individuals (Beck et al, 2017).

Diet

The NOF recommends universal guidelines for all adults for the prevention of osteoporosis that includes adequate calcium and vitamin D, and a balanced diet of low-fat dairy, fish, fruits, and vegetables. Although the NOF recommends the same amount of calcium intake as the IOM, the NOF recommends higher amounts of vitamin D than the IOM for those 50 years and older (800 to 1000 IU/day). If these intake goals are not reached by food, supplements should be considered. In addition, achieving and maintaining a healthy weight and consuming a lower sodium diet is recommended for optimal bone health for women.

TREATMENT OF OSTEOPOROSIS

Medical Nutrition Therapy

Calcium (1000 to 1200 mg/day) and vitamin D₃ (800 IU/day) are typically recommended for patients being treated with one of the bone drugs, either antiresorptive or anabolic; ideally patients should achieve these nutrients levels from dietary sources, but if necessary, supplemental forms can be used (Gallagher, 2013; Rizzoli et al, 2014). These amounts are considered both safe and sufficient for bone formation.

Because of the range of nutrients involved in bone health, a healthy diet emphasizing the key nutrients seems most promising in achieving an intake for optimal bone health (Higgs et al, 2017). The registered dietitian nutritionist should evaluate the client's diet for all bone-related nutrients and tailor recommendations based on personal preferences, cultural differences, nutrient recommendations, need for supplements, and strategies that enhance quality of life (Dorner et al, 2018).

Exercise

For those with osteoporosis, recommendations include daily balance exercises, weight-bearing aerobic exercise 5 or more days a week, resistance training 2 or more days a week, and limiting twisting or other activities leading to poor alignment of the spine (Giangregorio et al, 2015). It is important to note that each client's situation with osteoporosis is unique and, therefore, should be evaluated by a health professional to determine appropriate exercises based on the client's specific medical history (Giangregorio et al, 2015).

FDA-Approved Drugs for Prevention and Treatment of Osteoporosis

Most medications approved for the prevention of osteoporosis when BMD is low or there is a high risk of fracture are also approved for the treatment of osteoporosis. These include bisphosphonates (alendronate, risedronate, ibandronate, zoledronic acid), peptide hormones (teriparatide and calcitonin), estrogen (in the form of menopausal hormone therapy), estrogen agonists or selective estrogen receptor modulators (SERMs), and a biologic agent (denosumab). However, because of potential side effects, nonestrogen treatment is recommended, especially if menopausal symptom relief is not a goal.

The **bisphosphonates** act as antiresorbers on osteoclasts to reduce their bone-degradative activities. They act by inhibiting osteoclast-mediated bone resorption. Possible side effects include gastrointestinal problems and rare cases of jaw necrosis. Teriparatide is a form of PTH that works by increasing osteoblast number and function. Calcitonin is used to inhibit osteoclastic bone resorption by blocking the stimulatory effects of PTH on these cells. Calcitonin can be administered by nasal spray. It improves BMD, especially of the lumbar spine, and it may reduce the recurrence of fractures in patients with osteoporosis. **Estrogen agonists**

or antagonists used to be referred to as **selective estrogen receptor modulators (SERMs)** are able to stimulate **estrogen receptors (ER)** in bone tissue and yet have very little effect on the ERs of the breast or uterus. Two examples of these drugs are tamoxifen and raloxifene. The most common side effect is hot flashes. The biologic agent denosumab works by preventing the formation of osteoclasts. Possible side effects include joint and muscle pain.

For those with osteoporosis (men and women), often a bisphosphonate or denosumab (women) is prescribed. Because long-term effects are not clear, treatment is suggested for 5 years rather than lifelong. Patient preferences, risk of falling, other comorbidities, and the costs and benefits of medication should be discussed between client and physician to develop individualized care (Qaseem et al, 2017).

INTEGRATIVE APPROACHES

The most common integrative interventions for bone health include an anti-inflammatory diet, calcium and bone supportive micronutrients such as boron, magnesium and vitamin K and nutritive herbs such as nettle (*Urtica dioica*). Inflammation is a risk factor in many chronic diseases, including osteoporosis. Diet has been shown to be a contributing factor in inflammation and may accelerate bone loss, especially in women (Veronese et al, 2017) (See Chapter 7 and Appendix 22). Dietary supplements containing calcium and other bone support nutrients (covered in this chapter) are a common integrative intervention. For more information about safely recommending dietary supplements, see Chapter 11. Nettle is an anti-inflammatory herb and is a rich source of calcium, about 1400 mg per 100 grams dried herb or 430 mg cooked fresh herb (Suliburska, 2012) (Bauman, 2018). Because this plant contains tiny stinging hairs under the leaves, they must be thoroughly macerated, dried or cooked before eating. Nettles are commonly made into an infusion (¼ cup dried herb to 1 quart of cold water, soaked overnight) or used in soups, casseroles, homemade pesto and egg dishes. The Natural Medicines Database lists potential side effects as diarrhea and skin rash, however this is rare as most of the negative side effects are due to consuming fresh nettles with the stinging hairs in tact. Nettles are not recommended in pregnancy or lactation (Natural Medicines Database, 2019).

CLINICAL CASE STUDY

Grace, a 70-year-old white woman of Northern European ancestry, developed lactose intolerance during her early 50s when she had a serious gastrointestinal infection. She currently is retired, lives alone, and stays indoors most of each day watching television. Approximately 3 years ago at age 67, she had dual-energy x-ray absorptiometry (DEXA) measurements that showed that she had low bone mineral density (BMD) values of her proximal femur and lumbar vertebrae (both values were classified as osteoporotic). Her height and weight at the time were 5'5" and 120 pounds. Her FRAX assessment was a 9.7% of fracture in the next 10 years. Her physician recommended that she start taking supplements of calcium (1000 mg/day) and vitamin D (800 units/day) because of her lactose intolerance and her lack of consumption of all dairy products. Because of the fragility of her bones, her exercise should focus on posture, balance, gait, coordination, and hip and trunk stabilization.

Grace took the supplements regularly for a year when a second set of DEXA measurements revealed that she had practically maintained her BMD values of 1 year earlier, with only a small decline in BMD. However, her continuing low measurements concerned her physician, and he ordered laboratory tests of calcium-regulatory hormones to see if she had any hormonal complications. These tests showed that her parathyroid hormone and 25-hydroxy vitamin D concentrations fell in the upper half of the normal range for each variable. Other routine measurements such as serum calcium and phosphate were normal. After discussion of her high risk of an osteoporotic fracture, her physician decided to place Grace on a bisphosphonate drug in addition to calcium and vitamin D.

After 1 year on the new therapy and continuation of the calcium and vitamin D, her BMD values (her third set of DEXA measurements) actually increased a few percentage points, even though they remained within the classification of osteoporosis. She and her physician decided to continue this for another 4 years before reevaluating her condition.

Nutrition Diagnostic Statement

- Inadequate calcium and vitamin D intake related to avoidance of dairy products as evidenced by diet history revealing less than 20% of estimated requirements.

Nutrition Care Questions

1. How would you classify Grace's calcium intake at the initial visit with her physician (who did not take a diet history or estimate her calcium intake)? Her vitamin D intake? Her exposure to sunlight?
2. What would you have recommended to improve her calcium intake from foods so that she could reduce her supplemental calcium to 500 mg/day? Why would you recommend foods to provide calcium rather than supplements? Could you make similar recommendations for improving her intake of vitamin D from foods?
3. Design a set (3 days minimum) of daily menus that provide approximately 800 mg of calcium from foods alone, which, coupled with a 500-mg supplement, would provide a total of 1300 mg, the current adequate intake for calcium. Similarly, design these same meals to include 400 units of vitamin D, with another 400 units coming from supplements.

Diet and nutrition play key roles in tooth development, integrity of the **gingiva** (gums) and mucosa, bone strength, and the prevention and management of diseases of the oral cavity. Diet has a local effect on tooth integrity; the type, form, and frequency of foods and beverages consumed have a direct effect on the oral pH and microbial activity, which may promote dental decay. Nutrition systemically affects the development, maintenance, and repair of teeth and oral tissues.

Nutrition and diet affect the oral cavity, but the reverse is also true: that is, the status of the oral cavity may affect one's ability to consume an adequate diet and achieve nutritional balance. Indeed, there is a lifelong synergy between nutrition and the integrity of the oral cavity in health and disease related to the known roles of diet and nutrients in the growth, development, and maintenance of the oral cavity structure, bones, and tissues (Touger-Decker and Mobley, 2013).

NUTRITION FOR TOOTH DEVELOPMENT

Primary tooth development begins at 2 to 3 months' gestation. Mineralization begins at approximately 4 months' gestation and continues through the preteen years. Therefore maternal nutrition must supply the preeruptive teeth with the appropriate building materials. Inadequate maternal nutrition consequently affects tooth development.

Teeth are formed by the mineralization of a protein matrix. In **dentin**, protein is present as collagen, which depends on vitamin C for normal synthesis. Vitamin D is essential to the process by which calcium and phosphorus are deposited in crystals of **hydroxyapatite**, a naturally occurring form of calcium and phosphorus that is the mineral component of **enamel** and dentin. Fluoride added to the hydroxyapatite

provides unique caries-resistant properties to teeth in prenatal and post-natal developmental periods.

Diet and nutrition are important in all phases of tooth development, eruption, and maintenance (Fig. 24.1). Posteruption diet and nutrient intake continue to affect tooth development and mineralization, enamel development and strength, and eruption patterns of the remaining teeth. The local effects of diet, particularly **fermentable carbohydrates** and eating frequency, affect the production of organic acids by oral bacteria and the rate of tooth decay as described later in this chapter.

DENTAL CARIES

Dental caries (described below) remains the most common chronic disease in both children and adults despite the fact that it is preventable (National Institute of Dental and Craniofacial Research website). Unfortunately, differences are evident in caries prevalence; approximately 20% to 25% of U.S. children have 80% of the dental caries. Trends in dental caries have demonstrated that children who come from homes in which parents have a college education have fewer caries than children from homes in which parents have less than a college education (Centers for Disease Control and Prevention [CDC], 2017). These differences, or health disparities, may happen as a result of lack of access to care, cost of care not reimbursed by third-party payers (e.g., insurance, Medicaid), lack of knowledge of preventive dental care, or a combination of factors. The CDC cites the percent of U.S. children aged 5 to 19 with untreated dental caries between 2011 and 2014 was 18.6%. The percent of U.S. adults aged 20 to 44 during that same time frame was 31.6%.

Pathophysiology

Dental caries is an oral infectious disease in which organic acid metabolites lead to gradual **demineralization** of tooth enamel, followed

Portions of this chapter were written by Diane Rigassio Radler, PhD, RDN.

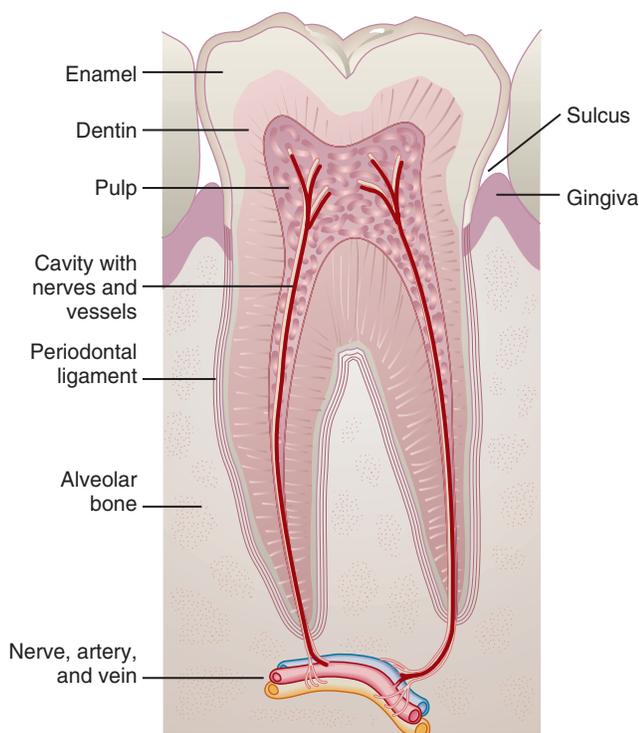

Fig. 24.1 Anatomy of a tooth.

by rapid proteolytic destruction of the tooth structure. Caries can occur on any tooth surface. The cause of dental caries involves many factors. Four factors must be present simultaneously: (1) a susceptible host or tooth surface; (2) microorganisms such as *Streptococcus* or *Lactobacillus* in the dental plaque or oral cavity; (3) fermentable carbohydrates in the diet, which serve as the substrate for bacteria; and (4) time (duration) in the mouth for bacteria to metabolize the fermentable carbohydrates, produce acids, and cause a drop in salivary pH to less than 5.5. Once the pH is acidic, which can occur within minutes, oral bacteria can initiate the demineralization process. Fig. 24.2 shows the formation of dental caries.

Susceptible Tooth

The development of dental caries requires the presence of a tooth that is vulnerable to attack. The composition of enamel and dentin, the location of teeth, the quality and quantity of saliva, and the presence and extent of pits and fissures in the tooth crown are some of the factors that govern susceptibility. Alkaline saliva has a protective effect and acidic saliva increases susceptibility to decay.

The Oral Microbiome

The microbiome plays an important role in our health and well-being. The oral cavity represents one of the most diverse microbial communities in the human body made up of at least 700 species (Duran-Pinedo and Frias-Lopez, 2015). Microorganisms from the oral cavity are the etiologic agents for a number of infectious diseases, including dental caries, periodontal disease, alveolar osteitis (also known as dry socket that occurs after a tooth is extracted), and tonsillitis. Several studies have linked oral diseases to systemic and chronic diseases including cardiovascular disease, preterm birth, diabetes, pneumonia, and even cancer (Whitmore and Lamont, 2014). The big question in this relationship is whether the changes in the oral microbiota are the cause or the consequence of the pathologic process.

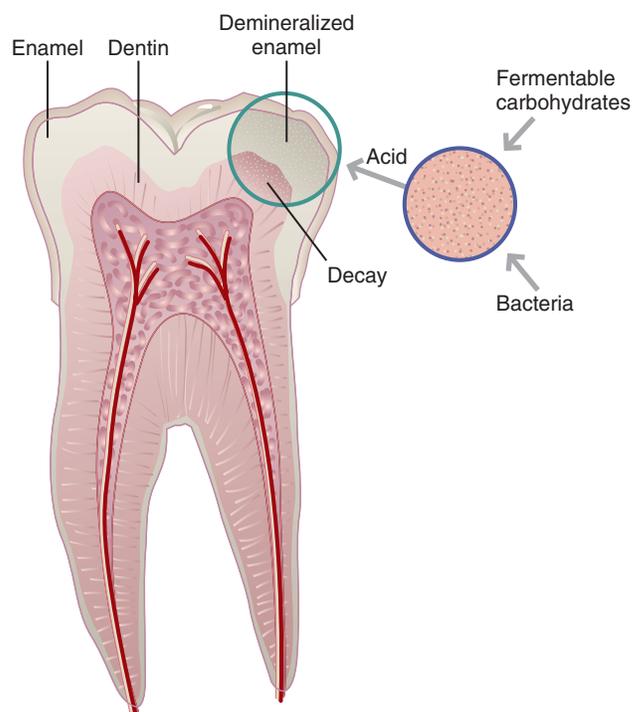

Fig. 24.2 Formation of dental caries.

A number of acid-producing species of bacteria have been associated with dental caries. *Streptococcus mutans* is the most prevalent, followed by *Lactobacillus casei* and *Streptococcus sanguis*. *Bifidobacterium*, *Propionibacterium*, and *Scardovia* have also been associated with caries. In juxtaposition, some bacteria help maintain homeostasis through ammonia production from arginine and urea. For example, *Streptococcus salivarius*, one of the major alkali producers in the mouth, expresses the urease gene under acidic pH and in the presence of excessive carbohydrates (Duran-Pinedo and Frias-Lopez, 2015). Genetic variations of the type and quantity of bacteria present in the oral cavity contribute to an individual's increased risk for caries and periodontal disease, but the quantity and quality of oral hygiene contributes directly to the risk of oral infectious disease.

Substrate

Fermentable carbohydrates, those carbohydrates susceptible to the actions of salivary amylase, are the ideal substrate for bacterial metabolism. The acids produced by their metabolism cause a drop in salivary pH to less than 5.5, creating the environment for decay. Bacteria are always present and begin to reduce pH when they have exposure to fermentable carbohydrates.

Because the Dietary Guidelines for Americans and the MyPlate Food Guidance system support a diet high in carbohydrates, it is important to be aware of the cariogenicity of foods. **Cariogenicity** refers to the caries-promoting properties of a diet or food. The cariogenicity of a food varies, depending on the form in which it occurs, its nutrient composition, when it is eaten in relation to other foods and fluids, the duration of its exposure to the tooth, and the frequency with which it is eaten (Box 24.1). Individuals should be aware of the form of food consumed and the frequency of intake to integrate positive diet and oral hygiene habits to reduce risk of oral disease.

Fermentable carbohydrates are found in three of the five MyPlate food groups: (1) grains, (2) fruits, and (3) dairy. Although some vegetables may contain fermentable carbohydrates, little has been

BOX 24.1 Factors Affecting Cariogenicity of Foods

Frequency of consumption
 Food form (liquid or solid, slowly dissolving)
 Sequence of eating certain foods and beverages
 Combination of foods
 Nutrient composition of foods and beverages
 Duration of exposure of teeth

reported about the cariogenicity, or caries-promoting properties, of vegetables. Examples of grains and starches that are cariogenic by nature of their fermentable carbohydrate composition include crackers, chips, pretzels, hot and cold cereals, and breads.

All fruits (fresh, dried, and canned) and fruit juices may be cariogenic. Fruits with high water content, such as melons, have a lower cariogenicity than others, such as bananas and dried fruits. Fruit drinks, sodas, ice teas, and other sugar-sweetened beverages; desserts; cookies; candies; and cake products may be cariogenic. Dairy products sweetened with fructose, sucrose, or other sugars can also be cariogenic because of the added sugars; however, dairy products are rich in calcium, and their alkaline nature may have a positive influence, reducing the cariogenic potential of the food.

Like other sugars (glucose, fructose, maltose, and lactose), sucrose stimulates bacterial activity. The causal relationship between sucrose and dental caries has been established (Moynihan and Kelly, 2014). All dietary forms of sugar, including honey, molasses, brown sugar, agave, and corn syrup solids, have cariogenic potential and can be used by bacteria to produce acids that erode enamel.

Caries Promotion by Individual Foods

It is important to differentiate between cariogenic, cariostatic, and anticariogenic foods. **Cariogenic** foods are those that contain fermentable carbohydrates, which, when in contact with microorganisms in the mouth, can cause a drop in salivary pH to 5.5 or less and stimulate the caries process.

Cariostatic foods do not contribute to decay, are not metabolized by microorganisms, and do not cause a drop in salivary pH to 5.5 or less within 30 minutes. Examples of cariostatic foods are protein foods such as eggs, fish, meat, and poultry; most vegetables; fats; and sugarless gums. According to the American Dental Association (ADA) (ADA, 2014), sugarless gum may help to reduce decay potential because of its ability to increase saliva flow and because it uses noncarbohydrate sweeteners.

Anticariogenic foods are those that, when eaten before an acidogenic food, prevent plaque from recognizing the acidogenic food. Examples are aged cheddar, Monterey Jack, and Swiss because of the casein, calcium, and phosphate in the cheese. The five-carbon sugar alcohol, **xylitol**, is considered anticariogenic because bacteria cannot metabolize five-carbon sugars in the same way as six-carbon sugars such as glucose, sucrose, and fructose. It is not broken down by salivary amylase and is not subject to bacterial degradation. Salivary stimulation leads to increased buffering activity of the saliva and subsequent increased clearance of fermentable carbohydrates from tooth surfaces. Another anticariogenic mechanism of xylitol gum is that it replaces fermentable carbohydrates in the diet. *S. mutans* cannot metabolize xylitol and is inhibited by it. The antimicrobial activity against *S. mutans* and the effect of gum chewing on salivary stimulation are protective. Consumers should be advised to look for chewing gum in which xylitol is listed as the first ingredient.

Remineralization is mineral restoration of the hydroxyapatite in dental enamel. Casein phosphopeptide-amorphous calcium phosphate (CPP-ACP) is a substance that promotes remineralization of enamel surfaces (Cochrane et al, 2012). It is currently available as an ingredient trademarked as Recaldent (Cadbury Enterprises, Australia) in some brands of chewing gum. A randomized prospective study on its efficacy in a specific population with early caries showed no effect (Beerens et al, 2017).

Factors Affecting Cariogenicity of Food

Cariogenicity also is influenced by the volume and quality of saliva; the sequence, consistency, and nutrient composition of the foods eaten; dental plaque buildup; and the genetic predisposition of the host to decay.

Form and Consistency

The form and consistency of a food have a significant effect on its cariogenic potential and pH-reducing or buffering capacity. Food form determines the duration of exposure or retention time of a food in the mouth, which, in turn, affects how long the decrease in pH or the acid-producing activity will last. Liquids are rapidly cleared from the mouth and have low adherence (or retentiveness) capabilities. Solid foods such as crackers, chips, pretzels, dry cereals, and cookies can stick between the teeth (referred to as the *interproximal spaces*) and have high adherence (or retention) capability.

Consistency also affects adherence. Chewy foods such as gum drops and marshmallows, although high in sugar content, stimulate saliva production and have a lower adherence potential than solid, sticky foods such as pretzels, bagels, or bananas. High-fiber foods with few or no fermentable carbohydrates, such as popcorn and raw vegetables, are cariostatic.

Exposure

The duration of exposure may be best explained with starchy foods, which are fermentable carbohydrates subject to the action of salivary amylase. The longer starches are retained in the mouth, the greater their cariogenicity. Given sufficient time, such as when food particles become lodged between the teeth, salivary amylase makes additional substrate available as it hydrolyzes starch to simple sugars. Processing techniques, either by partial hydrolysis or by reducing particle size, make some starches rapidly fermentable by increasing their availability for enzyme action.

Sugar-containing candies rapidly increase the amount of sugar available in the oral cavity to be hydrolyzed by bacteria. Sucking on hard candies such as lollipops or sugared breath mints results in prolonged sugar exposure in the mouth. Simple carbohydrate-based snacks and dessert foods (e.g., potato chips, pretzels, cookies, cakes, and doughnuts) provide gradually increasing oral sugar concentrations for a longer duration because these foods often adhere to the tooth surfaces and are retained for longer periods than candies. In school-age children, more frequent snacking on carbohydrate-containing foods was associated with greater incidence of dental caries (Garcia et al, 2017).

Nutrient Composition

Nutrient composition contributes to the ability of a substrate to produce acid and to the duration of acid exposure. Dairy products, by virtue of their calcium- and phosphorus-buffering potential, are considered to have low cariogenic potential. Evidence suggests that cheese and milk, when consumed with cariogenic foods, help to buffer the acid pH produced by the cariogenic foods. Because of the anticariogenic properties of cheese, eating cheese with a fermentable

TABLE 24.1 Nutrition Messages Related to Oral Health for 3- to 10-Year-Old Children and Their Caregivers

Message	Rationale
Eat starchy, sticky, or sugary foods with nonsugary foods.	The pH will rise if a nonsugary item that stimulates saliva is eaten immediately before, during, or after a challenge.
Combine dairy products with a meal or snack.	Dairy products (nonfat milk, yogurt) enhance remineralization and contain calcium.
Combine fibrous foods such as fresh fruits and vegetables with fermentable carbohydrates.	Fibrous foods induce saliva production and buffering capacity.
Space eating occasions at least 2 hours apart and limit snack time to 15-30 minutes.	Fermentable carbohydrates eaten sequentially one after another promote demineralization.
Limit bedtime snacks.	Saliva production declines during sleep.
Limit consumption of acidic foods such as sports drinks, juices, and sodas.	Acidic foods promote tooth erosion that increases risk for caries.
Combine proteins with carbohydrates in snacks. Examples: tuna and crackers, apples and cheese	Proteins act as buffers and are cariostatic.
Combine raw and cooked or processed foods in a snack.	Raw foods encourage mastication and saliva production, whereas cooked or processed foods may be more available for bacterial metabolism if eaten alone.
Encourage use of xylitol- or sorbitol-based chewing gum and candies immediately after a meal or snack.*	Five minutes of exposure is effective in increasing saliva production and dental plaque pH.
Recommend sugar-free chewable vitamin and mineral supplements and syrup-based medication.	Sugar-free varieties are available and should be suggested for high caries risk groups.
Encourage children with pediatric GERD to adhere to dietary guidelines.	GERD increases risk for dental erosion and thus increases risk for caries.

*Gum is not recommended for children younger than 6 years old.

GERD, Gastroesophageal reflux disease.

Modified from Mobley C: Frequent dietary intake and oral health in children 3 to 10 years of age, *Building Blocks* 25:17, 2001.

carbohydrate, such as dessert at the end of a meal, may decrease the cariogenicity of the meal and dessert (Ravishankar et al, 2012).

Nuts, which do not contain a significant amount of fermentable carbohydrates and are high in fat and dietary fiber, are cariostatic. Protein foods such as seafood, meats, eggs, and poultry, along with other fats such as oils, margarine, butter, and seeds, are also cariostatic.

Sequence and Frequency of Eating

Eating sequence and combination of foods also affect the caries potential of the substrate. Bananas, which are cariogenic because of their fermentable carbohydrate content and adherence capability, have less potential to contribute to decay when eaten with cereal and milk than when eaten alone as a snack. Milk, as a liquid, reduces the adherence capability of the fruit. Crackers eaten with cheese are less cariogenic than when eaten alone.

The frequency with which a cariogenic food or beverage is consumed determines the number of opportunities for acid production. Every time a fermentable carbohydrate is consumed, a decline in pH is initiated within 5 to 15 minutes, causing caries-promoting activity. Small, frequent meals and snacks, often high in fermentable carbohydrate, increase the cariogenicity of a diet more than a diet consisting of three meals and minimal snacks. Eating several cookies at once, followed by brushing the teeth or rinsing the mouth with water, is less cariogenic than eating a cookie several times throughout a day. Table 24.1 lists messages that can be given to children to reduce the risk of developing dental caries.

The Decay Process

The carious process begins with the production of acids as a byproduct of bacterial metabolism taking place in the dental plaque. Decalcification

of the surface enamel continues until the buffering action of the saliva is able to raise the pH above the critical level. See Box 24.2 for prevention guidelines and the Practice Paper of the Academy of Nutrition and Dietetics on Oral Health and Nutrition (Mallonee et al, 2014).

Plaque is a sticky, colorless mass of microorganisms and polysaccharides that forms around the tooth and adheres to teeth and gums. It harbors acid-forming bacteria and keeps the organic products of their metabolism in close contact with the enamel surface. As a cavity develops, the plaque blocks the tooth, to some extent, from the buffering and remineralization action of the saliva. In time the plaque combines with calcium and hardens to form **calculus**.

An acidic pH is also required for plaque formation. Soft drinks (diet and regular), sports beverages, citrus juices and “ades” (such as Gatorade and Powerade, etc.), and chewable vitamin C supplements have high acid content and may contribute to erosion (Tedesco et al, 2012). Research using National Health and Nutrition Examination Survey III data reported significantly more dental caries in children

BOX 24.2 Caries Prevention Guidelines

- Brush at least twice daily, preferably after meals.
- Rinse mouth after meals and snacks.
- Chew sugarless gum for 15-20 min after meals and snacks.
- Floss twice daily.
- Use fluoridated toothpastes.
- Pair cariogenic foods with cariostatic foods.
- Snack on cariostatic and anticariogenic foods such as cheese, nuts, popcorn, and vegetables.
- Limit between-meal eating and drinking of fermentable carbohydrates.

(ages 2 to 10 years) who consumed large amounts of carbonated soft drinks or juices compared with children who had high consumption of water or milk (Sohn et al, 2006). Other beverages and foods contribute to **dental erosion**, a loss of minerals from tooth surfaces by a chemical process in the presence of acid (Garcia et al, 2017). The current popular practice of drinking fruited water is a hazard to dental enamel. Fruited waters like water with lemon or other citrus added have been shown to have pH levels as low as 3. Regular tap water has a pH of 6 to 8.

Roles of Saliva

Salivary flow clears food from around the teeth as a means to reduce the risk of caries. The bicarbonate-carbonic acid system, calcium, and phosphorus in saliva also provide buffering action to neutralize bacterial acid metabolism. Once buffering action has restored pH above the critical point, remineralization can occur. If fluoride is present in the saliva, the minerals are deposited in the form of **fluoroapatite**, which is resistant to erosion. Salivary production decreases as a result of diseases affecting salivary gland function (e.g., Sjögren's syndrome); as a side effect of fasting; as a result of radiation therapy to the head and neck involving the parotid gland; normally during sleep and aging; with the use of medications associated with reduced salivary flow; or with **xerostomia**, dry mouth caused by inadequate saliva production. An estimated 400 to 500 medications currently available by prescription or over the counter may cause dry mouth. The degree of xerostomia may vary but may be caused by medications such as those to treat depression, hypertension, anxiety, human immunodeficiency virus (HIV), and allergies.

Caries Patterns

Caries patterns describe the location and surfaces of the teeth affected. **Coronal caries** affects the crown of the tooth, the part of the tooth visible above the gum line, and may occur on any tooth surface. Although the overall incidence of decay in the United States has declined, many states report 40% to 70% of children having some decay by age 8 (CDC, 2017).

Root caries, occurring on the root surfaces of teeth secondary to gingival recession, affects a large portion of the older population. Root caries is a dental infection that is increasing in older adults, partly because this population is retaining their natural teeth longer. The gums recede in older age, exposing the root surface. Other factors related to the increased incidence of this decay pattern are lack of fluoridated water, poor oral hygiene practices, decreased saliva, frequent eating of fermentable carbohydrates. Dementia appears to increase risk of dental caries, which is likely related to a decline in self-care and motor skills (Brennan and Strauss, 2014). Management of root caries includes dental restoration and nutrition counseling. Poor oral health from caries, pain, or edentulism often adversely affects dietary intake and nutritional status in older adults. (See Chapter 19.)

Lingual caries, or caries on the lingual side (surface next to or toward the tongue) of the anterior teeth, is seen in persons with gastrointestinal reflux, bulimia, or anorexia-bulimia (see Chapter 21). Frequent intake of fermentable carbohydrates, combined with regurgitation or induced vomiting of acidic stomach contents, results in a constant influx of acid into the oral cavity. The acid contributes to erosion of tooth surfaces that can result in tooth sensitivity and dental caries. The pattern of erosion may be indicative of erosion from reflux versus from foods or beverages (Schlueter et al, 2012).

Fluoride

Fluoride is an important element in bones and teeth (Palmer and Gilbert, 2012). Used systemically and locally, it is a safe, effective public

health measure to reduce the incidence and prevalence of dental caries (ADA, 2014; CDC, 2017). Water fluoridation began in 1940; by 1999 the CDC listed water fluoridation as one of the top 10 greatest public health achievements of the 20th century because of its influence on decreasing the rate of dental caries (CDC, 2017). The effect of fluoride on caries prevention continues with water fluoridation, fluoridated toothpastes, oral rinses, and dentifrices, as well as beverages made with fluoridated water. Optimal water fluoridation concentrations (0.7 to 1.2 ppm) can provide protection against caries development without causing tooth staining (ADA, 2014). Despite the positions from the ADA and the Academy of Nutrition and Dietetics (AND), and the data from the CDC on fluoride for oral health, there is a controversy over the use of topical fluoride on teeth and systemic fluoridation in water supplies. Arguments against widespread fluoride use include claims that it can be carcinogenic and toxic; however, consumers should be urged to read the evidence.

Mechanism of Action

There are four primary mechanisms of fluoride action on teeth: (1) when incorporated into enamel and dentin along with calcium and phosphorus, it forms fluoroapatite, a compound more resistant to acid challenge than hydroxyapatite; (2) it promotes repair and remineralization of tooth surfaces with early signs of decay (incipient carious lesions); (3) it helps to reverse the decay process while promoting the development of a tooth surface that has increased resistance to decay; and (4) helps to deter the harmful effects of bacteria in the oral cavity by interfering with the formation and function of microorganisms.

Food Sources

Most foods, unless prepared with fluoridated water, contain minimal amounts of fluoride, except for brewed tea, which has approximately 1.4 ppm (Morin, 2006). Fluoride may be added unintentionally to the diet in a number of ways, including through the use of fluoridated water in the processing of foods and beverages. Fruit juices and drinks, particularly white grape juice produced in cities with fluoridated water, may have increased fluoride content; however, because of the wide variation in fluoride content, it is difficult to estimate amounts consumed.

Supplementation

Health professionals should consider a child's fluid intake as well as food sources and the availability of fluoridated water in the community before prescribing fluoride supplements. Because bones are repositories of fluoride, bone meal, fish meal, and gelatin made from bones are potent sources of the mineral. In communities without fluoridated water, dietary fluoride supplements may be recommended for children ages 6 months to 16 years.

Fluoride can be used topically and systemically. When consumed in food and drink, it enters the systemic circulation and is deposited in bones and teeth. Systemic sources have a topical benefit as well by providing fluoride to the saliva. A small amount of fluoride enters the soft tissues; the remainder is excreted. The primary source of systemic fluoride is fluoridated water; food and beverages supply a smaller amount. Table 24.2 contains a schedule of fluoride supplementation.

Fluoride supplements are not recommended for formula-fed infants or for breastfed infants living in fluoridated communities if these infants receive drinking water between feedings. If the infant does not drink water between feedings or drinks bottled water when on a diet of only breastmilk, fluoride supplementation is recommended according to established guidelines. Fluoride supplements must be prescribed by the child's health care provider; they are not available as over-the-counter supplements (ADA, 2014).

TABLE 24.2 Dietary Fluoride Supplement Schedule

FLUORIDE ION LEVEL IN DRINKING WATER (ppm)*			
Age	<0.3 ppm	0.3-0.6 ppm	>0.6 ppm
Birth-6 mo	None	None	None
6 mo-3 yr	0.25 mg/day [†]	None	None
3-6 yr	0.50 mg/day	0.25 mg/day	None
6-16 yr	1.0 mg/day	0.50 mg/day	None

*1 ppm = 1 mg/L.

[†]2.2 mg of sodium fluoride contains 1 mg of fluoride ion.

Approved by The American Dental Association, The American Academy of Pediatrics, and The American Academy of Pediatric Dentistry, 1994.

Topical fluoride sources include toothpastes, gels, and rinses used by consumers daily, along with more concentrated forms applied by dental professionals in the form of gels, foams, and rinses. Frequent fluoride exposure via topical fluorides, fluoridated toothpastes, rinses, and fluoridated water is important in maintaining an optimal concentration of fluoride, but excess intake should be avoided.

Excess Fluoride

Fluorosis occurs when too much fluoride is provided during tooth development and can range from mild to severe and present on teeth from unnoticeable to very apparent dark spots on teeth. Causes of mild fluorosis from excessive fluoride intake include misuse of dietary fluoride supplements, ingestion of fluoridated toothpastes and rinses, or excessive fluoride intake secondary to fluoride in foods and beverages processed in fluoridated areas and transported to other areas. Topical fluorides, available as fluoridated toothpastes and mouthwashes, are effective sources of fluoride that can be used in the home, school, or dental office. Caries prevention efforts in preschool children include diet modification, water fluoridation, or supplements in nonfluoridated areas, and supervised tooth brushing with fluoridated toothpaste (ADA, 2014).

Children younger than 6 years of age should not use fluoridated mouthwashes, and older children should be instructed to rinse, but not swallow, mouthwash. No more than a pea-size amount of toothpaste should be placed on a child's toothbrush to reduce the risk of accidental fluoride. Fluoride is most effective when given from birth through ages 12 to 13, the period when mineralization of unerupted permanent teeth occurs.

EARLY CHILDHOOD CARIES

Early childhood caries (ECC), often called “baby-bottle tooth decay,” describes a caries pattern in the maxillary anterior teeth of infants and young children. Characteristics include rapidly developing carious lesions in the primary anterior teeth and the presence of lesions on tooth surfaces not usually associated with a high caries risk. Because tooth decay remains a common oral disease of childhood, caries is a primary marker for a child's oral health. Good behavioral habits and child nutrition patterns must be encouraged, beginning in infancy.

Pathophysiology and Incidence

Often ECC follows prolonged bottle-feeding, especially at night, of juice, milk, formula, or other sweetened beverages. The extended contact time with the fermentable carbohydrate-containing beverages, coupled with the position of the tongue against the nipple, which causes pooling of the liquid around the maxillary incisors, particularly

Fig. 24.3 Early childhood caries. (From Swartz MH: *Textbook of physical diagnosis, history, and examination*, ed 5, Philadelphia, 2006, Saunders.)

during sleep, contributes to the decay process. The mandibular anterior teeth usually are spared (Fig. 24.3) because of the protective position of the lip and tongue and the presence of a salivary duct in the floor of the mouth. In general, children from low-income families and minority populations experience the greatest amount of oral disease, the most extensive disease, and the most frequent use of dental services for pain relief; yet these children have the fewest overall dental visits (CDC, 2017).

Nutrition Care

Management of ECC includes diet and oral hygiene education for parents, guardians, and caregivers. Messages should be targeted to counter the health habits that contribute to this problem: poor oral hygiene, failure to brush a child's teeth at least daily, frequent use of bottles filled with sweetened beverages, and lack of fluoridated water. Dietary guidelines include removal of the bedtime bottle and modification of the frequency and content of the daytime bottles. Bottle contents should be limited to water, formula, or milk. Infants and young children should not be put to bed with a bottle. Teeth and gums should be cleaned with a gauze pad or washcloth after all bottle feedings. All efforts should be made to wean children from a bottle by 1 year of age. Educational efforts should be positive and simple, focusing on oral hygiene habits and promotion of a balanced, healthy diet. Between-meal snacks should include cariostatic foods. When foods are cariogenic, they should be followed by tooth brushing or rinsing the mouth. Parents and caregivers need to understand the causes and consequences of ECC and how they can be avoided.

CARIES PREVENTION

Caries prevention programs focus on a balanced diet, modification of the sources and quantities of fermentable carbohydrates, and the integration of oral hygiene practices into individual lifestyles. Meals and snacks should be followed with brushing, rinsing the mouth vigorously with water. Positive habits should be encouraged, including snacking on anticariogenic or cariostatic foods, chewing sugarless gum after eating or drinking cariogenic items, and having sweets with meals rather than as snacks. Despite the potential for a diet that is based on the dietary guidelines to be cariogenic, with proper planning and good oral hygiene a balanced diet low in cariogenic risk can be planned (see Fig. 24.4 for a sample diet).

Practices to avoid include sipping sugar-sweetened and low-pH beverages for extended periods. Adding lemon and other fruits to water has become a common practice but this lowers the pH and in general should be avoided. Frequent snacking and eating sugared breath mints or hard candies is discouraged. Over-the-counter chewable or liquid medications and vitamin preparations, such as chewable vitamin C or liquid cough syrup, may contain sugar and contribute to caries risk. Patients with dysphagia may use thickening agents in

Breakfast:	1½ cups toasted oat cereal + 1 cup low-fat milk or 2 slices wheat toast with 1 oz melted cheese 1 cup fresh berries coffee + low-fat milk BRUSH TEETH
Lunch:	2 slices of mushroom pizza small salad with 2 Tbs Italian dressing 16 oz spring water banana FOLLOW WITH 2 PIECES XYLITOL GUM
Afternoon snack:	1 cup pretzels + 1 oz cheese
Dinner:	tossed salad with 2 Tbs grated cheese 1½ cups spaghetti + 1 cup marinara sauce + ½ cup sauteed peppers 1 cup fresh fruit salad 1 slice Italian bread with 1 pat margarine ½ cup ice cream 1 cup low-fat milk
Snack:	4 cups popcorn BRUSH TEETH BEFORE BED

Fig. 24.4 A balanced diet plan with low cariogenic risk.

beverages or liquid foods (soups) to reduce the risk of aspiration. Good oral hygiene should be emphasized in these situations because the thickening agent may contain fermentable carbohydrate and can be sticky, and the type of dysphagia may contribute to inadequate clearing of food from the oral cavity.

Fermentable carbohydrates such as candy, crackers, cookies, pastries, pretzels, snack crackers, chips, and even fruits should be eaten with meals. Notably, “fat-free” snack and dessert items and “baked” chips and snack crackers tend to have a higher simple sugar concentration than their higher-fat-containing counterparts.

TOOTH LOSS AND DENTURES

Tooth loss (**edentulism**) and removable prostheses (dentures) can have a significant effect on dietary habits, masticatory function, olfaction, and nutritional adequacy. As dentition status declines, masticatory performance is compromised and may have a negative effect on food choices, resulting in decreased intake of meat, whole grains, fruits, and vegetables (Tsakos et al, 2010). This problem is more pronounced in older adults, whose appetite and intake may be compromised further by chronic disease, social isolation, and the use of multiple medications (see Chapter 19).

Dentures must be checked periodically by a dental professional for appropriate fit. Changes in body weight or changes in alveolar bone over time possibly may alter the fit of the dentures. This is a common problem in the elderly that interferes with eating. Counseling on appropriate food choices and textures is advocated.

Nutrition Care

Full dentures replace missing teeth but are not a perfect substitute for natural dentition. Before and after denture placement, many individuals may experience difficulty biting and chewing. The foods found to cause the greatest difficulty for persons with complete dentures include fresh whole fruits and vegetables (e.g., apples and carrots), hard-crust breads, and whole muscle meats. Therefore dietary assessment and counseling related to oral health should be provided to the denture wearer. Simple guidelines should be provided for cutting and preparing fruits and vegetables to minimize the need for biting and reduce the amount of chewing. The importance of positive eating habits must be stressed as a component of total health. Overall, guidelines that reinforce the importance of a balanced diet should be part of the routine counseling given to all patients.

OTHER ORAL DISORDERS

Oral diseases extend beyond dental caries. Deficiencies of several vitamins (riboflavin, folate, B₁₂, and C) and minerals (iron and zinc) may be detected first in the oral cavity because of the rapid tissue turnover of the oral mucosa. Periodontal disease is a local and systemic disease. Select nutrients play a role, including vitamins A, C, and E; folate; beta-carotene; and the minerals calcium, phosphorus, and zinc (see Chapter 5).

Oral cancer, often a result of tobacco and alcohol use, can have a significant effect on eating ability and nutritional status. This problem is compounded by the increased caloric and nutrient needs of persons with oral carcinomas. In addition, surgery, radiation therapy, and chemotherapy are modalities used to treat oral cancer that also can affect dietary intake, appetite, and the integrity of the oral cavity. Some but not all problems affecting the oral cavity are discussed here with relevant nutrition care. Patients may try over-the-counter natural products to prevent or treat oral disease or conditions (see *Clinical Insight: Natural Products in Oral Health*).

PERIODONTAL DISEASE

Pathophysiology

Periodontal disease is an inflammation of the gingiva with infection caused by oral bacteria and subsequent destruction of the tooth attachment apparatus. Untreated disease results in a gradual loss of tooth attachment to the bone. Progression is influenced by the overall health of the host and the integrity of the immune system. The primary causal factor in the development of periodontal disease is plaque. Plaque in the **gingival sulcus**, a shallow, V-shaped space around the tooth, produces toxins that destroy tissue and permit loosening of the teeth. Important factors in the defense of the gingiva to bacterial invasion are (1) oral hygiene, (2) integrity of the immune system, and (3) optimal nutrition. The defense mechanisms of the gingival tissue, epithelial barrier, and saliva are affected by nutritional intake and status. Healthy epithelial tissue prevents the penetration of bacterial endotoxins into subgingival tissue.

Nutritional Care

Deficiencies of vitamin C, folate, and zinc increase the permeability of the gingival barrier at the gingival sulcus, increasing susceptibility to periodontal disease. Severe deterioration of the gingiva is seen in individuals with scurvy or vitamin C deficiency. Vitamins A and E, beta-carotene, and protein have a role in maintaining gingival and immune system integrity, and there is now evidence that some antioxidants can mediate the inflammation associated with periodontal

CLINICAL INSIGHT**Natural Products in Oral Health**

Natural products include herbal and dietary supplements and probiotics (National Center for Complementary and Integrative Health [NCCIH], 2015). The following lists some herbal and dietary supplements that may be used to prevent or treat oral health issues. See Chapter 11 for more information about the efficacy and safety of natural products before choosing to use them in addition to or in place of conventional therapy.

Oral Use(s)	Natural Product	Use	Considerations
Mucositis	Hyaluronic acid	Topically (oral gel)	May cause allergic reaction in individuals sensitive to the daisy family.
	German chamomile	Oral rinse	
	Glutamine	Oral rinse	
	Iodine	Oral rinse (in chemotherapy treatment)	
	Kaolin	Oral rinse (in radiation treatment)	
	Aloe	Oral rinse	
Mucosal lesions	Slippery elm	Topically (lozenges)	Only the gel should be ingested. Avoid whole leaf and aloe latex.
Periodontal disease	Coenzyme Q ₁₀	Systemically	
	Xylitol	In chewing gum or in place of fermentable carbohydrate	

Natural Medicines Comprehensive Database (www.naturaldatabase.com).

disease (Najeeb et al, 2016). When periodontal disease causes pain and avoidance of foods, nutrient intake may be limited and should be monitored (Staudte et al, 2012). Modified food textures may be beneficial to minimize nutrient deficits. The roles of calcium and vitamin D relate to the link between osteoporosis and periodontal disease, in which bone loss may be the common denominator.

In societies in which malnutrition and periodontal disease are prevalent, poor oral hygiene is also usually evident. In such instances it is difficult to determine whether malnutrition is the cause of the disease or one of many contributing factors, including poor oral hygiene, heavy plaque buildup, insufficient saliva, or coexisting illness.

Management strategies for the patient or client with periodontal disease follow many of the same guidelines as for caries prevention listed in Box 24.2. Severe periodontal disease may be treated surgically. Diet adequacy is particularly important before and after periodontal surgery, when adequate nutrients are needed to regenerate tissue and support immunity to prevent infection. Adequacy of calories, protein, and micronutrients should be part of the postoperative care plan.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASE

Acute systemic diseases such as cancer and infections, as well as chronic diseases such as diabetes mellitus, autoimmune diseases, and chronic kidney disease, are characterized by oral manifestations that may alter the diet and nutritional status. Cancer therapies, including irradiation of the head and neck region, chemotherapy, and surgeries to the oral cavity, have a significant effect on the integrity of the oral cavity and on an individual's eating ability, which may consequently affect nutrition status (see Chapter 35).

If the condition of the mouth adversely affects one's food choices, the person with chronic disease may not be able to follow the optimal diet for medical nutrition therapy. For example, poorly controlled diabetes may manifest in xerostomia or candidiasis, which may then affect the ability to consume a diet to appropriately control blood sugar, further deteriorating glucose control.

In addition, many medications alter the integrity of the oral mucosa, taste sensation, or salivary production. Phenytoin (Dilantin) may cause severe gingivitis. Many of the protease inhibitor drugs used to treat HIV and acquired immune deficiency syndrome (AIDS) are associated with altered taste and dry mouth. Reduced saliva contributes to increased caries risk and also may alter the ability to form a bolus and swallow foods, especially dry foods that crumble with mastication. Care should be taken to assess the effects of medication on the oral cavity and minimize these effects using alterations in diet or drug therapy.

Diabetes Mellitus

Diabetes is associated with several oral diseases, many of which occur only in periods of poor glucose control. These include burning mouth syndrome, periodontal disease, candidiasis, dental caries, and xerostomia. The microangiopathic conditions seen in diabetes, along with altered responses to infection, contribute to risk of periodontal disease in affected persons. Tooth infection, more common in those with diabetes, leads to deterioration of diabetes control (Al-Khabbaz, 2014).

Fungal Infections

Oropharyngeal fungal infections may cause a burning, painful mouth and dysphagia. The ulcers that accompany viral infections such as herpes simplex and cytomegalovirus cause pain and can lead to reduced oral intake. Very hot and cold foods or beverages, spices, and sour or tart foods may cause pain and should be avoided. Consumption of temperate, moist foods without added spices should be encouraged. Small, frequent meals followed by rinsing with lukewarm water or brushing to reduce the risk of dental caries are helpful. Once the type and extent of oral manifestations are identified, a nutrition care plan can be developed. Oral high calorie–high protein supplements in liquid or pudding form may be needed to meet nutrient needs and optimize healing.

Head and Neck Cancers

Head, neck, and oral cancers can alter eating ability and nutrition status because of the surgeries and therapies used to treat these cancers.

TABLE 24.3 Effects of Oral Infections

Location	Problem	Effect	Diet Management
Oral cavity	Candidiasis, KS, herpes, stomatitis	Pain, infection, lesions, altered ability to eat, dysgeusia	Increase kilocalorie and protein intake; administer oral supplements; provide caries risk reduction education
	Xerostomia	Increased caries risk, pain, difficulty with mastication, lack of saliva to form bolus, tendency of food to stick, dysgeusia	Moist, soft, nonspicy foods; “smooth” cool or warm foods and fluids; caries risk reduction education
Esophagus	Candidiasis, herpes, KS, cryptosporidiosis	Dysphagia, odynophagia	Try oral supplementation first; if that is unsuccessful, initiate NG feedings using a silastic feeding tube or PEG
	CMV, with or without ulceration	Dysphagia, food accumulation	PEG

CMV, Cytomegalovirus; KS, Kaposi’s sarcoma; NG, nasogastric; PEG, percutaneous endoscopic gastrostomy.

Surgery, depending on the location and extent, may alter eating or swallowing ability, as well as the capacity to produce saliva. Radiation therapy of the head and neck area and chemotherapeutic agents can affect the quantity and quality of saliva and the integrity of the oral mucosa. Thick, ropy saliva is often the result of radiation therapy to the head and neck area, causing xerostomia. Dietary management focuses on the recommendations described earlier for xerostomia, along with modifications in food consistency after surgery (see Chapters 35 and 39).

HIV Infection and AIDS

Viral and fungal infections, stomatitis, xerostomia, periodontal disease, and Kaposi’s sarcoma are oral manifestations of HIV that can cause limitations in nutrient intake and result in weight loss and compromised nutrition status. These infections often are compounded by a compromised immune response, preexisting malnutrition, and gastrointestinal consequences of HIV infection (see Chapter 36). Viral diseases, including herpes simplex and cytomegalovirus, result in painful ulcerations of the mucosa.

Stomatitis, or inflammation of the oral mucosa, causes severe pain and ulceration of the gingiva, oral mucosa, and palate, which makes eating painful. **Candidiasis** on the tongue, palate, or esophagus can make chewing, sucking, and swallowing painful (odynophagia), thus compromising intake. Table 24.3 outlines the effects of associated oral infections.

Xerostomia

Xerostomia (dry mouth) is seen in poorly controlled diabetes mellitus, Sjögren’s syndrome, other autoimmune diseases, and as a consequence of radiation therapy and certain medications (Box 24.3). Xerostomia from radiation therapy may be more permanent than that from other causes. Radiation therapy procedures to spare the parotid gland should be implemented when possible to reduce the damage to the salivary gland. Efforts to stimulate saliva production using the medication pilocarpine and citrus-flavored, sugar-free candies may ease eating difficulty.

BOX 24.3 Medications that May Cause Xerostomia

Antianxiety agents	Diuretics
Anticonvulsants	Narcotics
Antidepressants	Sedatives
Antihistamines	Serotonin reuptake inhibitors
Antihypertensives	Tranquilizers

Individuals without any saliva at all have the most difficulty eating; artificial salivary agents may not offer sufficient relief. Lack of saliva impedes all aspects of eating, including chewing, forming a bolus, swallowing, and sensing taste; causes pain; and increases the risk of dental caries and infections. Dietary guidelines focus on the use of moist foods without added spices, increased fluid consumption with and between all meals and snacks, and judicious food choices.

Problems with chewy (steak), crumbly (cake, crackers, rice), dry (chips, crackers), and sticky (peanut butter) foods are common in persons with severe xerostomia. Alternatives should be suggested, or the foods should be avoided to avert dysphagia risk. Drinking water with a lemon or lime twist or citrus-flavored seltzers or sucking on frozen tart grapes, berries, or sugar-free candies may help. Because these foods or beverages may contain fermentable carbohydrate or contribute to reduced pH, good oral hygiene habits are important in reducing the risk of tooth decay and should be practiced after all meals and snacks.

CLINICAL CASE STUDY

Gina is a 74-year-old white woman with a history of type 2 diabetes, hypertension, and arthritis. She states that her dentist told her she has xerostomia and periodontal disease and will need multiple tooth extractions and a full maxillary (upper) and partial mandibular (lower) denture. Because of the condition of her teeth she consumes soft foods and lots of diet soda because her mouth always feels dry. She takes glyburide for glucose control, amlodipine (Norvasc) for blood pressure control, and glucosamine and chondroitin to alleviate her arthritis. She is 5’1” and weighs 176 lb. She lives alone but receives assistance with food shopping and cooking from her family and friends. She occasionally conducts self-monitoring fasting glucose via fingerstick and states that her usual reading is 150 mg/dL.

Nutrition Diagnostic Statements

- Chewing difficulty related to poor dentition and xerostomia as evidenced by patient report and choice of soft foods.
- Altered nutrition-related laboratory value (glucose) related to diabetes and high glycemic diet as evidenced by hyperglycemia and periodontal disease.

Nutrition Care Questions

1. What are the cultural, educational, socioeconomic, and environmental influences affecting dental and nutritional health?
2. What are the diet counseling recommendations for the dental conditions (anticipated extractions, dry mouth, full and partial dentures)?
3. List an appropriate intervention for each of the diagnostic statements. How would you evaluate the impact of your intervention?
4. What would you assess at your follow-up (monitoring) appointment with Gina?

Medical Nutrition Therapy

This section contains chapters that reflect the evolution of nutritional science, from the identification of nutrient requirements and the practical application of this knowledge, to the concepts that relate nutrition to the prevention of chronic and degenerative diseases and optimization of health. The role of nutrition in reducing inflammation, a major contributor to chronic disease, supports the awareness of diet in disease prevention and management.

Medical nutrition therapy (MNT) includes assessment, nutrition diagnosis, interventions, monitoring, and evaluation of disease. In some cases, MNT is a powerful preventive measure. The list of diseases amenable to nutrition intervention continues to increase, especially because many diseases and illnesses are now known to have a genetic component and a connection with the nutrient-gene expression pathway.

Sophisticated feeding and nourishment practices place an increased responsibility on those who provide nutrition care. The nutrition-related disorders included in this section can be managed by changes in dietary practices based on current knowledge. The goal of MNT is to move the individual from the continuum of disease toward better nutritional health and overall well-being.

Medical Nutrition Therapy for Adverse Reactions to Food: Allergies and Intolerances

L. Kathleen Mahan, MS, RDN, CD

Kathie Madonna Swift, MS, RDN, LDN, FAND

KEY TERMS

adverse reactions to food	epitope	lipid transfer protein syndrome (LTPS)
allergen	FAILSAFE diet	lymphocyte
allergen immunotherapy (AIT)	Food Allergen Labeling and Consumer Protection Act (FALCPA)	mast cells
anaphylaxis	food allergen-specific serum IgE testing	microbiome
antibodies	food allergy	non-IgE-mediated reactions
antigen	food and symptom record	oral allergy syndrome (OAS)
antigen-presenting cell (APC)	food autoimmune or immune reactivity	oral food challenge (OFC)
atopic dermatitis	food-dependent, exercise-induced anaphylaxis (FDEIA)	oral tolerance
“atopic march”	food intolerance	pollen-food allergy syndrome (PFAS)
atopy	food protein-induced enterocolitis syndrome (FPIES)	prebiotics
basophils	food protein-induced proctocolitis or proctitis (FPIP)	precautionary allergen labeling (PAL)
B-cells	food sensitivity	probiotics
B-regulatory (B-reg) cells	galactose- α -1, 3-galactose (alpha-gal)	sensitivity-related illness (SRI)
component resolved diagnostics (CRD)	granulocyte	sensitization
cow’s milk protein allergy (CMPA)	gut-associated lymphoid tissue (GALT)	six-food elimination diet (SFED)
cross-reactivity	histamine	skin-prick test (SPT)
cytokines	histamine-N-methyltransferase (HNMT)	step up 2-4-6-food elimination diets
diamine oxidase (DAO)	increased intestinal permeability or “leaky gut”	systemic nickel allergy syndrome (SNAS)
dendritic cells (DCs)	IgE-mediated reactions	T-cells
double-blind, placebo-controlled food challenge (DBPCFC)	immunoglobulin (Ig)	Th cells
dual-allergen hypothesis	inflammatory mediators	Th1 cells
dysbiosis	latex-fruit syndrome or latex-food syndrome	Th2 cells
elimination diet		T-regulatory (T-reg) cells
eosinophilic esophagitis (EoE)		T-suppressor cells
eosinophilic gastroenteritis (EGE)		tyramine
eosinophils		
epigenetic		

Adverse reactions to food are common and implicated in many conditions as a result of the involvement of major organ systems, including the dermatologic, respiratory, gastrointestinal, and neurologic systems. The management of adverse reactions to food is complex because of the diverse response by which the body reacts to food and food components and the multifaceted nature of the mechanisms involved. The clinical relevance of adverse reactions to food should be carefully assessed and evaluated using the nutrition care process (Fig. 25.1).

DEFINITIONS

Adverse reactions to food encompass food allergies and food intolerances, both of which can involve multiple systems, cause diverse symptoms, and negatively impact health.

Food allergy is defined as an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food. A food is defined as “any substance—whether processed, semiprocessed, or raw—that is intended for human consumption, and

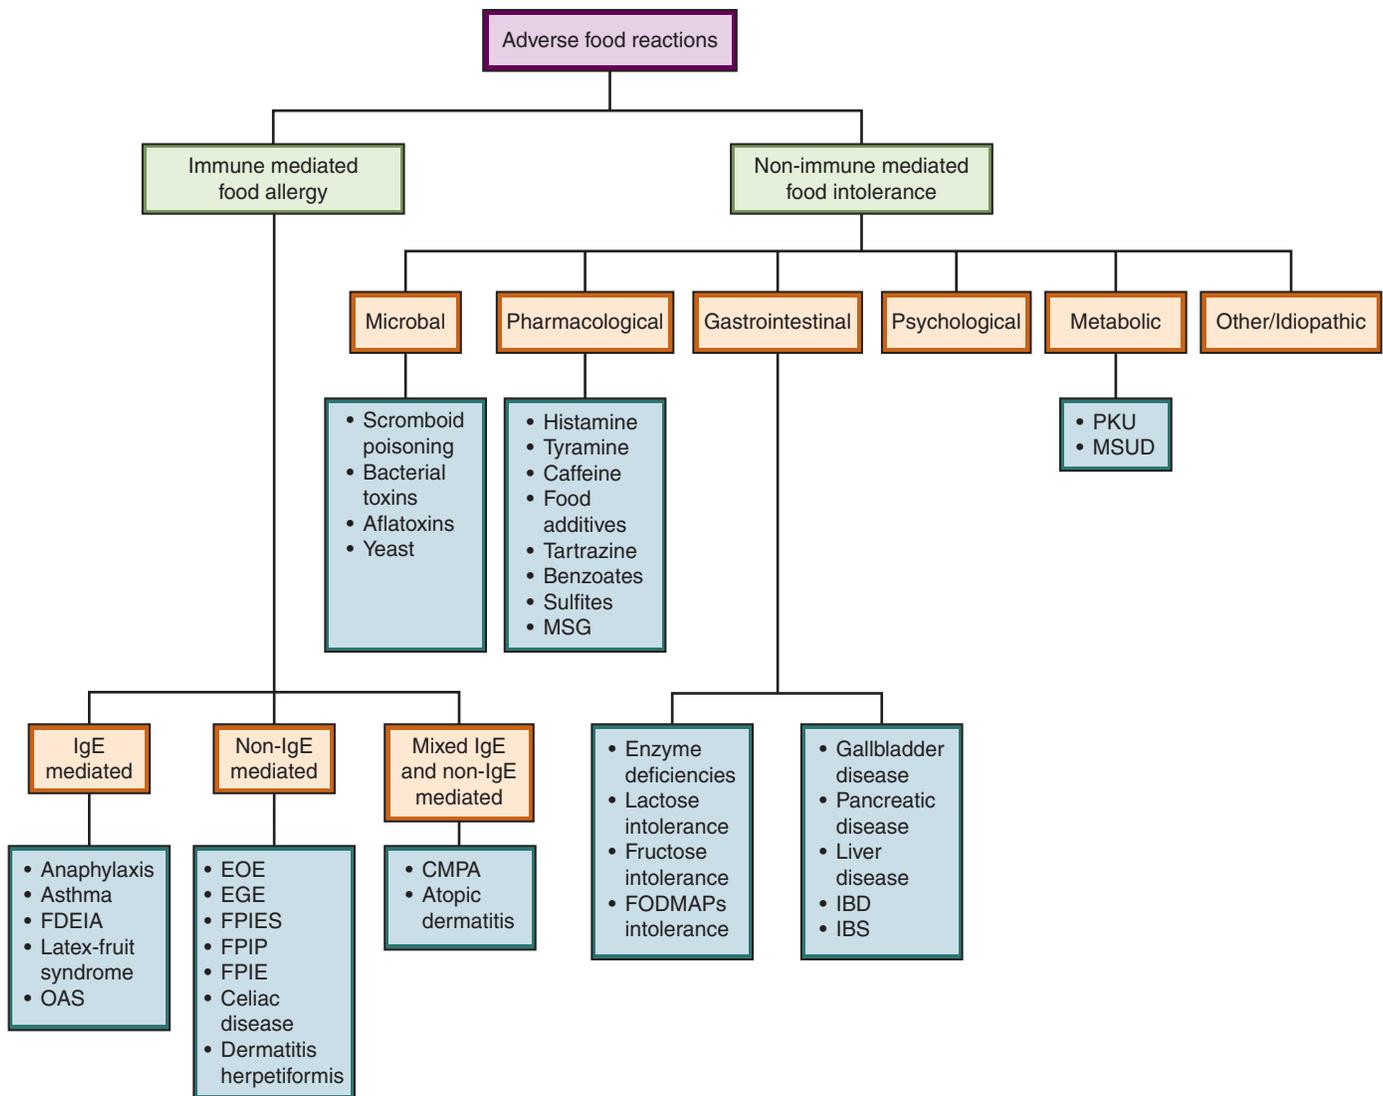

Fig. 25.1 Adverse reactions to food. *CMPA*, Cow's milk protein allergy; *EGE*, eosinophilic gastroenteritis; *EoE*, eosinophilic esophagitis; *FDEIA*, food-dependent, exercise-induced anaphylaxis; *FODMAPs*, fructo-, oligo-, di-, monosaccharides, and polyols syndrome; *FPIE*, food protein-induced enteropathy; *FPIES*, food protein-induced enterocolitis syndrome; *FPIP*, food protein-induced proctocolitis; *IBD*, inflammatory bowel disease; *MSUD*, maple syrup urine disease; *OAS*, oral allergy syndrome; *PKU*, phenylketonuria.

includes drinks, chewing gum, food additives and dietary supplements.” The components within foods that trigger immunologic reactions are called antigens, and most often are glycoproteins that interact with immune cells and initiate the development of a food allergy (National Academies of Sciences, Engineering, and Medicine [NASEM], 2017).

Symptoms can range from urticaria to life-threatening anaphylaxis. Food allergy elicits reactions to foods that include the following:

- Reactions that elicit production of specific immunoglobulins such as IgE
- Reactions that result from release of inflammatory mediators in response to IgE produced against nonfood materials such as inhaled pollens or latex
- Reactions that result from inflammatory mediators released from granulocytes such as eosinophils in the digestive tract
- Reactions that affect the digestive system (enteropathies) due to proteins in milk or soy

- Gastrointestinal disorders such as celiac disease (gluten sensitive enteropathy) which has an immune component

Food intolerance is an adverse reaction to a food or food component that lacks an identified immunologic pathophysiology. It results from the body's inability to digest, absorb, or metabolize a food or component of the food. These nonimmune mediated reactions are caused by metabolic, toxicologic, pharmacologic, microbial, and undefined mechanisms (Sicherer and Sampson, 2018). For example, an individual can be intolerant to milk because of an inability to digest the carbohydrate lactose or intolerant to histamine-containing foods due to enzyme deficiencies or other mechanisms (Table 25.1).

Other terms are used by clinicians, researchers, patients, and the media but are not formally accepted by major food allergy organizations. The term **food sensitivity** is used when it is unclear whether the reaction is immunologically related or due to a biochemical or physiologic defect (Jones, 2013). **Food autoimmune or immune reactivity** has been proposed by Vojdani to refer to the concept that when the

TABLE 25.1 Some Examples of Food Intolerances

Cause	Associated Food(s)	Symptoms
Gastrointestinal Disorders		
Enzyme Deficiencies		
Lactose intolerance (lactase deficiency)	Foods containing lactose and mammalian milk	Bloating, flatulence, diarrhea, abdominal pain
Glucose-6 phosphate dehydrogenase deficiency	Fava or broad beans	Hemolytic anemia
Fructose intolerance	Foods containing fructose or sucrose	Bloating, flatulence, diarrhea, abdominal pain
FODMAPs intolerance	Foods containing fructo-, oligo-, di-, and monosaccharides and polyols	Bloating, flatulence, diarrhea, cramping, abdominal pain
Diseases		
Cystic fibrosis	Symptoms may be precipitated by many foods, especially high-fat foods	Bloating, loose stools, abdominal pain, malabsorption
Gallbladder disease	Symptoms may be precipitated by high-fat foods	Abdominal pain after eating
Pancreatic disease	Symptoms may be precipitated by eating	Anorexia, nausea, dysgeusia, and other gastrointestinal symptoms
Inflammatory bowel disease		
Inborn Errors of Metabolism		
Phenylketonuria	Foods containing phenylalanine	Elevated serum phenylalanine levels, mental retardation
Galactosemia	Foods containing lactose or galactose	Vomiting, lethargy, failure to thrive
Psychological or Neurologic Reactions		
Psychological or neurologic disorder	Symptoms may be precipitated by any food	Wide variety of symptoms involving any system
Reactions to Pharmacologic Agents in Foods		
Phenylethylamine	Chocolate, aged cheeses, red wine	Migraine headaches
Tyramine	Aged cheeses, brewer's yeast, red wine, canned fish, chicken liver, bananas, eggplant, tomatoes, raspberries, plums	Migraine headaches, cutaneous erythema, urticaria, and hypertensive crisis in patients taking monoamine oxidase inhibitors (MAOIs)
Histamine and histamine releasing agents	Aged cheeses, fermented foods (e.g., sauerkraut, yogurt, kefir), processed meats (e.g., sausage, bologna, salami), canned and smoked fish, red beans, soybeans, citrus, avocado, eggplant, olives, tomatoes and tomato products, chocolate, cocoa, tea, yeast, many spices, many food additives and preservatives, shellfish, egg whites, avocado, strawberries, pineapple, spinach, nuts, peanuts, alcohol	Dizziness, flushing, hives, erythema, runny nose, headaches, decreased blood pressure, nausea, vomiting, shortness of breath, edema, urticaria, eczema, pruritus
Reactions to Food Additives		
Artificial colors: tartrazine or FD&C yellow #5 and other azo dyes	Artificially colored yellow or yellow-orange foods, soft drinks, some medicines	Hives, rash, asthma, nausea, headaches
Benzoates: benzoic acid or sodium benzoate	Processed foods as antimicrobial preservatives; color preservatives; bleaching agents Naturally occurring in berries, cinnamon and other spices, tea Dishes with spicy sauces and curry powder, avocado, dried fruits, some carbonated drinks, alcoholic mixers, milk shake syrup, some canned foods like beans, flavored chips, salad dressing	Hives, rash, asthma, angioedema, nasal congestion, headache, contact dermatitis, diverse digestive tract symptoms
Butylated hydroxyanisole (BHA); butylated hydroxytoluene (BHT)	Processed foods: used as antioxidants; also used in food packaging materials	Skin reactions such as hives
Monosodium glutamate (MSG)	Processed foods (canned foods, chips, gravy, flavor packets for instant soups, etc.) added as a flavor enhancer; often used in Asian cuisine. Naturally occurring glutamic acid is found in aged cheeses like Parmesan, fish sauce, mushrooms, spinach, marmite	Facial numbness, tingling and numbness in hands and feet, dizziness, balance problems, visual disturbances, headaches, asthma, flushing, diverse digestive tract symptoms

TABLE 25.1 Some Examples of Food Intolerances—cont'd

Cause	Associated Food(s)	Symptoms
Nitrates and nitrites	Processed foods containing sodium nitrite, sodium nitrate, potassium nitrite and potassium nitrate; commonly found in cured meats, canned meats, smoked fish, pate, pickled meats	Flushing, hives, migraine, other headaches, digestive tract symptoms
Salicylates	Naturally occurring in a variety of fruits, vegetables, and spices	Angioedema, asthma, hives; people sensitive to aspirin at higher risk for developing intolerance
Sulfites		
Sodium sulfite, potassium sulfite, sodium metabisulfite, potassium metabisulfite, sodium bisulfite, potassium bisulfite, sulfur dioxide	Shrimp, avocado, instant potatoes, instant mashed potatoes, French fries, sausage, canned fruits and vegetables, dried fruits and vegetables, acidic juices, wine, beer, cider, colas, fresh fruits and vegetables treated with sulfites to prevent browning, and many other processed foods	Acute asthma and anaphylaxis in people with asthma; reactions in skin and mucous membranes
Reactions to Microbial Contamination or Toxins in Foods		
<i>Proteus</i> , <i>Klebsiella</i> , or <i>Escherichia coli</i> bacteria cause histidine to break down to a histamine	Unrefrigerated scombroid fish (tuna, bonito, mackerel); heat-stable toxin produced	Scombroid fish poisoning (itching, rash, vomiting, diarrhea); anaphylactic-type reaction

body's normal tolerance of friendly antigenic substances (autoantigens produced by the individual's immune system) is disrupted because of disease, injury, shock, trauma, drugs, or blood transfusion, the ingestion of foods containing antigenic substances with a composition similar to those of the body's autoantigens can result in the production of antibodies that react to the food antigens and the body's own tissues (Vojdani, 2015a). **Sensitivity-related illness (SRI)** has also been proposed as a condition that occurs when an individual is exposed to some type of toxin or stressor and then becomes sensitive to a food,

inhalant, or chemical, although the mechanisms are unclear (Genuis, 2010) (Box 25.1).

PREVALENCE

There is evidence that adverse food reactions are more prevalent than in the past, with a dramatic increase in food allergies in recent decades. It is estimated that 10.8% of U.S. adults have at least one food allergy, as evidenced from symptoms typical of an IgE-mediated reaction. But

BOX 25.1 Adverse Reactions to Foods: Definitions

- **Adverse food reactions:** encompass food allergies and food intolerances, both of which can result in distressing symptoms and adversely affect health
- **Allergens:** the components in foods that trigger adverse immunologic reactions; most often are specific proteins, glycoprotein, or haptens that can interact with the body's immune cells in a way that leads to development of a food allergy
- **Atopy:** a condition of genetic predisposition to produce excessive IgE antibodies in response to an allergen that results in the development of typical symptoms such as asthma, rhinitis, conjunctivitis, or eczema
- **Cross-reactivity:** when an antibody reacts not only with the original allergen but also with a similar allergen; occurs when a food allergen shares structural or sequence similarity with a different food allergen or aeroallergen (i.e., a pollen), which may then trigger an adverse reaction similar to that triggered by the original food allergen; cross-reactivity is common, for example, among different shellfish and different tree nuts, and in pollen-food allergy syndrome (PFAS)
- **Desensitization:** a state of clinical and immunologic nonresponsiveness to a food allergen that can be induced by careful, medical-guided administration of gradually increasing amounts of the allergen over a short period of time (hours to days); the maintenance of such desensitization usually requires continued regular exposure to the allergen
- **Dual-allergen exposure:** hypothesis that environmental exposure to food allergens through the skin or exposure to airborne particles early in life can lead to sensitization and allergy, and that the oral consumption of these same foods during a developmentally appropriate period, also early in life, results in tolerance
- **Food allergy:** an adverse immune-mediated reaction to a food, usually a food protein or specific glycoprotein that the person has been sensitized to, and which, when eaten, causes the release of inflammatory mediators or chemicals that act on body tissues and result in symptoms. The reaction can be either IgE-mediated or non-IgE-mediated and occurs reproducibly upon exposure to that food
- **Food autoimmune or immune reactivity:** the concept that when the body's normal tolerance of friendly antigenic substances (autoantigens produced by an individual's body) is disrupted because of disease, injury, shock, trauma, surgery, drugs, blood transfusion, or environmental triggers, the ingestion of foods containing antigenic substances with a composition similar to those of the body's autoantigens can result in the production of antibodies that react to the food antigens and the body's own tissues (Vojdani, 2015)
- **Food intolerance:** an adverse reaction to a food or food component that lacks an identified immunologic pathophysiology
- **Food sensitivity:** a term often used to describe a reaction when it is unclear whether it is immunologically mediated or not
- **Oral tolerance:** the process that allows an individual to eat food that is "foreign" without any ill effects or reactions to it
- **Sensitivity-related illness:** the concept that an individual who is exposed to some type of toxicant or insult may then, by as yet unclear mechanisms, become sensitive to a food, inhalant, or chemical (Genuis, 2010)

Source: IOM Global Report: Finding a Path to Safety in Food Allergy: Assessment of the Global Burden, Causes, Prevention, Management and Public Policy.

only about half of those food allergic adults have been diagnosed by a physician. Of even more interest is the estimate that 19% believe they have a food allergy (Gupta et al, 2019). In Australia it may be as high as 10% (Renz et al, 2018). There are also documented worldwide increases in food allergy in rapidly emerging areas of Asia, such as China. Estimates suggest that 20% of the population alter their diet due to perceived adverse food reactions (Turnbull et al, 2015).

However, there are gaps in the precise prevalence of adverse food reactions due to misuse of the terms “food allergy” and “food intolerance,” variations in study design and methodologies, and inflated self-reporting. Geographic variations; diet exposure effects; differences in age, race, and ethnicity; and other factors also complicate data reporting. Despite the lack of precise prevalence data, there is agreement that changes in diet, lifestyle, and environmental influences, interacting with genetic predisposition and microbiome alterations, can be implicated in the escalation of adverse food reactions and the parallel rise in other chronic disorders such as asthma and autoimmune diseases (Sicherer and Sampson, 2018; NASEM, 2017).

ETIOLOGY

Adverse food reactions illustrate the critical importance of appreciating “biochemical uniqueness” as a core clinical concept in nutrition assessment. Numerous factors have been identified that play a role in influencing immune- and nonimmune-mediated responses to food or food components and their ultimate interpretation by the body as either “friend” or “foe,” including:

Individual Factors

Age

Genetics and epigenetics

Early life factors (maternal nutrition, birth delivery method, breast or formula feeding)

Immunocompetence and personal differences in immune function

Intestinal and skin barrier defects

Microbiome

Increased hygiene

Use of medications (e.g., antacids, nonsteroidal antiinflammatory medications)

Underlying disease

Presence of chronic stress

Environmental influences (toxin and chemical exposures sometimes referred to as the exposome)

Food-related factors

Modern westernized diet

Prenatal perinatal, and maternal nutrition

Allergen type, dose, and route of exposure

Microbial products and contamination with microorganisms

Food matrix (proteins, lipids, and glycosylated sugars)

Cooking temperature

Epithelial barrier insulting agent (alcohol, additives, toxins, unknown ingredients) (Sampson et al, 2018).

Genetics and Epigenetics

It has been recognized for more than a century that genetics plays a role in allergies and asthma. Familial aggregations and heritability estimates from twin studies provide initial evidence for genetic predisposition for food allergy, although among siblings, an increased rate of sensitization does not equate to clinical reactivity. A number of monogenic disorders associated with atopy and food allergy have been identified; however, the genetics of food allergy have shifted from identifying a single change or polymorphism in a gene to the inclusion of

a multitude of contributing genetic and nongenetic risk factors (Carter and Frischmeyer-Guerrero, 2018).

Genetic mechanisms that play a role in pathogenesis of food allergy are multifactorial and complex. The expression of food allergy is influenced by the environment, gene-environment interactions, and **epigenetic** modification of the genome (“epigenome”). The epigenome is largely established in utero and is relevant to early life origins of allergic disease (NASEM, 2017; Carter and Frischmeyer-Guerrero, 2018).

More recently, genome wide association studies (GWASs) identified genes associated with food allergies. One GWAS study examined 1500 children with food allergies in Germany and the United States. This study examined more than five million genetic variations or single nucleotide polymorphisms (SNPs) in each child in the study and compared the frequency of these SNPs with the control subjects. In addition to the large number of subjects, unlike other studies, the researchers also included an oral food challenge to confirm the allergy diagnosis. The study identified five genetic risk loci for food allergies, and four of them showed a strong association with loci for **atopic dermatitis** (hereditary eczematous rash), asthma, and other chronic inflammatory and autoimmune diseases. The *SERPINB* gene cluster on chromosome 18 was pinpointed as a specific genetic risk locus for food allergies. The genes in this particular cluster are expressed in the skin and mucous membrane of the esophagus, which are involved in maintaining epithelial barrier integrity (Marenholz et al, 2017).

Another GWAS study included a meta-analysis of two phenotypes, peanut allergy and food allergy, and examined seven studies from Canadian, American, Australian, German, and Dutch populations. Multiple genes were identified as risk factors for peanut allergy and food allergy and are involved in epigenetic regulation of gene expression (Asai et al, 2018).

Unlike other diseases, the number of identified loci for food allergies is relatively small. Most of the identified candidate genes encode for products influencing immune mechanisms toward a Th2 inflammatory shift. It is hypothesized that genetic predispositions in the context of certain environmental influences such as intestinal viral infection may result in immune system dysfunction and result in food allergy (NASEM, 2017). (See Chapters 6 and 7).

PATHOPHYSIOLOGY OF FOOD ALLERGY

Major advances in research are providing further insights into the mechanisms leading to food allergies. A basic understanding of the immune system is essential since the mechanisms entail multiple molecules involved in immune regulation.

IMMUNE SYSTEM BASICS

Antibodies are specialized immune proteins that are produced in response to the introduction of an **antigen** (an **allergen**, toxin, or foreign substance) into the body. Because of their association with the immune system, antibodies are referred to as **immunoglobulins (Ig)**. Five distinct classes of antibodies have been identified: IgA, IgD, IgE, IgG, and IgM. Each Ig has a specific function in immune-mediated reactions (Box 25.2).

The production of antibodies is a major function of the immune system and is carried out by a particular type of **lymphocyte** (white blood cell). There are two important groups of lymphocytes: **B-cells** arising from stem cells in the bone marrow, and **T-cells**, also originated from stem cells but later transported to the thymus gland where they mature, hence the name T-cells. Monocytes and macrophages are primarily phagocytes that engulf foreign material, break it apart, and display specific molecules of the material on their surfaces, making

BOX 25.2 The Immunoglobulins**IgA**

Found in two forms—serum IgA and secretory IgA (sIgA). The latter is present in mucus secretions in the mouth, respiratory and gastrointestinal tracts, vagina, and colostrum in mammalian milk. It includes a “secretory piece” in its structure that protects it from protein-destroying enzymes in the digestive tract so that it survives in an active form as a “first-line” defense against antigens entering from the external environment. Serum IgA, which does not have the secretory piece, is in the second highest amount in circulation, exceeded only by IgG.

IgD

Found in small amounts in the tissues that line the belly and chest; involved in immunoglobulin class switching. Signals B cells to be activated. Suggestion that IgD-producing B cells are auto reactive lymphocytes and may be involved in autoimmune disease. Its role in allergy is probably minimal.

IgE

The classic allergy antibody of hay fever, asthma, eczema, food-induced allergy, food-induced anaphylaxis, pollen-food allergy syndrome (PFAS), and latex-fruit allergy. Immediate allergic reactions usually involve IgE and are the most clearly understood mechanisms.

IgG

The only antibody that crosses the placenta from mother to baby and is the most common antibody in the blood. Defends against pathogens and persists long after the threat is over. Four subtypes include IgG1, IgG2, IgG3, and IgG4. Food protein-specific IgG antibodies tend to rise in the first few months after the introduction of a food and then decreases even though the food may continue to be consumed. It appears to be part of the process of development of tolerance to food. A rise in antigen-specific IgG4 accompanied by a drop in IgE often indicates tolerance of the food. People with inflammatory bowel disorders such as untreated celiac disease or ulcerative colitis often have high levels of IgG and IgM (Stapel et al, 2008), possibly indicating the passage of food molecules as “foreign invaders” into circulation.

IgM

The largest antibody, a first-line defender that can mop up many antigens at one time. It is produced by the fetus in utero and its level rises in the presence of an in utero infection.

Stapel SO, Asero R, Ballmer-Weber BK, et al: Testing for IgG4 against foods is not recommended as a diagnostic tool: EAACI Task Force Report, *Allergy* 63:793–796, 2008.

them **antigen-presenting cells (APC)**. The antigenic component displayed on the surface is an **epitope** and is recognized by T-cells.

T-cells are a diverse group of lymphocytes with several different roles in the immune response under different circumstances, and they secrete different sets of **cytokines** (chemical messengers). **Th cells** are helper cells that adjust the system. **Th1 cells** regulate the activities of the B-cells to produce antibodies and direct damage to target cells, resulting in the destruction of antigens. This function is useful in defending against bacteria, viruses, and other pathogenic cells. **Th2 cells** mediate the allergic response by regulating the production by B-cells of IgE sensitized to food or other allergens. Other T-cells are **T-regulatory cells (T-reg cells)** and **T-suppressor cells** that regulate the immune response so that there is tolerance of the foreign but safe molecule.

Also involved in allergic reactions are **granulocytes**, cells that contain intracellular granules, which act as storage depots for defense chemicals or inflammatory mediators that, when released, not only protect the body from invading pathogens but also can produce allergic symptoms. Granulocytes called **mast cells** are located in the lungs, skin, tongue, and linings of the nose and intestinal tract, and those called **basophils** are in the circulation. Of importance in non-IgE mediated allergy are **eosinophils**, another form of granulocytes that are in blood and tissues and, when stimulated by cytokines produced by Th2 cells, migrate to the site of an allergic reaction.

When granulocytes degranulate they release **inflammatory mediators**, such as histamine, chymase, and tryptase and, in the case of mast cells, there is de novo synthesis of lipid metabolites of arachidonic acid—prostaglandins, leukotrienes, and plasma activating factor (PAF). Each of these mediators has a specific effect on local tissues and at other sites, resulting in the symptoms of an allergic reaction—vasodilation, increased vascular permeability leading to angioedema, nociceptive (painful) nerve activation causing itchiness, smooth muscle constriction, mucous secretion, and acute diarrhea.

Allergic Response

The pathophysiology of the allergic response can be described in three phases: the breakdown of oral tolerance, allergen sensitization, and reactivity to allergens leading to allergy symptoms.

Breakdown of oral tolerance. Humans are exposed to thousands of foreign molecules daily from food and the environment. Exposure to these foreign molecules in the digestive tract through ingested substances is usually followed by immune regulation or suppression, such that the substance or food is recognized as “foreign but safe,” which is a prerequisite for the development of tolerance to a food or food component. **Oral tolerance** is the mechanism by which potentially antigenic substances do not trigger an immune response and is the normal physiologic response to ingested antigens (Tordesillas and Berin, 2018). The development of immunologic and clinical tolerance is thus critical to preventing food allergies and other chronic inflammatory diseases. Oral tolerance is mediated by several immune cells, including APCs such as **dendritic cells (DCs)** and macrophages, and regulatory T-cells (T_{reg} cells) (Bauer et al, 2015). Tolerance is acquired with innate and adaptive immune responses acting in a coordinated manner to mount a response to antigen exposure. It is a process that starts in utero and persists throughout life (Renz et al, 2018).

The gut microenvironment supports and promotes expansion of the regulating activity of T-reg cells through multiple processes including the presence of retinoic acid (from vitamin A) and microbial metabolites, such as short-chain fatty acids. B-cells also inhibit hostile immune reactivity. **B-regulatory (B-reg) cells** act mainly through interleukin-10 (IL-10), an antiinflammatory cytokine to reduce infection and allergic inflammation and to promote tolerance. A breakdown in the tolerogenic process leads to a shift away from T-reg cell induction to the generation of proallergic Th2 cells and results in sensitization to food allergens (Renz et al, 2018; Sampson et al, 2018).

Sensitization. **Sensitization** to food antigens can take place in the gastrointestinal tract, oral cavity, skin, and occasionally in the respiratory tract (Sampson et al, 2018). Gastrointestinal (GI) function is key to the maintenance of oral tolerance, and avoidance of allergic sensitization and allergic response, since the vast majority of food proteins are broken down by gastric acid and digestive enzymes in the stomach and intestine.

Recognized as being increasingly essential to this function of the GI tract is the presence of the gut **microbiome**, the collection of different types of microbes (bacteria, bacteriophage, fungi, protozoa, and

viruses) that live inside the gut. The intestinal microbiome is responsible for regulating the expansion of T-reg cells and Th1 and Th2 type cells to promote immune balance. (Russler-Germain et al, 2017). **Dysbiosis** occurs when there is an imbalance in the microbial ecosystem, which can contribute to **increased intestinal permeability or “leaky gut,”** and the increased likelihood that intact food proteins and peptides will pass through the intestinal lumen and reach the lymphoid tissue, leading to immune sensitization and possibly reactivity (Plunkett and Nagler, 2017). The **gut-associated lymphoid tissue (GALT)** is the largest mass of lymphoid tissue in the body and antigen penetration and presentation to the GALT drives food sensitization (Fritscher-Ravens et al, 2014). Other conditions such as GI disease, malnutrition, fetal prematurity, and immunodeficiency also may be associated with increased gut permeability and risk of development of food allergy. Disruptions in the microbiome and the intestinal wall barrier are the result of various factors, including cesarean delivery, formula feeding, antibiotics, chronic stress, infections, and alterations in the microbiome due to disease (see Chapters 1 and 27 for further discussion of the microbiome).

Additional forces driving tolerance breakdown and potential sensitization might arise outside the intestine, as there is evidence that food allergen entry can occur through scratched, broken, and inflamed skin (Renz et al, 2018). Like the gut, the skin microbiome consists of thousands of microbial organisms and their byproducts that inhabit the skin. A harmonious balance of the gut-skin-microbiota is now thought to be vital to a well-functioning immune system.

Reaction. The third phase of the allergic response is reactivity whenever an allergen to which the immune system is now sensitized enters the body again. Because individuals can develop immunologic sensitization as evidenced by the production of allergen-specific IgE (sIgE) or other immune cell sensitization without having allergic symptoms upon subsequent exposure to those foods, an IgE-mediated or non-IgE-mediated food allergy requires the presence of not only loss of tolerance and sensitization but also the presence of clinical symptoms due to the release of inflammatory mediators already discussed (NASEM, 2017) (Fig. 25.2).

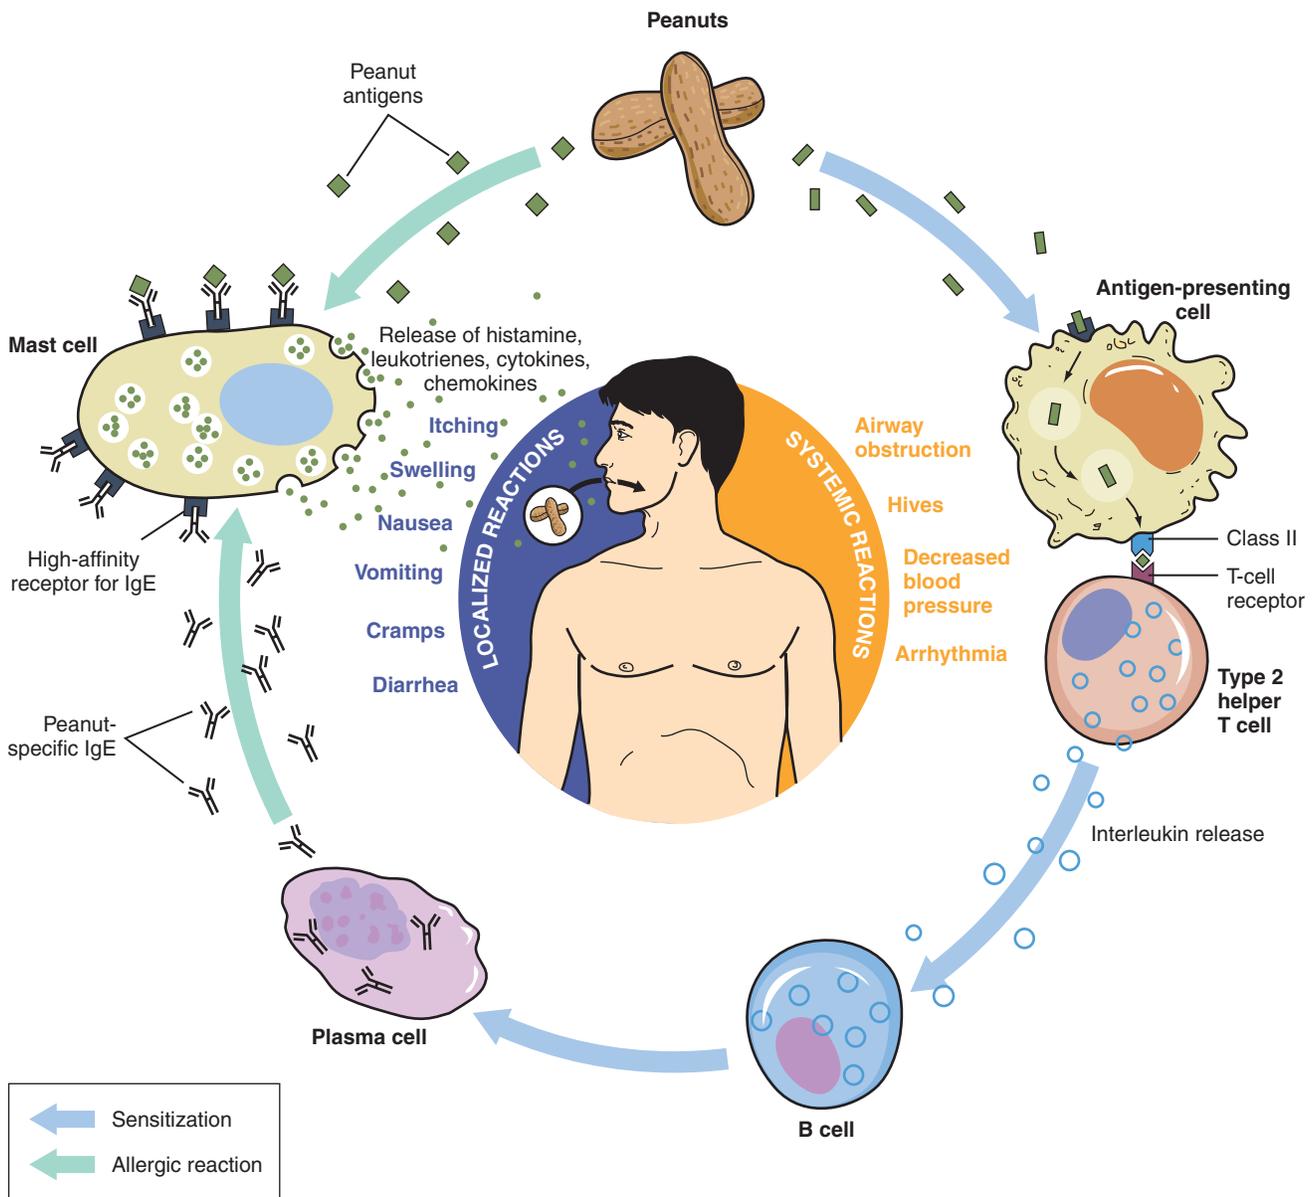

Fig. 25.2 Sensitization process and IgE-mediated allergic reaction.

IgE-mediated reactions occur when sIgE produced in response to the presence of the allergen attaches to matching sIgE antibodies on the mast cell or basophil, forming a “bridge” between them. This bridging activates the mast cell or basophil by a series of energy-requiring processes resulting in the cell’s degranulation and release of the inflammatory mediators, and the appearance of allergic symptoms.

IgE-mediated food allergic reactions are rapid in onset, occurring within minutes to a few hours of exposure through either inhalation, skin contact, or ingestion. A wide range of symptoms are attributed to this type of reaction, and usually involve the GI, dermatologic, or respiratory systems and can range from mild hives to life-threatening multiple organ anaphylaxis (Fig. 25.3).

Non-IgE-mediated reactions are based on the activation of cells other than IgE, such as eosinophils, and their degranulation and release of mediators. Non-IgE-mediated reactions are present in delayed or chronic reactions to food allergen ingestion. See Table 25.2 for a comparison of IgE- and non-IgE-mediated allergic reactions.

IgE-Mediated Food Allergies

Although any food can cause an allergic reaction, a small number of foods cause the vast majority of IgE-mediated food allergies. Foods

that are more likely to induce an allergic response vary by country and region of the world according to a population’s eating habits. In the United States the common allergenic foods are cow’s milk, eggs, peanuts, tree nuts, fish, shellfish, wheat, and soy (NASEM, 2017). Among U.S. adults with food allergies the five most common food allergies are shellfish (2.9%), peanut (1.8%), milk (1.9%), tree nuts (1.2%), and fin fish (0.9%) (Gupta et al, 2019). In other countries, for example, Japan, egg, cow’s milk, wheat, shellfish, fruit, and buckwheat account for approximately 75% of food allergies (Matsuo et al, 2015).

The main IgE-mediated allergic reactions are food-induced anaphylaxis; food-dependent, exercise-induced anaphylaxis (FDEIA); **cow’s milk protein allergy (CMPA)**; oral allergy syndrome (OAS), which recently is recognized as being two syndromes, pollen-food allergy syndrome (PFAS) and lipid transfer protein syndrome (LTPS); latex-fruit or latex-food syndrome; and systemic nickel allergy syndrome (SNAS).

Food-Induced Anaphylaxis

Food-induced **anaphylaxis** is an acute, systemic, often severe, and sometimes fatal immune response that usually occurs within a limited period following exposure to a food antigen. Multiple organ systems are affected. Symptoms include respiratory distress, abdominal pain, nausea, vomiting, cyanosis, arrhythmia, hypotension, angioedema, urticaria, diarrhea, shock, cardiac arrest, and death.

The vast majority of anaphylactic reactions to foods in adults in North America involve peanuts, tree nuts, fish, and shellfish. In children, peanuts and tree nuts are the most common causes of anaphylactic reactions, but anaphylactic reactions to cow’s milk and eggs have been reported. Peanuts are the most common food allergen in fatal anaphylactic reactions (Turnbull et al, 2015).

People with known anaphylactic reactions to food allergens should carry and be prepared to use epinephrine via a portable injectable device (often called an EpiPen) at all times. Epinephrine is the drug of choice to reverse an allergic anaphylactic reaction. Delayed use of epinephrine has been associated with an increased risk of biphasic reactions, in which a recurrence of symptoms 4 to 12 hours after the initial anaphylactic reaction may be fatal. See Simons (2014) for management of an anaphylactic reaction and the website for Food Allergy Research and Education (FARE). Immediate coordination of care and referral to a physician specializing in allergy medicine is essential for patient safety. If you witness a severe allergic response or anaphylaxis, call 911 immediately and be prepared to administer cardiopulmonary resuscitation (CPR) if necessary.

FOOD-DEPENDENT, EXERCISE-INDUCED ANAPHYLAXIS (FDEIA)

Food-dependent, exercise-induced anaphylaxis (FDEIA) is a rare distinct form of allergy in which an offending food triggers an IgE-mediated anaphylactic reaction only when the sensitized individual exercises within 2 to 4 hours after eating, or occasionally, before eating the food. Signs of developing anaphylaxis are urticaria (hives), pruritus (itching), and erythema (reddening) followed by breathing difficulty and GI symptoms. The ingestion of the food is not problematic in the absence of exercise, and exercise is not problematic in the absence of consumption of the food. FDEIA appears to be more common in adolescents and young adults, and in those with known food allergy or a history of anaphylaxis. Shellfish, seafood, certain fruits, cow’s milk, celery, a gliadin component in wheat, and other foods have been reported as offending agents (Asaumi and Ebisawa, 2018).

In FDEIA, the combination of a sensitizing food and exercise precipitates symptoms, possibly related to increased GI permeability and absorption, blood-flow redistribution, and increased osmolality.

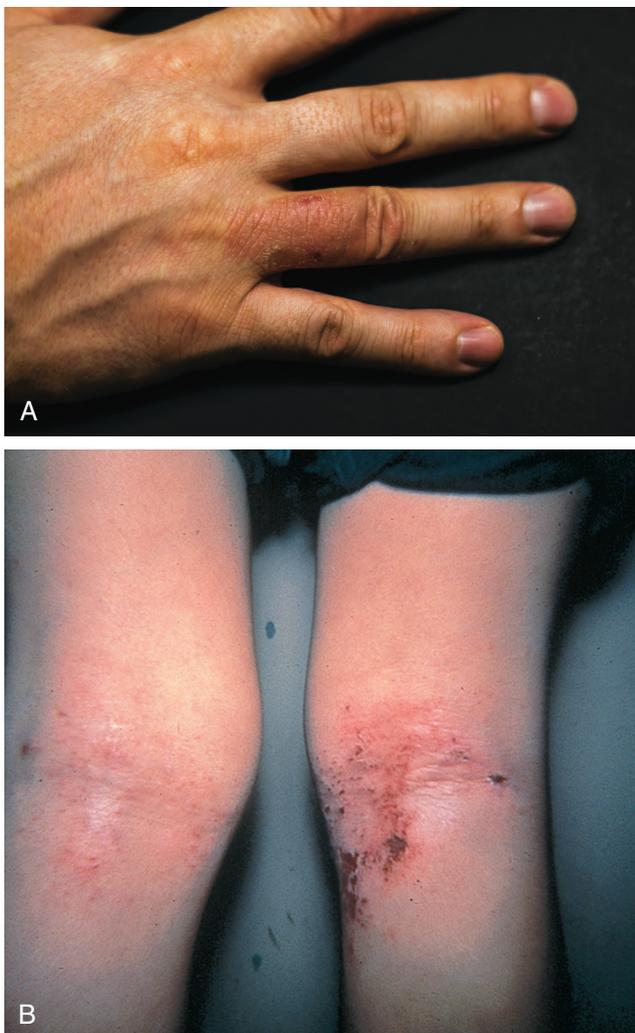

Fig. 25.3 A and B, Atopic eczema: An IgE-mediated skin reaction to a food allergen, commonly seen on the hands, back of knees, and the inside of elbows. A, From www.istockphoto.com.

TABLE 25.2 Comparison of IgE- and Non-IgE-Mediated Allergic Reactions

Characteristics/ Target Organ	IgE Mediated	Non-IgE-Mediated	Mixed IgE- and Non-IgE-Mediated
Mechanism	Th2 activation stimulates production of IgE by activated B-cell lymphocytes. Allergen binds with the receptors on sensitized IgE antibodies on mast cells or basophils. Upon binding, chemical inflammatory mediators are released.	T-cells and sometimes eosinophils are associated with triggering release of inflammatory mediators and development of symptoms.	A combination of IgE and non-IgE mechanisms
Timing	Quick onset First phase: immediate reaction—minutes to 1 hour* Late biphasic phase: may occur several hours (4 to 6) after initial reaction (e.g., alpha gal)	Delayed onset: >2 hours; often 4 to 6 hours; relapsing	Delayed onset: >2 hours; often 4 to 6 hours
Volume Required for Reaction	Small	Sometimes larger	Sometimes larger
Systemic	Anaphylaxis Food-associated exercise induced anaphylaxis (FEIA) NSAID-associated, aspirin-associated, or alcohol-associated food-induced anaphylaxis	NA	NA
Skin	Generalized urticaria Acute contact urticaria Angioedema Rash Itching Flushing	Contact dermatitis Dermatitis herpetiformis	Atopic dermatitis (eczema) (see Fig. 25.3)
Gastrointestinal Tract	Immediate gastrointestinal (GI) hypersensitivity or spasm Oral allergy syndrome (OAS) or pollen-food allergy syndrome (PFAS) Abdominal pain Nausea Vomiting Belching Bloating Diarrhea Constipation	Food protein–induced enteropathy syndromes (FPIES) Food protein–induced proctocolitis (FPIP) Celiac disease Eosinophilic esophagitis (EoE) Eosinophilic gastritis Eosinophilic gastroenteritis (EGE)	NA
Respiratory	Acute rhinitis (stuffy nose) Rhinorrhea (runny nose) Asthma Bronchospasm Laryngeal edema	NA	Asthma
Cardiovascular	Hypotension Dizziness or fainting	NA	NA

* In contrast to typical food anaphylaxis that occurs within minutes to 2 hours following ingestion of the trigger food, IgE-mediated alpha-gal-related reactions to mammalian meat, with the same anaphylaxis symptoms are delayed, occurring 3 to 8 hours after ingestion.

Additional factors such as concomitant ingestion of nonsteroidal antiinflammatory drugs (NSAIDs) or alcohol can act as accelerants to the reaction (Wauters et al, 2018). The prevalence and causative agents and effective methods of diagnosis in FDEIA continue to be explored.

Galactose- α -1,3-Galactose Anaphylaxis (Alpha-Gal)

An unusual form of anaphylaxis is the delayed anaphylaxis response to mammalian meat (most commonly beef, lamb, pork, bison, buffalo,

and venison). It involves IgE antibodies that the individual forms against the oligosaccharide **galactose- α -1,3-galactose (“alpha-gal”)**, which is typically introduced into the person during bites from ticks, most commonly the lone star tick. The lone star tick is most commonly seen in the southeast United States but its range is spreading to the Midwest from Texas to Iowa and in New England. Other ticks common in Europe or Australia can introduce alpha-gal into a person through their bite (Commins et al, 2016). Other ectoparasites such as cestodes, nematodes, and scabies in sub-Saharan

Africa can introduce alpha-gal and cause subsequent reactions (Commins, 2016).

About 4 to 6 weeks after the tick bite, the subsequent ingestion of mammalian meat, which contains alpha-gal for which there is now an IgE antibody in the previously bitten person, can lead to reactions that unlike usual immediate IgE-mediated reactions are delayed for several hours. The unique delay in the reaction is probably due to slow absorption of the complex lipids in the meat that harbor the antigen. The fattier the red meat, the more likely the reaction. High-fat dairy ice cream can also occasionally cause a reaction (Wilson and Platts-Mills, 2018).

Intradermal testing with commercially available beef, pork, and lamb extracts can be done safely and correlates well with clinically relevant alpha-gal allergy. In many cases alpha-gal allergy is not lifelong, and red meat can be reintroduced into the diet with medical supervision after 18 to 24 months of avoidance of red meat.

Fruit and Vegetable Allergies: Pollen-Food Allergy Syndrome (PFAS) and Lipid Transfer Protein Syndrome (LTPS)

What used to be called **oral allergy syndrome (OAS)** is now more accurately referred to as two different syndromes: **pollen-food allergy syndrome (PFAS)** and **lipid transfer protein syndrome (LTPS)** (Muluk and Cingi, 2018). Both syndromes are IgE-mediated reactions characterized by oropharyngeal symptoms of itchy mouth; scratchy throat; swelling of the lips, mouth, uvula, or tongue; and throat tightness. Itchy ears are sometimes reported. PFAS is usually a milder reaction confined just to the oral cavity. Symptoms are rapid and appear within 5 to 30 minutes after ingestion of the allergen-containing food and most often subside within 30 minutes. In LTPS the reaction not only affects the oral cavity but also can become systemic with hives, wheezing, vomiting, diarrhea, and low blood pressure, or even anaphylaxis. LTPS is a primary allergy and potentially more severe, requiring different management and even possible prescription of an epinephrine auto-injector device (ADI) (Turner and Campbell, 2014; Turner et al, 2015).

In PFAS the reaction results from contact with food allergen proteins similar to those in pollens (usually birch, ragweed, mugwort, or other grasses) that the person has already been sensitized to through the respiratory system. It is a situation of **cross-reactivity** between an inhaled and an ingested protein allergen that causes a reaction in the previously sensitized individual. PFAS is common in those with pollen allergies. The primary sensitization is to the pollen, not the food (Turner and Campbell, 2014; Turner et al, 2015).

The proteins resulting in PFAS are heat labile and are changed during cooking. Hence, it is the raw fruit or vegetable that causes the reaction; the cooked version can usually be consumed with no problems. Because reactions are immediate after ingestion of the raw food, most individuals can identify the food culprit. However, if it is not obvious from a thorough clinical history, use of component resolved diagnostic (CRD) testing or skin-prick testing (Table 25.3) can be useful.

LTPS is common in Mediterranean countries where lipid transfer protein (LTP) is a widely cross-reacting allergen in plant foods. In southern Europe LTPS is associated with higher risk of severe systemic reaction, but the reason for this is unknown. Because of this it is important to diagnose LTPS correctly and not misdiagnose it for the milder PFAS. The most frequently implicated foods, cooked or raw, include peaches, apples, pears, apricots, plums, cherries, walnuts, and hazelnuts (Asero et al, 2018; Venter et al, 2018). Box 25.3 lists foods and pollens associated with PFAS and LTPS.

Latex-Fruit or Latex-Food Syndrome

Natural rubber latex (NRL) or *Hevea brasiliensis*, used in latex rubber gloves, balloons, bottle nipples, children's rubber toys, elastic bands, exercise bands, and many other articles in the environment, contains many proteins that can be highly allergenic. An NRL-allergic reaction is IgE-mediated and is often seen in health care workers (8% to 17%), other workers using latex rubber gloves such as hairdressers or house cleaners, those working in the latex industry, and in those undergoing multiple surgical procedures in which they have been exposed to latex rubber surgical gloves and appliances (68% of children with spina bifida for example) (American Latex Allergy Association, 2018). Symptoms of NRL allergy include all the usual symptoms of an IgE-mediated allergy: urticaria, angioedema, runny nose, sneezing, headache, reddened and itchy eyes, sore throat, abdominal cramps, and even anaphylaxis.

It is estimated that 50% to 70% of people with latex allergies have IgE antibodies that can cross-react with antigens from foods, mostly fruits, and cause allergic symptoms of the **latex-fruit syndrome or latex-food syndrome**. Symptoms of latex-food allergy vary, with many being similar to those with NRL allergy, including anaphylaxis. Sensitization occurs from skin contact with latex, and the food allergy reaction is an IgE-mediated reaction to the latex cross-reacting proteins found in the food.

For those with NRL documented allergy, but with no symptoms after consumption of associated foods, it is important to keep in mind that every NRL-allergic individual reacts differently to foods with latex cross-reacting allergens. The most frequently reported foods in latex-food allergic reactions are avocado, banana, chestnut, kiwi, and mango, but other foods can be problematic (Joneja, 2013). Many latex products, especially powdered latex gloves, where inhalation of the powder increases the risk of becoming sensitized, are now banned from health care settings, making the occurrence of this latex-food allergic reaction less common. However, there are still many NRL-containing products in use (American Latex Allergy Association, 2018).

Many clinicians advise NRL-allergic individuals to avoid foods that have cross-reactivity in the interest of safety. However, it cannot be assumed that the NRL-allergic person will react to these foods, or that there will not be other NRL allergen-containing foods that may cause a reaction. Management is based on an elimination diet that begins with avoidance of foods known to be reactive for that individual. With the development of CRD testing (see Table 25.3), the problematic link between specific components of the latex protein and certain fruits is being elucidated.

Systemic Nickel Allergy Syndrome (SNAS)

Allergy to the mineral nickel begins as a contact dermatitis. It is more common in women and increases in incidence with advancing age. The individual is sensitized through prolonged skin or mucous membrane contact with nickel, usually from jewelry, buttons, metal studs, clips, watchbands, or occupations where metal contact is frequent. In this cell-mediated reaction lymphocytes produce cytokines at the site of nickel contact, which cause the itching, redness, and scaling of contact dermatitis. It is a delayed and chronic reaction that occurs with every subsequent contact with nickel at that site.

It is now recognized that the individual with nickel contact dermatitis can develop a secondary response of eczema or dermatitis even when the skin is not in contact with nickel, and it appears that this **systemic nickel allergy syndrome (SNAS)** in the sensitized individual is to nickel present in an ingested food.

Diagnosis of contact allergy to nickel is made using an atopy patch test (see Table 25.3), where the allergen (usually nickel sulfate) in the patch is left on the skin for up to 72 hours. After 48 hours the area

TABLE 25.3 Tests Used in the Assessment of Adverse Reactions to Foods

Skin Tests		
Skin testing (scratch, prick, or puncture)	A drop of antigen is placed on the skin, and the skin is then scratched or punctured to allow penetration of the antigen to reach sensitized IgE; assesses presence of antigen-specific IgE (sIgE) and sensitization	Screening test; cannot be relied upon as sole diagnostic tool; negative results confirm absence of IgE-mediated sensitivity; positive results only confirm presence of sIgE-mediated sensitization and not necessarily food allergy; need to be combined with thorough health history of food-symptom relationship
Atopy patch test	Small pads soaked with allergen are applied to unbroken skin for 48 hours and read at 72 hours	Variable sensitivity and specificity; used to assess delayed or non-IgE reactions; no clinical value in diagnosis of food allergy; combined with skin prick testing (SPT) or sIgE may have value in the diagnosis of atopic dermatitis (Hammond and Lieberman, 2018) or eosinophilic esophagitis (Spergel et al, 2012)
Blood Tests		
ImmunoCAP ImmunoCap ISAC Immulite	Test for allergen-specific IgE in serum (sIgE); serum is mixed with food on a paper disk and then washed with radioactively labeled IgE. Used for assessing IgE-mediated reactions; ISAC tests for a panel of 100 foods or more	High sensitivity, but low specificity for food allergy; detectable sIgE by itself not diagnostic of food allergy, but larger sIgE values correlate with increased likelihood of food allergy; most reliable for these foods: eggs, wheat, cow's milk, peanuts, and soy; has the potential for over diagnosing by detecting sensitization to foods that may not be clinically relevant
Molecular Allergen Analysis (MAA); Component-resolved diagnostic (CRD) testing	Measures sIgE to specific components of protein antigens in food, not to the whole food extract; augments accuracy of conventional sIgE testing	Identifies clinically relevant sIgE from irrelevant sIgE with prognostic benefit for clinical reaction and severity; especially useful in assessing peanut allergy, pollen-food allergy syndrome (PFAS), and lipid transfer protein syndrome (LTPS)
Basophil activation test (BAT)	Using fresh whole blood, measures basophil response to an allergen in a test tube and can be an in-vitro surrogate for an oral food challenge (OFC) (Hoffmann et al, 2015).	Mimics an allergic reaction, not just sensitization; becoming more widely used to test for sesame or peanut allergy (Appel et al, 2018); potentially can distinguish between those sensitized and those clinically allergic
Mast cell activation test (MCAT)	Using plasma, measures mast cell response to allergenic cross-linking sIgE on mast cell similar to BAT	Still experimental; may be used in testing for peanut allergy (Gomes-Belo et al, 2018)
Serum IgG4	Blood testing for food-specific IgG4	Not validated for diagnostic use; tends to indicate previous exposure to the food and tolerance, not allergic reaction; may be more useful as a ratio IgG4/IgE in EoE diagnosis; may be useful in CRD testing
Leukocyte activation testing <ul style="list-style-type: none"> Antigen leukocyte cellular antibody test (ALCAT) Mediator release test (MRT) 	Allergen is mixed with whole blood serum leukocyte suspension. Lysed leukocytes, primarily neutrophils, are assessed using DNA released; indicates release of inflammatory mediators and positive response to the food allergen	Measures non-IgE-mediated immune responses; indicates response to foods by innate immune cells; becoming more validated for diagnostic use (Ali et al, 2017; Garcia-Martinez et al, 2018)
Other Tests—Not Recommended		
Applied kinesiology, also called muscle strength testing	Subject's arm is extended and vial with the test food is placed in the subject's hand, and the muscle strength in the opposite arm is tested by placing light pressure on the arm; test is considered positive if muscle strength weakens and arm moves more easily	Nonstandardized; may result in false-positive or false-negative results; not reliable and not validated for diagnostic use (Hammond and Lieberman, 2018)
Sublingual testing	Drops of allergen extract are placed under the tongue and symptoms are recorded	May result in false-positive results; not validated for diagnostic use
Provocation testing and neutralization	Subcutaneous injection of allergen extract elicits symptoms; this is then followed by injection of a weaker or stronger preparation to neutralize symptoms; often the pulse increased by 16 beats per minute is considered a positive test	Not validated for diagnostic use; neutralization may cause severe adverse reaction in those with true IgE-mediated food allergy

under the patch is observed for redness, itchiness, or blister. Because the reaction is delayed, it may take 2 to 3 days to develop.

If, after removal of skin contact with nickel, the dermatitis persists, and there are also GI symptoms, allergy to ingested nickel in food is suspected. Dietary elimination of nickel and challenge with food nickel is the only way to determine whether nickel in food is the cause of the continuing chronic eczema and GI symptoms. A low-nickel diet (a nickel-free diet is impossible) is followed for 4 weeks until the symptoms subside. This is followed with a challenge of a high nickel food with observation (often for several weeks) of reoccurrence of symptoms (Joneja, 2013).

Nickel occurs naturally in all foods and may also be introduced through processing (metal containers) or cooking (metal utensils).

Some foods such as oats and oatmeal, cocoa, green lentils, soy beans, dried legumes, and some seeds are very high in nickel compared with others such as dairy products, many fish, and most vegetables (Joneja, 2013). It is also recommended that adding a probiotic supplement of *Lactobacillus reuteri* makes the low-nickel diet more effective in improving the GI symptoms (Randazzo et al, 2014).

An increasing number of studies are suggesting that the severity of nickel-related contact dermatitis can be reduced by oral exposure to nickel (Joneja, 2013; Di Gioacchino et al, 2014). There may be an initial worsening of the dermatitis, but prolonged exposure can reduce the clinical symptoms. The subject of nickel-contact dermatitis and nickel allergy and achievement of tolerance is complex and confusing and in need of more research.

Non-IgE-Mediated Reactions

Non-IgE-mediated allergic reactions to food continue to be elucidated. These are associated with delayed or chronic reactions, are often referred to as cell mediated, and are present in the eosinophilic GI diseases, food protein-induced enterocolitis syndrome (FPIES) and food protein-induced proctocolitis or proctitis (FPIP), and SNAS.

Eosinophilic Gastrointestinal Diseases (EGID)

Eosinophilic gastrointestinal diseases (EGID) are a group of GI disorders in which the accumulation of **eosinophils** (granulocytes capable of releasing inflammatory mediators) is present. These disorders include eosinophilic esophagitis, eosinophilic gastritis, eosinophilic gastroenteritis, eosinophilic enteritis, and eosinophilic colitis.

Eosinophilic esophagitis (EoE) and **eosinophilic gastroenteritis (EGE)** are the most studied, and are characterized by infiltration of the esophagus, stomach, or intestines with eosinophils. The conditions reflect a Th2 inflammation pattern. It is now thought that both conditions are mainly non-IgE-mediated allergic reactions, although there still may be an IgE-mediated component to the reaction. Almost half of the patients who present with EGID have atopic features (NASEM, 2014).

Eosinophilic Esophagitis (EoE)

Symptoms of EoE vary depending on the age of the person and may include early satiety and inability to manage varied food textures in young children, to reflux-like symptoms and vomiting in school-age children, and to dysphagia, refusal to eat, and food impaction in teenagers and adults. Because it is non-IgE mediated, as of yet there are no specific tests to identify the food triggers. EoE is most commonly treated with off-label use of swallowed topical corticosteroids (TCS), but the long-term efficacy and safety of this treatment is not yet established. Elimination diets are helpful and should be used if at all possible (Renz et al, 2018; Groetch et al, 2017).

The only way to know for certain that symptoms are caused by EoE is by esophageal tissue biopsy including the presence of eosinophils, and the use of an elimination diet for a period of time with resolution of the symptoms and histology normalization, followed by recurrence of symptoms and abnormal esophageal histology with reintroduction of the eliminated food (Groetch et al, 2017).

Ideally the reintroduction of each food is followed with an esophageal tissue biopsy; however, because biopsy is intrusive, time sensitive, and not always available, the Pediatric Eosinophilic Esophagitis Symptom Score (PEESS, v. 2.0) is used, especially with children. Use of this questionnaire with children 2 to 18 years of age has shown that reported symptoms of dysphagia most closely correlate with tissue markers of eosinophil activity; fewer reports of dysphagia correlate with improvement of EoE. The PEES is available at www.jaci-inpractice.org (Martin et al, 2015).

The goals for treatment of EoE are resolution of clinical symptoms and esophageal eosinophilic inflammation, maintenance of remission to prevent potential complications such as esophageal strictures or fibrosis, correction and prevention of nutritional deficiencies, prevention of treatment-related complications, and maintenance of quality of life (Groetch et al, 2017).

An elimination diet or elemental diet presently is used to identify trigger foods and begin treatment of EoE. An elemental diet has been found to be the most effective therapy with a histologic (tissue level) disease remission rate of 90.8% in children and adults and was as effective as steroid treatment in EoE symptom resolution (Arias et al, 2014). However, this diet is difficult to implement and maintain long-term, so a less aggressive elimination diet is now recommended (Molina-Infante and Lucendo, 2018; Groetch et al, 2017).

Since the most common food triggers in EoE are cow's milk, wheat/gluten, and chicken eggs in children and adults in the United States, Spain, and Australia, many EoE dietary treatment programs use the **step up 2-4-6-food elimination diets**. This approach begins

with a two-food (cow's milk and wheat/gluten) elimination diet. If after 6 weeks of strict adherence to this diet there is no remission of symptoms, a four-food elimination diet (cow's milk, wheat/gluten, egg, and soy) is started. If there is still no resolution, a **six-food elimination diet (SFED)** (cow's milk, wheat/gluten, egg, soy, peanuts/nuts, and fish/seafood) is implemented. This step up 2-4-6 approach usually results in prompt recognition of the majority of responders, reducing the number of endoscopies and costs, and shortening the diagnostic process (Molina-Infante and Lucendo, 2018). See **Box 25.4** for guidelines for the step up 2-4-6 approach for elimination diets. An elemental diet consisting of an amino acid-based formula free of peptides or intact proteins may be a useful supplement, especially in young children, where the elimination diet may be difficult to implement without causing hunger, nutritional inadequacy, frustration, and abandonment of the diet.

Once problematic foods are identified, a tailored elimination diet that the patient is able to follow lifelong has been shown to be very effective in inducing remission in the majority of patients with EoE

BOX 25.4 Step Up 2-4-6 Approach to Foods Elimination

Food—Animal Milk and Wheat/Gluten Elimination Diet

You can consume all these kinds of foods for 6 weeks, preferably raw, fresh, or uncooked:

- Vegetables, tubers (potato), and legumes
- Meat (excepting processed or precooked meats, like sausages and hamburgers)
- Fish and seafood (excepting processed or precooked fish)
- Egg
- Fruit
- Nuts

You cannot consume for 6 weeks any food known to trigger allergic symptoms such as itchy mouth, scratchy throat, hives, skin rash, or asthma.

Avoid as much as possible eating out to have a better control of foods.

Try to always pick fresh, raw whole foods and avoid those cooked with sauces or fried in pans where potential contamination with breaded and/or wheat sources is likely.

You can drink coffee, tea (without animal milk), tonic water, soda, cola, fruit juice, wine, gin, vodka, and rum. Beer and whiskey are forbidden since they are gluten-containing drinks.

You can have coffee with soy, rice, almond, walnut, nut, or quinoa drinks.

Gluten-free products for those with celiac disease are allowed provided they do not contain milk (they can contain egg or soy).

Animal Milk

As a general rule, you should avoid all foods you are not fully sure to be safe.

Foods to Avoid:

- All cow's, goat's, and sheep's milk (whole, low-fat, skim, butter milk, evaporated, condensed, powdered, formula milk, hot cocoa)
- Milk products (all kind of cheeses, yogurt, butter, margarine, ice creams, milkshakes, custard, creme caramel, and rice or tapioca pudding)
- Foods that may contain milk (biscuits, cookies, doughnuts, muffins, pancakes, waffles, crackers, cream desserts, sweets, candies, chocolate with milk, sausages, ham, pork sausage)

Foods Allowed:

Milks made of soy, rice, spelt, quinoa, almond, cashews, or other nuts.

Wheat/Gluten

Foods to Avoid:

All products containing wheat, barley, rye, oats, spelt, triticale, semolina, and kamut. This wide range of products may include:

- Wheat-containing: bread, toast, biscuits, cookies, doughnuts, muffins, pretzels, pancakes, waffles, crackers, cream desserts, sweets, candies, pasta, cream, soups, sauces, malted food, and breaded or floured vegetables.
- Beer, whiskey

Be sure to avoid foods that contain any of the following information:

- Flour or floured, farina, wheat enriched, malted or malt added, breaded.
- Starch, fiber, protein, vegetable protein, semolina, hydrolyzed protein, malt, malt extract, couscous, yeast, spices, flavorings.

Foods Allowed:

All products allowed for celiac patients provided they do not contain milk or milk protein.

Food—Animal Milk, Wheat/Gluten, Egg, and Legumes Elimination Diet

You can consume all these kinds of foods for 6 weeks, preferably raw, fresh, or uncooked:

- Vegetables and tubers (potato)
- Meat (excepting processed or precooked meats, like sausages and hamburgers)
- Fish and seafood (excepting processed or precooked fish)
- Fruit
- Nuts

The same instructions apply as with the 2-food elimination diet but with the additional **elimination of two more food groups: egg and legumes**.

Egg

Foods to Avoid:

All products containing egg, baked goods, pasta, cakes, biscuits, cookies, doughnuts, muffins, pretzel, pancakes, waffles, crackers, cream desserts, sweets, candies, processed meat, goose liver, mayonnaise, food coated and wrapped in bread, breaded or creamed vegetables, processed meat, sauces.

BOX 25.4 Step Up 2-4-6 Approach to Foods Elimination—cont'd

Be sure to avoid foods that contain any of the following information:

- Albumin, apovitellin, binder, coagulant, cholesterol-free egg substitute, dried egg, egg white, egg yolk, egg lecithin, egg lysosome, eggnog, egg wash, globulin, lecithin, livetin, lysozyme, meringue, meringue powder, simplese, surimi, ovalbumin, ovomucin, ovomucoid, ovomucin, ovomucoid, ovotransferrin, ovovitellin, powdered egg, trailblazer, vitellin, whole egg.

Legumes**Foods to Avoid:**

Soy, lentils, pea, chickpeas, beans, peanuts, lupin, guar gum, carob bean, alfalfa.

Be sure to avoid foods that contain any of the following information:

- Hydrolyzed vegetable protein, plant protein, vegetable gum, and vegetable starch. These products are usually present in canned or processed foods.
- Oil made with any of the aforementioned legumes.
- African and Asian ethnic foods often contain soy and peanuts.

Food—Animal Milk, Wheat/Gluten, Egg, Legumes, Nuts, and Fish/Seafood Elimination Diet

You can consume all these kinds of foods for 6 weeks, preferably raw, fresh, or uncooked:

- Vegetables and tubers (potato)
- Meat (excepting processed or precooked meats, like sausages and hamburgers)
- Fruit

The same instructions apply as with the 4-food elimination diet but with the **additional elimination of two more food groups: nuts and fish/seafood.**

Nuts**Foods to Avoid:**

Almond, artificial nuts, Brazil nut, beechnut, butternut, cashew, chestnut, chinquapin nut, coconut, filbert/hazelnut, gianduja (a chocolate-nut mixture),

ginkgo nut, hickory nut, litchi/lychee/lychee nut, macadamia nut, marzipan/almond paste, nangai nut, natural nut extract (e.g., almond, walnut), nut butters (e.g., cashew butter), nut meal, nut meat, nut milk (e.g., almond milk, cashew milk), nut paste (e.g., almond paste), nut pieces, pecan, pesto, pili nut, pine nut (also referred to as Indian, pignoli, piggiolia, pignon, piñon, and pin-yon nut), pistachio, praline, shea nut, walnut.

Be sure to avoid foods that contain any of the following information:

- Oil made with any of the aforementioned nuts.
- African and Asian ethnic foods often contain nuts.
- Tree nut proteins may be found in cereals, crackers, cookies, candy, chocolates, energy bars, flavored coffee, frozen desserts, marinades, barbecue sauces, and some cold cuts, such as mortadella. Some alcoholic beverages may contain nut flavoring.

Fish/Seafood**Foods to Avoid:**

- All kinds of fish (anchovies, bass, catfish, cod, flounder, grouper, haddock, hake, halibut, herring, mahi-mahi, perch, pike, pollock, salmon, scrod, swordfish, sole, snapper, tilapia, trout, tuna)
- All kinds of shellfish (crab, lobster, prawns, shrimps) and mollusks (cockles, mussels, octopus, oyster, snails, squid).

Be sure to avoid foods that contain any of the following information:

- Vegetable protein, plant protein, vegetable gum, and vegetable starch. These products are usually present in canned or processed foods.
- Oil or gelatin made with any of the aforementioned fish or seafood products.
- African and Asian ethnic foods usually contain fish and seafood and are considered high-risk.

See also “How to Read a Label” in Table 25.5.

Adapted from: Molina-Infante J, Lucendo AJ: Dietary therapy for eosinophilic esophagitis, *J Allergy Clin Immunol* 142:41, 2018.

and offering potential for long-term treatment (Lucendo et al, 2013; Groetch et al, 2017).

Eosinophilic Gastroenteritis (EGE)

EGE is an uncommon disease characterized by eosinophilic infiltration of the GI tract in the absence of any secondary causes for the eosinophils, and the etiology and pathophysiology are unclear. The stomach and duodenum are most commonly affected, but it can involve any segment including the rectum. Symptoms vary depending on the portion of the GI tract involved, and the localized or widespread infiltration by eosinophils. Abdominal pain and nausea and vomiting are the most frequent presenting symptoms in children and adults. Adolescents may present with growth retardation, failure to thrive, and delayed puberty or amenorrhea.

EGE can occur at any age, but it is most commonly seen in those 30 to 40 years of age, and is possibly more prevalent in females (Zhang and Li, 2017; Alhmod et al, 2016). Symptoms can easily be mistaken for other functional GI disorders. In patients with GI symptoms and a history of atopic conditions such as asthma, atopic dermatitis, allergic rhinitis, or PFAS there is high degree of clinical suspicion of EGE (Zhang and Li, 2017, NASEM, 2017). Tests for allergen-specific IgE are of no value in the identification of offending foods.

There is no consensus on the optimal treatment strategy for EGE because of a lack of large, randomized, controlled trials to clearly establish standard guidelines (Zhang and Li, 2017). However, since a high proportion of cases of EGE are associated with food allergy, an elimination or elemental diet can be recommended as a first step. The use of dietary treatment not only has been effective in reducing the need for corticosteroids, but also has improved the poor growth associated with the disease.

A proposed therapeutic strategy is to first have the patient follow an elimination diet avoiding specific airborne and food allergens. If this is not feasible or fails to achieve improvement, then glucocorticoid therapy is recommended, including starting with topical delivery and then considering systemic delivery (Zhang and Li, 2017).

Elimination diet therapy would be similar to that for EoE, beginning with an elemental diet if possible (exclusive feeding with amino acid–based formulas) or the empiric step up 2-4-6-food elimination diets. See Box 25.4 for guidelines for eliminating these foods from the diet. However, the high level of restriction and need for multiple endoscopies have hampered the implementation of elimination diets in clinical practice. Corticosteroids continue to be a widely used, clinically effective treatment.

Food Protein–Induced Enterocolitis Syndrome (FPIES)

Another non-IgE-mediated immune reaction to food is **food protein–induced enterocolitis syndrome (FPIES)**, with the major criterion being vomiting 1 to 4 hours after ingestion of a food but with the absence of IgE-mediated skin or respiratory symptoms. FPIES is characterized by delayed repetitive vomiting (up to 10 times in an episode) after ingestion of the food, and the infant is pale, lethargic, and limp. Severe dehydration and hypovolemic shock may occur, and there may be an episode of diarrhea 1 to 5 hours later. Symptoms usually resolve within 24 hours and the child is well in between episodes (Leonard et al, 2018).

Chronic FPIES is characterized by chronic or intermittent delayed vomiting, usually in infants less than 4 months of age who are consuming

cow's milk or soy formula regularly. The infant also exhibits chronic diarrhea, poor weight gain, and possibly failure to thrive. Chronic FPIES is usually diagnosed after an episode of acute FPIES when a history confirms that the symptoms have been chronic. When the trigger food is removed, the chronic FPIES resolves, but can reappear as an acute episode when the food is eaten again, usually accidentally. Oral food challenges (Table 25.4) may be needed if the diagnosis is not clear.

FPIES usually presents in infants when formula or solid foods are introduced between 2 and 7 months of age. Infants less than 2 months of age diagnosed with cow's milk or soy FPIES are more likely to present with diarrhea, bloody stools, and failure to thrive, in addition to vomiting, compared with those presenting

TABLE 25.4 Allergen Avoidance Guidelines

Sources	Other Terms	Nutrients Involved	Alternatives	
Milk *	Butter/many margarines or fat spreads, cheese, any mammalian milk (cow/sheep/goat), evaporated/condensed milk, cream, ghee, yogurt, ice creams, custard, dairy desserts, and manufactured food using any milk-based ingredient	Casein, caseinates, curd, lactoglobulin, lactose, milk solids, whey, buttermilk, milk sugar, whey sugar, whey syrup sweetener	Vitamin A, vitamin D, riboflavin, pantothenic acid, cyanocobalamin, calcium, magnesium, phosphate	Under 2 years: Extensively hydrolyzed (casein/whey) Hydrolyzed rice formulas [#] Amino acid–based formulas ^{##} Over 2 years Calcium-enriched, milk-free alternative drinks may be considered: <ul style="list-style-type: none"> • Rice milk (in some countries rice not allowed <4.5 years due to high arsenic content) • Soy milk • Oat milk • Chufa milk • Potato milk • Almond milk • Coconut milk • Pea milk Other foods: Milk-free versions of spreading fats/margarine, cheese, yogurts, ice cream, and cream
Egg **	Egg white and yolk, cakes, biscuits, specialty breads, mayonnaise	Albumin, dried egg, egg powder, egg protein, frozen egg, globulin, lecithin, livetin, ovalbumin, ovomucin, ovovitellin, pasteurized egg, vitellin	Riboflavin, biotin, protein, vitamin A, cyanocobalamin, vitamin D, vitamin E, pantothenic acid, selenium, iodine, folate	Egg replacers Adjust recipes with extra liquid or fruit purees Variety of egg-free products such as mayonnaise, cakes, muffins, puddings, and omelet mix
Wheat ***	Bread, breakfast cereals, pasta, cakes, biscuits, crackers, cold cooked meat, pies, batter, flour, cake flour, enriched flour, high-gluten flour, high-protein flour, graham flour, semolina, couscous, bottled sauces and gravies	Bran, cereal filler, farina, farro, starch, wheat, durum wheat, semolina, spelt, kamut, wheat bran, wheat gluten, wheat starch, wheat germ oil, hydrolyzed wheat protein, triticale, bulgur wheat, einkorn wheat, emmer wheat	Fiber, thiamine, riboflavin, niacin, calcium, iron, folate if fortified	Corn, rice, potato, cassava, yam, quinoa, millet, chickpea, sago, tapioca, amaranth, buckwheat Wheat-free and/or gluten-free foods, barley, rye, and regular oats may be tolerated by some individuals with wheat allergy or intolerance; however, they contain gluten Gluten-free oats may be tolerated by some individuals with celiac disease Use of alternative grains should be individualized and based on tolerance as determined by clinician and/or dietitian.

TABLE 25.4 Allergen Avoidance Guidelines—cont'd

	Sources	Other Terms	Nutrients Involved	Alternatives
Fish	All types of white and fatty fish, anchovy, (Worcestershire sauce), aspic, Caesar salad, Gentleman's Relish, kedgeree, caponata, fish sauce, paella, bouillabaisse, gumbo Some people may tolerate canned fish Fish oil capsules may cause reactions in highly sensitized individuals	Surimi Caviar	All fish: protein, iodine Fish bones: calcium, phosphorus, fluoride Fatty fish: vitamins A and D, omega-3 fatty acids	
Shellfish	Crayfish, crab, lobster, shrimp, prawns		Similar nutrients to white fish. Crab and mussels: good sources of omega-3, selenium, zinc, iodine, and copper	
Mollusks	Clams, mussels, oysters, octopus, squid, snails, scallops	Health food preparations such as green-lipped mussel extract, oyster sauce	Varying amounts of protein (scallop), calcium (clam), zinc (oysters), and iron (clam)	
Peanut****	Peanuts, defatted peanuts, peanut flakes, expeller-pressed peanut oil, peanut flour, peanut butter, peanut snacks, satay sauce May contain peanut: sprouts, confectionery, frozen desserts, Asian dishes (Indonesian, Malaysian, Thai, and Chinese), trail mix, energy or sports bars, rice crackers, cereal bars, cookies, brownies, nut toppings on ice cream, vegetarian/vegan foods, breakfast cereals, pesto sauce may sometimes contain peanut	Arachis oil, hypogeaia, peanut protein, groundnut, earth nut, monkey nut, mandelonas, mixed nuts	Vitamin E, niacin, magnesium	
Tree nut Almond, hazelnut, walnut, cashew nut, pecan nut, Brazil nut, pistachio nut, macadamia nut, Queensland nut	Similar foods as peanut Amaretto contains almond flavor Worcester sauce (walnuts) Korma sauce (almonds)	Hazelnut: filbert, cob nut Macadamia: Queensland nut, candle nut Pecan: Hickory nut Note: Nutmeg, coconut, pine nut, and palm nut are not classified as nuts	Depends on type of nut	
Sesame seed	Sesame seeds, sesame oil, halva, tahini, hummus, seeded bread/rolls, gomashio, Asian foods made with sesame oil, Greek, Iranian, Lebanese, and Turkish food, Aqua Libra is sometimes made with sesame	Gomasio—sesame seed and salt seasoning	Protein, fats, vitamin E, calcium, potassium, phosphorus, vitamin B and iron Avoidance has no significant effect on nutrition	

Continued

TABLE 25.4 Allergen Avoidance Guidelines—cont'd

	Sources	Other Terms	Nutrients Involved	Alternatives
Celery/celeryiac	Primary allergy: celery and celeryiac in its raw, cooked, juiced, canned, and dried (celery spice) form		Fiber Avoidance has no significant effect on nutrition	In PFAS and LTPS, dried celery/celeryiac may be tolerated
Mustard	Mustard Mustard seed Curry powder Pizza Sauces, marinades, dressings		Mainly fat and protein Avoidance has no significant effect on nutrition	
Soy*****	Soy beans, soy flour, soy nuts, soy sauce, shoyu sauce, soy products (soy cheese, soy fiber, soy ice cream), meat substitutes, breads, vegetarian/vegan foods, Asian cuisine, processed meat (e.g., hot dogs), peanut butter, foods labeled as “diet” and “high-protein” or “low-fat,” sport or energy bars	Edamame Tofu Miso Natto Soy protein/gum/starch Texturized (or hydrolyzed) vegetable protein Soy flavoring Soy lecithin Chee-fan Ketjap	Thiamin, riboflavin, pyridoxine, folate, calcium, phosphorus, magnesium, iron, zinc, protein, fiber	Cow's milk Rice milk (in some countries rice not allowed <4.5 years due to high arsenic content) Oat milk Chufa milk Potato milk Almond milk Coconut milk Pea milk Meat, fish, poultry, or other soy-free vegetarian alternatives
Lupin	Often used in Europe in pastries, bread, pizza, and lupin-seeded breads		Protein, fat, fiber, thiamin, riboflavin and vitamin E Avoidance has no significant effect on nutrition	

* Goat and sheep milk proteins are similar to cow milk protein, and those with cow milk allergy could experience similar symptoms with ingestion of these alternatives. All mammalian milk should be avoided initially. Goat milk is not recommended as a cow milk substitute because it has a high renal solute load and is very low in folic acid compared with cow milk.

** People with allergy to chicken egg may also be allergic to other types of eggs, such as goose, turkey, duck, or quail eggs. All should be avoided initially.

*** Note that nonfood products such as cosmetics, supplements, and medications can contain wheat ingredients and may cause an adverse reaction.

**** There is a high risk of contamination of utensils when eating out at Asian, Chinese, Mexican, Thai, Mediterranean, and Indian restaurants. Nonfood products such as cosmetics, supplements, and medications can contain peanut ingredients and may cause an adverse reaction.

***** Several studies indicate that individuals who are soy allergic frequently tolerate soy lecithin and soy oil. There is a high risk of soy cross-contamination when eating out, especially at Asian restaurants. Nonfood products such as cosmetics, supplements, and medications can contain soy ingredients.

Partially hydrolyzed: nonhypoallergenic; contains partially digested proteins that have a molecular weight greater than extensively hydrolyzed formula. May cause a reaction in one third to one half of individuals with a cow's milk protein allergy.

Free amino acid–based infant formula: hypoallergenic; peptide-free formula that contains essential and nonessential amino acids. Usually tolerated by those allergic to extensively hydrolyzed formulas.

LTPS, Lipid transfer protein syndrome; PFAS, pollen-food allergy syndrome.

Sources: Venter C, Groetch M, Netting M, Meyer R: A patient-specific approach to develop an exclusion diet to manage food allergy in infants and children, *Clin Exp Allergy* 48:121, 2018.

Joneja JV: *The Health Professional's Guide to Food Allergies and Intolerances*, Chicago, 2013, Academy of Nutrition and Dietetics.

later (Nowak-Węgrzyn et al, 2017). A Japanese cohort reported FPIES symptoms in 10% of infants after breastfeeding, presumably because of the problematic food protein in the breastmilk from maternal ingestion. Similarly an Australian report found this in 5% of infants (Nomura et al, 2011; Mehr et al, 2017).

Symptoms consistent with FPIES may present in older children and adults with delayed vomiting, often after the ingestion of fish, shellfish, or egg (Leonard et al, 2018). Studies from various countries show that

the most common food triggers are cow's milk, soy, and grains (oats/rice) in the United States and South Korea, fish in Italy and Spain, and rice in Australia (Mehr et al, 2017).

The pathophysiology of FPIES is not well understood, but it is thought that a reaction to a consumed food protein leads to gut inflammation, which causes increased intestinal permeability and a fluid shift resulting in vomiting, diarrhea, abdominal pain, and possibly shock (Leonard et al, 2018). Food-specific IgE antibodies have no

TABLE 25.5 Food Challenge Protocols

Double-blind, placebo-controlled food challenge	Allergen is disguised and given orally and patient monitored for reaction; patient and physician blinded; also tested with placebo.	“Gold standard” for food allergy testing.
Single-blind food challenge	Suspect food is disguised from patient and orally given by physician in a clinical setting.	Less time-consuming than DBPCFC; may be used in instances in which patient experiences symptoms secondary to fear or aversion to suspect food.
Open oral food challenge	Suspect food is orally given to patient in undisguised, natural form in gradual doses under medical supervision.	Less time-consuming than DBPCFC; should not be used in instances in which patient experiences symptoms secondary to fear or aversion to suspect food.

value in the diagnosis; a thorough history followed with a specific food elimination diet and an oral food challenge (OFC) of the suspected food under medical supervision is the only way at present to make a FPIES diagnosis. It is challenging because FPIES mimics many other GI inflammatory disorders.

Treatment of FPIES focuses on removal of the offending food(s) and management of vomiting, dehydration, and shock. For infants with cow's milk or soy FPIES, breastfeeding or use of an extensively hydrolyzed casein formula is encouraged. If cow's milk or soy FPIES exists in the formula-fed infant, supervised introduction of one or the other (soy or cow's milk) formula can be considered. See Table 25.4 for cow's milk-free and soy-free formulas. Maternal avoidance of a breastfeeding infant's FPIES triggers is not recommended if the infant is thriving and asymptomatic (Nowak-Węgrzyn et al, 2017). Mothers should avoid trigger food(s) if a reaction occurs after breastfeeding or if the infant is failing to thrive. If symptoms still do not resolve, discontinuing breastfeeding and introducing an extensively hydrolyzed formula (EHF) should be considered. See Nowak-Węgrzyn et al (2017) for feeding guidelines.

Nutritional adequacy, feeding skill development, and diet expansion is vital to any infant's nutrition and development, especially in those with multiple food FPIES or feeding issues. FPIES patients should be monitored regularly for the development of tolerance and eventually diet expansion, with medically supervised oral food challenges (Table 25.5).

Food Protein–Induced Proctitis or Proctocolitis (FPIP)

In **food protein–induced proctocolitis or proctitis or (FPIP)**, bloody and mucus-laden stools are seen in an otherwise apparently healthy baby, often at about 2 months of age. Parents are concerned when they see flecks of blood in their baby's stool, but it is usually slight and further development of anemia is rare. Common trigger foods are cow's milk protein or soy protein from infant formula, and their removal from the infant's diet usually solves the problem. In the case of the breastfed infant, the mother should remove these foods from the diet and continue to breastfeed. For the formula-fed infant, it becomes necessary to switch to an EHF, such as any of those listed in Table 25.4. However, sometimes the infant requires an elemental formula, examples of which are also listed in Table 25.4 and in Chapter 15. The bleeding usually disappears within 3 days of implementing a formula change or change in the breastfeeding mother's diet. In most cases the FPIP resolves itself by the time the baby is 1 to 2 years old, and offending foods can be introduced with monitoring of the baby's stool for blood (Meyer et al, 2018; NASEM, 2017).

FOOD INTOLERANCES

Food intolerances are adverse reactions to food that result in clinical symptoms caused by nonimmunologic mechanisms including

microbial, pharmacologic, GI, metabolic, psychological and behavioral, or idiosyncratic. They are believed to be far more common than food allergies and are usually triggered by small-molecular weight chemical substances such as food additives and biologically active components of food such as biogenic amines. Symptoms induced by food intolerances are often similar to those of food allergy and may include GI, cutaneous, respiratory, and neurologic manifestations. Clinically, it is important to distinguish food intolerance from immune-mediated food allergy because food allergies can cause life-threatening anaphylactic reactions, whereas food intolerances do not (see Table 25.2).

Gastrointestinal Manifestations

Lactose Intolerance

Intolerance to the disaccharide lactose is the most common adverse reaction to food, and most cases result from a genetically influenced reduction of intestinal lactase. It is estimated that about 70% of the world's population has low production of lactase (hypolactasia) (Ugidos-Rodríguez et al, 2018). Symptoms of lactose intolerance, abdominal bloating and cramping, flatulence, and diarrhea, usually appear several hours (even up to 24) after lactose ingestion and last for several hours. Because some of the GI symptoms are similar, lactose intolerance is often confused with allergy to cow's milk. However, most individuals who are allergic to cow's milk also have symptoms in other organ systems, including the respiratory tract, skin, and, in severe cases, systemic anaphylactic reactions. Deficiencies of lactase and other carbohydrate-digesting enzymes and their management are discussed further in Chapter 27.

FODMAPs Intolerance

Maldigestion and malabsorption of the fructo-, oligo-, di-, and monosaccharides and polyols (FODMAPs) appear to be becoming more common. Humans lack the hydrolase enzymes necessary to break down the bonds in the fructose polymer chains, so in many individuals, intake of large quantities of FODMAPs will lead to bloating, diarrhea, cramping, and flatulence. FODMAPs intolerance appears to be more common in individuals who have an underlying functional GI disorder, such as irritable bowel syndrome and small intestine bacterial overgrowth (SIBO). See Chapter 27 for more information about FODMAPs.

Gluten Intolerance

Nonceliac gluten intolerance (or sensitivity) is a condition that is being diagnosed more frequently. It is best defined as intestinal or extraintestinal symptoms that occur when gluten-containing grains are included in the diet, which resolve when the offending grains are removed from the diet. It can easily be confused with a food allergy, but it is not an allergic reaction, at least not based on our present understanding

(DeGeeter and Guandalini, 2018). It remains controversial whether gluten proteins found in wheat, rye, and barley are the cause of symptoms for those with gluten intolerance.

There is some research suggesting that fructan intolerance may be the cause of symptoms for some people, not the gluten proteins (Igbinedion et al, 2017). Because of this, the term nonceliac wheat sensitivity (NCWS) is often used to describe this condition. This is different than the other gluten-related disorder, celiac disease, which is an autoimmune reaction that occurs in the presence of gluten proteins in the diet. See Chapter 27 for a discussion of celiac disease and its dietary management.

Pharmacologic

An adverse reaction to a food may be the result of a response to a pharmacologically active component in that food. A wide range of allergy-like symptoms can result from ingestion of biogenic amines such as histamine and tyramine. Salicylates, monosodium glutamate, or food additives such as benzoates can also cause reactions.

Histamine

Histamine is a biogenic amine produced endogenously with very important functions. It is released as the first inflammatory mediator in an allergic reaction or in a physical defense reaction. When it is released and reaches a certain level, it can cause vasodilation, erythema, increased permeability of cell membranes, digestive tract upset, pruritus (itching), urticaria (hives), angioedema (tissue swelling), hypotension, tachycardia (heart racing), chest pain, nasal congestion (rhinitis), runny nose (rhinorrhea), conjunctivitis (watery, reddened, irritated eyes), headache, panic, fatigue, confusion, and irritability.

Everyone has a level of histamine that is tolerated, and when that level is exceeded in the body the symptoms of excessive histamine develop. Basal levels of 0.3 to 1 ng/mL are considered normal

(Joneja, 2017). Individuals can have increased levels of histamine due to stress, hormonal changes, and GI impairment, including inflammation or infection. Some people are more sensitive to histamine than others, usually because of a genetically determined inability to catabolize or break down histamine fast enough to keep the levels low so that histamine-induced symptoms are not triggered. One percent of the U.S. population suffers from histamine intolerance, and 80% of those sufferers are middle-aged (Maintz and Novak, 2007).

Symptoms of excessive histamine may be indistinguishable from those of food allergy because of histamine's mediator function in allergic reactions. However, histamine intolerance does not have an IgE-based mechanism as food allergy does. In histamine intolerance there is excessive histamine for the following reasons: (1) certain foods naturally contain large amounts of histamine, or its precursor histidine (which through fermentation becomes histamine), which then causes a reaction in the histamine sensitive individual; (2) some individuals are not able to deactivate or metabolize histamine in a timely manner because of a deficiency of the enzymes **diamine oxidase (DAO)** or **histamine-N-methyltransferase (HNMT)**; or (3) there is the presence of other amines that also influence the histamine reaction.

Foods with a high histamine content include fermented foods, sauerkraut, aged cheeses, processed meats and fish, alcoholic beverages (beer and wine), and leftovers. Strawberries, citrus fruits, pineapple, tomatoes, spinach, egg whites, fish, shellfish, and some food additives (e.g., tartrazine) and preservatives (e.g., benzoates) stimulate histamine release from mast cells. The mechanisms for this reaction are not clear. Histamine intolerance or sensitivity may be suspected when an allergic cause for symptoms has been ruled out (Joneja, 2017). With true histamine intolerance, treatment with a histamine-restricted diet (Box 25.5) can be very helpful. The diet should be implemented for 6 weeks, with the patient keeping records of intake and symptoms followed by evaluation of progress in reduction in symptoms.

BOX 25.5 Histamine-Restricted Diet

General Description

This eating plan is designed to remove foods that contain high levels of histamine and foods and food additives that release histamine in the body. It is a test diet for people with high histamine levels and associated symptoms for which other treatments have been of little value.

Food Sources of Histamine

Histamine is present in large quantities in fermented foods. Microbial enzymes convert the amino acid histidine (present as a constituent of all proteins) to histamine in a biochemical process known as decarboxylation.

Any foods that have been subjected to microbial fermentation in their manufacture, for example: Continental sausages such as bologna, salami, pepperoni, wieners, most cheeses, soy sauce, miso, sauerkraut, alcoholic beverages, "de-alcoholized" beverages, and vinegars contain histamine.

Foods that have been exposed to microbial contamination will contain histamine: the level is determined by the rapidity of action of microbial metabolism. Histamine levels will rise to a reactive level long before any signs of spoilage occur in the food. This is particularly important in fish and shellfish. Bacteria in the gut will start to convert histidine to histamine as soon as the fish dies. The longer the fish remains ungutted, the higher the level of histamine in the flesh.

Some foods, such as eggplant (aubergine), pumpkin, tomato, olives, and spinach, contain high levels of histamine naturally.

In addition, a number of food additives such as certain food dyes (e.g. tartrazine) and preservatives (e.g. benzoates) are known to mediate the release of histamine. Some of these, for example, benzoates, occur naturally in foods,

especially fruits, and have the same ability to release histamine as the food additive.

The histamine-restricted diet excludes all the foods, which are known to contain high levels of histamine, and chemicals that can release histamine when they enter the body.

Histamine-Restricted Diet

Avoid the following foods during the 4 week trial elimination period.

Meat, Poultry, Fish

- Fish and shellfish whether fresh, frozen, smoked, or canned, if processing is unknown
 - If the fish is freshly caught, gutted and cooked within ½ hour, it may be eaten
- Egg
 - A small quantity of cooked egg in a baked product such as pancakes, muffins, or cakes is allowed
- Processed, smoked, and fermented meats such as luncheon meat, sausage, hot dog or wiener, bologna, salami, pepperoni, smoked ham, cured bacon

Milk and Milk Products

- All fermented milk products, including:
 - Cheese:
 - Any kind of fermented cheese such as cheddar, Colby, blue cheese, Brie, Camembert, feta, Romano, and so on.

BOX 25.5 Histamine-Restricted Diet—cont'd

- Cheese products such as processed cheese, cheese slices, cheese spreads
- Cottage cheese
- Ricotta cheese made with microbial culture (read label)
- Yogurt
- Buttermilk
- Kefir
 - Any milk product that is curdled rather than fermented is allowed (e.g., paneer)

Fruits

- Citrus (orange, grapefruit, lemon, lime)
- Cherries
- Strawberries
- Apricots
- Raspberries
- Pineapple
- Cranberries
- Prunes
- Loganberries
- Dates
- Raisins
- Currants (fresh or dried)

Vegetables

- Tomatoes, tomato sauces, ketchup
- Spinach
- Eggplant
- Pumpkin
- Olives
- Pickles, relishes, and other foods containing vinegar

Food Additives

- Tartrazine and other artificial food colors

- Preservatives, especially benzoates, sulfites, and butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT)
 - Note: Many medications and vitamin pills contain these additives; ask your pharmacist to recommend additive-free supplements and medications

Seasonings

- Cinnamon
- Cloves
- Thyme
- Chili powder
- Anise
- Vinegar (except distilled)
- Curry powder
- Nutmeg

Miscellaneous

- Fermented soy products (such as soy sauce, miso)
- Fermented foods (such as sauerkraut)
- Tea (regular or green)
- Chocolate, cocoa, and cola drinks
- Alcoholic beverages of all types
- “Dealcoholized” beverages (e.g., beer, ale, wine, etc.)

This diet excludes all:

- Foods with naturally high levels of histamine
- Fermented foods
- Artificial food colors, especially tartrazine
- Benzoates including food sources of benzoates, benzoic acid, and sodium benzoate
- Sulfites
- BHA and BHT

Source: Joneja, JA: Histamine Intolerance: a Comprehensive Guide for Healthcare Professionals, 2017, e-published.

Tyramine

Tyramine is a biogenic amine formed from the amino acid tyrosine that is found naturally in some foods, plants, and animals. Like histamine, it can also be produced in foods as a result of fermentation, curing, aging, or spoilage of produce, dairy products, and meats. Because of the rate and extent of these processes, the tyramine content of foods varies widely. Examples of foods high in tyramine are aged cheeses, soy sauce, aged meats, pickled fish, tofu, sauerkraut, and tap beer.

Tyramine can have pharmacologic activity and can cause a rise in blood pressure. Because of this the body produces monoamine oxidase (MAO), an enzyme that guards against the build up of too much tyramine and other amines in the body, including monoamine neurotransmitters (e.g., norepinephrine, dopamine, and serotonin), and changes them into harmless compounds that can be excreted from the body safely. MAO is present in the GI tract, the liver, nerve endings, and the brain. An individual can develop an intolerance to tyramine when there is too much tyramine present in the diet, or when there is not enough MAO activity to keep its level in check. Intolerance is evidenced by blood pressure changes. Large amounts of tyramine can cause the release of excess norepinephrine, which constricts the blood vessels, causing blood pressure to rise, sometimes to a dangerously high level, known as a hypertensive crisis.

Ingestion of tyramine-containing foods also may cause migraine headaches or chronic hives in tyramine-sensitive individuals, with the response being dose dependent (Skypala et al, 2015b).

Tyramine intolerance can develop in some individuals who are taking the medication monoamine oxidase inhibitors (MAOIs), which interfere with the breakdown of tyramine. Fortunately, these medications are not prescribed as frequently today as in the past.

Other Amines and Food Additives

When histamine or tyrosine are present in foods, other biogenic amines such as lesser known putrescine, cadaverine, tryptamine, 2-phenylethylamine, spermine, and spermidine may also be present. Like histamine and tyramine, they are mainly produced by microbial decarboxylation of amino acids in the foods and can cause reactions.

Some food components are actually added to foods, and they also appear to be able to cause reactions, although they are poorly understood. Food additives such as salicylates, carmine (cochineal extracts), artificial food dyes and colorings such as FD&C yellow #5, and preservatives such as benzoic acid, sodium benzoate, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), nitrates, sulfites, and monosodium glutamate (MSG) can cause adverse reactions in certain individuals (Vojdani and Vojdani, 2015).

Sulfites are widely used as preservatives and antioxidants in many food products. Reactions to sulfites, including sodium metabisulfite and sodium sulfite, result in a diverse range of symptoms in sulfite-sensitive individuals. These can include dermatitis, urticaria, hypotension, abdominal pain, diarrhea, and life-threatening asthmatic and anaphylactic reactions (Vally and Misso, 2012). The mechanisms remain unclear.

Adverse reactions to MSG were originally reported as the “Chinese restaurant syndrome” because of its use in Chinese cooking. Complaints of headache, nausea, flushing, abdominal pain, and asthma occurred after ingestion. MSG is widely distributed in the food supply (e.g., bouillon, meat tenderizers, canned food, frozen food, condiments) and occurs naturally in tomatoes, Parmesan cheese, mushrooms, and other foods. Results from double-blind, placebo-controlled food challenges (DBPCFCs) found symptoms from MSG to not be persistent, clear, consistent, or serious (Geha et al, 2000; Williams and Woessner, 2009).

However, more recent data in animals and humans have indicated that MSG consumption may be a contributing factor to increased risk of overweight, independent of physical activity and total energy intake (He et al, 2011). Considering the ongoing debate about this common flavoring agent as an obesogenic agent, nutrition practitioners should be aware of MSG sensitivity (Savcheniuk et al, 2014).

A diet that is being used for those individuals with suspected intolerances to dietary amines, salicylate, and food additives is the **FAILSAFE diet**, a diet “free of additives, low in salicylates, amines, and flavor enhancers” designed by the Royal Prince Alfred Hospital in Australia. This diet is intended to be used for the investigation and management of people with suspected food intolerance. The FAILSAFE diet excludes strong-tasting and smelling foods and environmental chemicals, in particular:

1. **About fifty artificial food additives**, including colors (like tartrazine, sunset yellow), flavors, preservatives, and antioxidants (sulfites, nitrates, benzoates, sorbates, parabens).
2. **Salicylates (aspirin)** and polyphenols (natural flavors, colors, and preservatives) found in a wide range of fruits and vegetables.
3. **Neurotransmitters in food:** free glutamates (MSG) and amines (histamine, serotonin, dopamine, phenylethylamine, tyramine, and others) found in aged proteins and fermented foods like cheese, chocolate, game, and aged meat.
4. **Aromatic (strong-smelling and tasting) chemicals** found in perfumes, cleaning products, commercial cosmetics, and scented and colored toiletries, especially mint and menthol products.
5. **Some pharmaceutical drugs**, including aspirin, NSAIDs and other COX II inhibitors including ibuprofen, and the methyl-salicylates found in decongestants and antiinflammatory creams.

Practicalities of the diet can be found at www.FAILSAFEdiet.com.

Microbial Contamination and Toxins

Food toxicity or food poisoning results from microbial contamination of food and causes myriad symptoms, including nausea, vomiting, diarrhea, abdominal pain, headache, and fever, many of which can be confused with an allergic reaction. It is estimated that in the United States 9.4 million people per year are affected by foodborne illness, with 31 known pathogens identified (Scallan et al, 2011). Fortunately, most episodes are self-limiting and should be distinguished from food allergy or intolerance from a thorough history. If the cause of the symptoms cannot be determined to be a food toxin or microbial contamination, then a single food elimination diet followed by a challenge of that food may be necessary (see Table 25.4).

Psychogenic and Behavioral Factors

Evidence for the role of food allergy or intolerance in various disorders such as anxiety, depression, migraine headache, attention/

deficit-hyperactivity disorder, and mood disorders is emerging. Increased intestinal permeability, dysbiosis, neurotransmitter production by the gut, and gut immune system response are currently being investigated as contributing factors (see Chapters 27 and 40). If a food-symptom relationship cannot be shown for the food intolerance, but food avoidance is perceived as helpful because of the patient’s personal experience, appropriate medical nutrition therapy may include food elimination and other therapeutic interventions.

MEDICAL NUTRITION THERAPY

Assessment

A thorough history and timeline including perinatal, prenatal, and birth history (e.g., vaginal or C-section), early feeding practices (breastfed vs. formula), childhood illnesses, past and current medical history, medications (for example, antibiotics, proton-pump inhibitors, etc.) dietary supplements (including probiotics), exercise patterns, and lifestyle factors (stress, sleep, relationships), along with a comprehensive diet history and food habits, helps to determine possible root causes contributing to adverse food reactions.

Anthropometric measurements are also essential as a component of nutritional assessment. The infant’s and child’s anthropometric data should be plotted on a growth chart and evaluated over time (see Appendix 4). Because decreased weight-for-height measurements may be related to malabsorption or food avoidance due to allergy or intolerance, patterns of growth and their relationship to the onset of symptoms should be explored (Meyer et al, 2014).

A nutrition-focused physical examination is also important in assessing the patient with adverse food reactions. Clinical signs of malnutrition should be assessed and monitored with ongoing dietary therapy (see Chapter 5 and Appendix 11).

A 7- to 14-day **food and symptom record** is extremely useful for uncovering adverse food reactions (Fig. 25.4). The food and symptom record should include the time the food is eaten, the quantity and type of food, all food ingredients if possible, the time symptoms appear relative to the time of food ingestion, and any supplements or medications taken before or after the onset of symptoms. Other influences such as stress, physical exercise, urine and bowel elimination, and sleep patterns, along with environmental factors, provide valuable information in piecing together the factors that affect adverse food reactions. The more thorough the information obtained about the adverse reaction, the more useful the record. For example, a reaction that appears to be caused by a food actually may be caused by a pet or a chemical or another environmental factor. A patient may prefer to use an app designed to track this type of data (see Chapter 4). The comprehensive food and symptom record is used to assess nutritional adequacy and also serves as a tool for future therapeutic interventions.

DIAGNOSIS

Diagnosis of adverse food reactions requires identification of the suspected food or food ingredient, proof that the food ingestion causes the adverse response, and verification of an immune or nonimmune-mediated response. The detailed food and symptom record as part of a comprehensive nutrition assessment is also a diagnostic tool. This information may be followed with appropriate immunologic testing by a physician; however, tests for food allergy are not completely definitive and should always be used in conjunction with a comprehensive physical examination, clinical history, and nutrition assessment (Boyce et al, 2010; Skypala et al, 2015). See Table 25.3 for a complete description of tests used in diagnosis of food allergy.

3-DAY FOOD JOURNAL

Name: _____

It is important to keep an accurate record of your usual food and beverage intake as a part of your treatment plan. Please complete this Food Journal for three consecutive days including one weekend day.

- Do not change your eating behavior at this time, as the purpose of this food record is to analyze your present eating habits
- Record information as soon as possible after the food as been consumed
- Please describe all foods and beverages consumed as accurately and in as much detail possible including estimated amounts, brand names, cooking method, etc.
- Record the amount of each food or beverage consumed using standard measurements such as 8 ounces, 1/2 cup, 1 teaspoon, etc.
- Included any added items, for example: tea with 1 tsp honey, potato with 2 tps butter, etc.
- List all beverages and types, including water, coffee, tea, sports drinks, sodas/ diet sodas, etc.
- Please comment on any noted emotional or physical symptoms including hunger level, stress, bloating, fatigue, adverse reaction experienced, etc.
- Include comments about eating habits and environment such as reasons for skipping a meal, when a meal was eaten at a restaurant, etc. and any additional details that may be important
- Each day please note all bowel movements, describe their consistency (regular, loose, firm, etc.), frequency, and any additional information
- If desired, an online site or app such as myfitness pal, www.fitday.com, etc. can be used—be sure to send me your login username and password.

Immunologic Testing

Skin-Prick Test

In **skin-prick tests (SPT)** drops of standard food extracts are placed on the skin of the arm or back. The skin is then scratched or pricked with a lancet with each drop of extract. The areas of application are then observed for the development of the classic “wheal and flare” reaction. In theory, if the underlying mast cells have attached sIgE, inflammatory mediators are released. The wheal and flare reaction results from the action of the mediators, especially histamine, on the surrounding tissue. These skin-prick tests are the most economic immunologic tests of an Ig-E mediated reaction, providing results within 15 to 30 minutes. Comparison with the positive control (histamine)

and the negative control (saline) provide parameters necessary for accurate readings (Fig. 25.5). All skin-prick tests are compared with the control wheal. Test wheals that are 3 mm greater than the negative control usually indicate a positive result.

Negative skin-prick tests have good negative predictive accuracy and strongly suggest the absence of an IgE sensitization and therefore an IgE-mediated reaction. Positive skin-prick test results, however, indicate only IgE sensitization and the possibility of a food allergy reaction. In the patient with a suspected food allergy, the skin-prick test is useful in supporting the diagnosis. For children younger than 2 years of age, the skin test is reserved to confirm immunologic mechanisms after symptoms have been confirmed by a positive test result from a

Fig. 25.5 A skin-prick test showing the wheal and flare of the reaction to the allergen. From www.istockphoto.com

supervised food challenge, or when the history of the reaction is impressive.

All foods that test positive must correlate with a strong exposure history or be proven to cause allergic reactions through food challenges before they can be considered allergenic (see Table 25.4). The most common food allergens in the United States (milk, egg, peanut, soy, wheat, shellfish, fish, and tree nuts) account for most of the positive food skin-prick tests (NASEM, 2017).

Serum Antibody Tests

Food allergen–specific serum IgE testing is used to identify foods that may be causing the allergic response. The two systems in use are ImmunoCAP or ImmunoCAP ISAC system, and the Immulite system. They are similar in that they measure for the presence of IgE antibodies sensitized to various allergens. This type of test provides a quantitative assessment of sIgE antibodies; higher levels of antibodies are often, but not always, predictors of clinical symptoms. It is a fairly effective test, as shown by testing known food-allergic children whose food allergies had been previously proven with DBPCFCs (NASEM, 2017).

Test results should be followed with either food elimination and challenge, or DBPCFCs to complete the diagnostic process. It should be noted that ImmunoCap or Immulite results or skin-testing results for IgE sensitization may remain positive even after the child has resolved the food allergy, and the food can be eaten without symptoms.

Component resolved diagnostics (CRD) testing is emerging as a useful tool in assessing food allergy. CRD involves testing for IgE sensitized to specific component proteins in foods and not just the whole protein extract. The aim of the test is based on the understanding that some proteins within a food may be more potent in causing an allergic reaction than others within the same food. For example, clinically relevant proteins may resist digestion, and IgE immune responses against such proteins may have a greater diagnostic value for systemic allergy than immune responses against more labile proteins that degrade easily and are not systemically absorbed and therefore will not cause a reaction. Much research is being done using CRD to determine which components of peanut protein are likely to cause anaphylaxis or a severe allergic response to peanuts and which will not (NASEM, 2017) (see Table 25.3).

Other Tests

A number of laboratory tests are now available that attempt to identify an individual's specific adverse reactions to foods. Some of these tests

measure IgA, IgG, and IgG4 levels and are not considered reliable. Others (ALCAT and MRT) measure the amount of cytokines released by lymphocytes and granulocytes upon degranulation in response to food antigen exposure and may be useful identifying food intolerances that are not IgE mediated (Garcia-Martinez et al, 2018). Continued scientific investigation into the validity of various types of food reactivity testing is warranted (Vojdani, 2015b; see Table 25.3).

Nonimmunologic tests that may be useful in diagnosing food intolerance versus food allergy include:

- a comprehensive metabolic profile with complete blood count and differential
- stool tests for inflammatory markers, ova, parasites, or occult blood
- breath hydrogen tests for intestinal bacterial imbalance and SIBO
- genetic tests for celiac disease and gluten sensitivity, or for histamine intolerance

INTERVENTION

Elimination Diets

The **elimination diet**, which entails both an elimination phase and a systematic food challenge or food reintroduction phase, is the most useful tool in both the diagnosis and management of adverse food reactions. With the elimination diet, suspect foods are eliminated from the diet for a specified period determined by the nutrition assessment (usually 2 to 8 weeks), which is then followed by a reintroduction or food challenge phase. All forms (i.e., cooked, raw, frozen) of a suspected food trigger are removed from the diet, and a food and symptom record (see Fig. 25.4) is kept during the elimination phase. This record is used to ensure that all forms of suspected foods have been eliminated from the diet, to evaluate the nutritional integrity of the diet, and to document reactions when suspected foods are reintroduced.

Diets must be personalized and may entail excluding only one or two suspect foods at a time to see if there is improvement in symptoms, or it may mean eliminating several foods if multiple foods are suspected. This would entail a more limited diet such as the SFED, as shown in Box 25.4, but again the diet should be individualized as much as possible. The elimination of multiple foods can compromise nutritional integrity, especially if the individual is already at nutritional risk due to symptoms that affect dietary intake (e.g., eosinophilic esophagitis) (Skypala and McKenzie, 2018).

Elemental formulas, medical foods, or hypoallergenic formulas also may be used for additional nutrition support when using an elimination diet. An elemental formula provides high-quality calories in an easily digestible, hypoallergenic form and helps to optimize nutritional intake. These products are usually reserved for highly restrictive diets. A hydrolyzed infant formula (HF) or EHF may be required for the allergic infant who is not being completely breastfed, and who needs to avoid several foods as the diet is expanded (see Table 25.4).

After the designated elimination phase, foods are systematically reintroduced into the diet one at a time to determine any adverse reactions while the person is carefully monitored. If symptoms persist with careful avoidance of suspect foods, other causes for the symptoms should be considered. If a positive result has been obtained on a skin-prick test or sIgE blood test and symptoms improve unequivocally with the elimination of the food, that food should be excluded from the diet until an OFC is appropriate. The OFC will further prove or disprove a food-symptom relationship. If symptoms improve with the elimination of multiple foods, then multiple food challenges will be necessary.

An **oral food challenge (OFC)** is conducted in a supervised medical setting once symptoms have resolved, and when the person is not taking certain medications, such as antihistamines. Foods are challenged one at a time on different days while the person is carefully observed in a medical setting for the recurrence of symptoms (see Table 25.5). The form of the challenged food may be important in the nutritional assessment of adverse food reactions. For example, if someone is allergic to milk or eggs, they may be able to tolerate baked (heat-denatured) forms of these proteins but not the unbaked form (Venter et al, 2018).

Allergic individuals and their families need guidelines and suggestions for avoiding allergenic foods and ingredients, substituting permissible foods for restricted foods in meal planning and preparation, and selecting nutritionally adequate replacement foods.

Care providers and school personnel working with the food-allergic child must be trained to read labels carefully before purchasing or serving food. The Food Allergy and Anaphylaxis Network, a non-profit organization created to support children with food allergies, has worked with board-certified allergists and dietitians to develop an excellent education program for parents and day-care or school programs.

To help identify and avoid offending foods, allergy-specific lists that describe foods to avoid, state key words for ingredient identification, and present acceptable substitutes are useful and necessary in counseling (see Table 25.4).

Food ingredients to be avoided may be hidden in the diet in unfamiliar forms. When a person ingests a hidden allergen, the most common reason is that the “safe” food was contaminated. This may happen as a result of using shared serving utensils, such as at an ice cream stand (e.g., where the same scoop and rinsing water is used for both ice cream and dairy-free sorbet), salad bar, or deli (e.g., where the meat slicer may be used to slice meat and cheese). Another practice may be using the same oil to fry potatoes and fish or using the same toaster for gluten and nongluten breads (Box 25.6). Manufacturing plants or restaurants may use the same equipment to produce two different products (e.g., peanut butter and almond butter) and despite cleaning, traces of an allergen may remain on the equipment between uses.

The unknowing ingestion of an allergenic food can also occur when one product is used to make a second product, and only the

BOX 25.6 Reasons for Accidental Exposure to Allergens

- Common serving utensils used to serve different foods when some may contain the allergen
- Grocery store bulk bins contaminated with an allergen from another product bin
- Manufacture of two different food products using the same equipment without proper cleaning in between
- Misleading or inaccurate labels (e.g., nondairy creamers that contain sodium caseinate)
- Ingredients added for a specific purpose are listed on the label only in general terms of their purpose rather than as a specific ingredient (e.g., egg white that is simply listed as an “emulsifier”)
- Addition of an allergenic product to a second product that bears a label listing only the ingredients of the second product (e.g., mayonnaise, without noting eggs)
- Switching of ingredients by food manufacturers (e.g., a shortage of one vegetable oil prompting substitution with another)
- A child being offered a food by an individual who is uneducated about the allergy

BOX 25.7 Allergen Labeling of Foods

Since January 1, 2006, the updated **U.S. Food Allergen Labeling and Consumer Protection Act (FALCPA)** requires the top allergens to be clearly listed by manufacturers as an ingredient or following the ingredient list on food labels. This includes ingredients in any amount and also mandates specific ingredients to be listed, such as the type of nut or seafood.

Requirements of the Law

- **Top eight allergens must be clearly listed** by manufacturers as an ingredient or following the ingredient list on food labels of any food product containing allergens
- Applies to all packaged foods sold in the United States
- Does not apply to U.S. Department of Agriculture (USDA)-regulated products, including meat, poultry products, and some egg products
- Does not list sources of possible contamination
- Does not apply to prescription medication or alcoholic beverages
- Does not apply to foods packaged or wrapped after being ordered by the consumer

Top Allergens

- Any ingredient containing or derived from the top eight allergens—milk, eggs, fish, shellfish, tree nuts, peanuts, wheat, or soybeans
- For tree nuts, fish, and shellfish, the specific type must be listed (e.g., walnut, pecan, shrimp, tuna)

Reading the Food Label

- Ingredients may be included within the food's ingredient list directly or in parentheses following the name, if an ingredient does not clearly identify the allergen
- Following the list of ingredients all food allergens may be listed in a “Contains” statement
- Manufacturers may voluntarily list potential unintended allergens that may be present due to cross contamination in a clear way that does not interfere with the required food ingredient list. This is called precautionary allergen label (PAL).

Note: In 2013 the FDA issued a final rule defining “gluten-free” for food labeling. This final rule requires that items labeled “gluten-free” meet a defined standard for gluten content.

Note: It is being proposed that sesame be added to the list of top allergens required on labels.

ingredients of the second product are listed on the food label. An example is the listing of mayonnaise as an ingredient in a salad dressing without specifically listing egg as an ingredient of the mayonnaise. Labels must be read thoroughly to ensure that ingredients have not changed in the processing of the food. The U.S. **Food Allergen Labeling and Consumer Protection Act (FALCPA)** and the **precautionary allergen labeling (PAL)** regulations are described in Box 25.7.

MONITORING AND EVALUATION

The nutritional adequacy of the diet should be monitored on a regular basis when implementing elimination diets. An ongoing evaluation of the patient's food and symptom records is essential since the omission of foods from the diet can affect the nutritional status of the individual.

Individuals, especially children with multiple food allergies, that limit their dietary intake or those who are already on restricted diets for other reasons (e.g., vegan, ketogenic, intermittent fasting) are at the greatest risk of nutritional compromise. Malnutrition and poor

growth may occur in children who consume improperly planned and nutritionally inadequate elimination diets for long periods of time (Keller et al, 2012). Nutritional shortcomings with elimination diets depend on which foods are being excluded.

When foods are removed from the diet, alternative nutrient sources must be provided. For example, a child with cow's milk allergy may have lower intakes of calcium, zinc, and vitamins D and B₂, whereas when eggs are omitted, other foods must provide choline, vitamin D, protein, and energy (Skypala and McKenzie, 2018) (Table 25.6). Dietary supplementation, including vitamins and minerals, may also need to be considered to support nutritional integrity, especially when multiple foods are excluded.

Because food is an important part of a person's culture, the social aspects of eating can make adherence to an elimination diet challenging. Nutritional issues can also arise due to increased anxiety and stress encountered with changes in lifestyle associated with elimination diets. In addition, the plethora of online sources of information and social media now available can contribute to increased confusion about what is best to eat (Skypala and McKenzie, 2018). Continued personalized dietary support from an experienced registered dietitian nutritionist (RDN) is needed to optimally guide patients managing food allergies and intolerances and to minimize the effect of dietary and lifestyle changes on family and social life. Strategies listed in Box 25.8 can help families and individuals cope with adverse food reactions and still maintain quality of life.

TABLE 25.6 Suggested Replacements for Foods Excluded in an Elimination Diet

Food Excluded	Nutrients Provided by That Food	Substitute Foods/Foods with Similar Nutrients	Comments on Problematic Substitutes
Cow's milk	Energy, protein, calcium, B vitamins, iodine. In the United States milk is commonly fortified with vitamins A and D.	Infants: extensively hydrolyzed formula/amino acid formula Children >2 yrs and adults: plant-based milk substitutes with added calcium and vitamin D and protein (e.g., soy milk, almond, cashew, coconut and other nut milks, oat milk, rice milk, and hemp milk). Plant foods such as legumes, broccoli, and dark leafy vegetables and some grains, provide B vitamins and calcium. Fish, containing bones, and tofu set with calcium compounds are also sources of calcium. For some individuals, especially those excluding other foods in addition to milk, supplements may be necessary to meet requirements for energy, protein, and calcium.	Rice milk naturally contains inorganic arsenic, which may be a problem, and in the United Kingdom is not recommended for children under the age of 5 years. Goat or sheep milk products, or mozzarella cheese made from buffalo milk, are not suitable for those with cow's milk allergy or lactose intolerance.
Eggs	Energy, protein, B vitamins (thiamin, riboflavin, niacin, B ₆ , biotin), selenium, vitamin D	These nutrients are widely found in other animal products such as meat, seafood, vitamin D–fortified milk, and other fortified foods. Egg replacement products are available for cooking and baking. These products provide a similar consistency if a recipe calls for eggs but do not provide much nutrition. Products made from algae, yeast, pea, or soy will have more nutrition than those derived from potato starch. Potato starch is a good source of resistant starch for gut microbes.	
Peanuts (legume) and tree nuts	Energy, protein, healthy fats, a range of vitamins and minerals depending on the type of nut, including B vitamins (folic acid, thiamin, B ₆), vitamin E, calcium, selenium, magnesium	Other nuts that do not cause symptoms may be eaten (professional advice should determine which nuts are safe). Individuals with pollen-food allergy syndrome (PFAS) can often tolerate problematic nuts when roasted. Seeds eaten in quantity will provide a similar nutrient profile to nuts, and healthy fats can be obtained from avocados and high-quality vegetable oils.	
Fruits and vegetables	Fiber, a variety of phytonutrients, which act as antioxidants, a variety of vitamins and minerals depending on the fruit or vegetable, including B vitamins (folic acid, thiamin, riboflavin), vitamin C, beta-carotene, calcium, iron, and magnesium	Only those foods that cause symptoms should be excluded, ensuring that a variety of other plant foods are consumed. Individuals with PFAS can usually tolerate problematic foods when they cooked or processed.	

TABLE 25.6 Suggested Replacements for Foods Excluded in an Elimination Diet—cont'd

Food Excluded	Nutrients Provided by That Food	Substitute Foods/Foods with Similar Nutrients	Comments on Problematic Substitutes
Seafood	Protein, calcium (fish bones), iodine, vitamins A and D, vitamin B ₁₂ , omega-3 fatty acids	Individuals with seafood allergy are rarely allergic to all seafood. People with fish allergy may be able to eat shellfish, and those allergic to shellfish may tolerate fin fish. Even those with shellfish allergy may be tolerant of other types of shellfish (e.g., an individual allergic to prawns [crustaceans] may be able to eat mollusks, e.g. clams, mussels, scallops, or oysters). Flaxseeds/linseeds are also a source of omega-3 fatty acids, as are some animal products to a limited extent. Iodine is added to iodized table salt. Sea greens, milk, and eggs are other sources of iodine.	
Soy and other legumes	Energy, protein, fiber, B vitamins, calcium, magnesium, iron, and zinc	Soy and other legumes, along with nuts, are significant sources of protein in plant-based diets. Whole grains are also an important source. It is important that only those foods causing symptoms are avoided.	
Wheat	Energy, protein, fiber, B vitamins (folic acid, niacin, pantothenic acid, riboflavin, thiamin, B ₆), iron, magnesium, phosphorous, selenium, zinc	A variety of nonwheat flours are available for cooking and baking, such as oat, barley, rye, amaranth, buckwheat, millet, quinoa, rice, sorghum, tapioca, and teff. Milk and eggs provide energy, protein, calcium, and B vitamins. Fiber can be obtained from other plant foods. Good sources of iron are meat/fish/poultry and some plant foods. Iron supplementation may be necessary. Those avoiding both milk and wheat, especially if vegetarian or vegan, may need supplements of B vitamins, calcium, iron, and trace minerals.	The grains barley, oat, and rye must also be avoided when gluten also needs to be also eliminated. Fiber can be obtained from other whole grains and plant foods.

PREVENTION OF FOOD ALLERGIES

Intensive research is being focused on prevention strategies for allergic disease, with emphasis on potential genetic, epigenetic, environmental, and modifiable lifestyle risk factors. There is growing interest in the role of microbiome-based therapies in an attempt to promote immunologic tolerance and the central role that nutritional interventions play in manipulating the microbiome. Primary food allergy prevention aims to reduce the infant's risk of sensitization to food allergens, whereas secondary prevention aims to prevent the clinical expression of allergic disease in individuals who are either allergen sensitized or who already manifest other allergic disorders such as eczema or asthma. Allergy prevention guidelines have gradually shifted away from prolonged allergen avoidance to a greater focus on the early introduction of complementary or "solid foods" into the diets of infants (Heine, 2018; West, 2017).

The Canadian Healthy Infant Longitudinal Development (CHILD) study is one of the largest longitudinal studies, involving more than 1000 Canadian mothers and infants, to advance knowledge about the genetic and environmental determinants of atopic diseases (CHILD study, 2018). Data from this study and others have contributed to guidelines on prevention and interventions that appear to reduce the risk of developing food allergy (Box 25.9). A number of hypotheses have been proposed for the prevention of food allergy that warrant further examination.

Microbial Exposure Hypotheses

The interplay between the gut microbiome and environmental microbial burden plays a major role in the immunologic events that lead to

food allergy (Heine, 2018). The microbial hypothesis proposes that a decrease in early childhood exposure to microbes impairs the development of immune regulation and oral tolerance. It incorporates two earlier concepts referred to as the "hygiene hypothesis" and the "old friends hypothesis." These hypotheses assume that immune dysregulation is due to reduced microbial exposure and a lack of fecal microbial diversity.

The hygiene hypothesis was proposed by Dr. David Strachan in 1989 and posits that the increasing incidence of both allergic and autoimmune diseases could be explained by a lack of early childhood exposure to infectious agents which suppressed immune system development. A protective effect against developing allergic rhinitis was observed with an increasing number of siblings in a household. This was related to the shared exposure of common pathogens transmitted through direct contact with other siblings. However, the International Scientific Forum on Home Hygiene (IFH; <https://www.ifh-homehygiene.org>) proposes that the term hygiene hypothesis be abandoned and instead recommends a "targeted hygiene" framework to maximize protection against pathogen exposure while allowing the spread of essential microbes between family members (Bloomfield et al, 2016).

The old friends hypothesis, proposed by Dr. Graham Rook in 2003, maintains that microbe exposure present in primate evolution and hunter-gatherer times was vital to keeping the human immune system in balance and preventing overreactions, which is an underlying cause of allergies. It is hypothesized that another protective effect in reducing the risk of asthma and allergic disease is growing up in a rural environment with exposure to pets and animals versus urban living, although results examining the relationship between animal exposure and food allergies are inconsistent. Changes in lifestyle and environment, such

BOX 25.8 Strategies for Coping with Food Allergy

Food Substitutions

Try to substitute item-for-item at meals. For example, if the family is eating pasta for dinner, substitution of a gluten-free pasta may be better accepted for the gluten-sensitive or wheat-allergic person than a dissimilar item.

Dining Out and Eating Away from Home

Eating meals away from home can be risky for individuals with food allergies. Whether at a fancy restaurant or a fast-food establishment, inadvertent exposure to an allergen can occur, even among the most knowledgeable individuals. Here are some precautions to take:

- Bring “safe” foods along to make eating out easier. For breakfast, bring along an appropriate milk if others will be having cereal with milk.
- Alert the wait staff to the potential severity of the food allergy or allergies.
- Question the wait staff carefully about ingredients.
- Always carry medications.

Special Occasions

Call the host family in advance to determine what foods will be served. Offer to provide an acceptable dish that all can enjoy.

Grocery Shopping

Be informed about what foods are acceptable and read labels carefully. Product ingredients change over time; continue to read the labels on foods, even if they were previously determined to be “safe” foods. Allow for the fact that shopping will take extra time.

Label Reading

Labeling legislation (see Box 25.7) makes it easier to identify certain potential allergens from the ingredient list on food labels. For example, when food manufacturers use protein hydrolysates or hydrolyzed vegetable protein, they must now specify the source of protein used (e.g., hydrolyzed soy or hydrolyzed corn). Although reactions to food colors or food dyes are rare, individuals who suspect

an intolerance will find them listed separately on the food label, rather than categorized simply as “food color.”

Early Feeding

- Exclusive breastfeeding for 4 to 6 months
- If exclusive breastfeeding is not possible, use whey-based, partially hydrolyzed formula

Introduction of Complementary Foods

- From 4 months, early introduction of potential food allergens (peanut, egg, and others) in infants at high risk of developing food allergies

Microbiome-Modifying Interventions

- Human milk oligosaccharides
- Prebiotics (e.g., fructo-oligosaccharides and galacto-oligosaccharides)
- Probiotics (e.g., *Lactobacillus rhamnosus*)

Immune Modulating Nutrients

- Maternal omega-3 polyunsaturated fatty acid supplementation (docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA))
- Vitamin D

General

- Strengthen immunity by increasing connection to natural environments, pets, and farms
- Strengthen immunity by regular exercise
- Consume fermented food or other probiotic preparations to strengthen immune system
- Use antibiotics only when necessary; the majority of microbes are useful and help build healthy immune function
- Do not smoke; parental and family smoking around infants and children can increase risk of asthma

Sources: Heine RG: Food allergy prevention and treatment by targeted nutrition, *Ann Nutr Metabol* 72(suppl 3):34, 2018.

BOX 25.9 Recommendations to Promote Oral Tolerance and Prevent Allergy

- Support breastfeeding and delay introduction of solid foods until 4 to 6 months.
- Strengthen immunity by increasing connection to natural environments, pets, and farms.
- Strengthen immunity by regular physical exercise.
- Use antibiotics only when necessary; the majority of microbes are useful and help build healthy immune function.
- Consume fermented food or other probiotic preparations to strengthen immune system.
- Do not smoke: parental and family smoking around infants and children can increase risk of asthma.

From Haahtela T et al: The biodiversity hypothesis and allergic disease: world allergy organization position statement, *World Allergy Organ J* 6:3, 2013.

as rapid urbanization, highly processed diet, and excessive antibiotic use, have had profound effects that likely contribute to the onset and rise in allergic disease due to immune system aberrations from a lack of early microbial exposure and diversity. Other environmental factors

contributing to the microbial exposure hypothesis include route of delivery at birth and immunizations (Bloomfield et al, 2016).

Route of Delivery

When an infant is born by cesarean delivery, the infant is not exposed to the microbial wash of the mother’s vagina. Vaginally delivered infants have bacterial communities reflecting the mother’s vaginal microbiota, whereas infants born by cesarean delivery have bacterial communities similar to those found on the skin (Dominguez-Bello et al, 2010). Studies examining mode of delivery and risk of food allergy have yielded conflicting results, although one systematic review did find an association between increased risk of developing food allergy or food sensitization in children delivered by cesarean section (Marrs et al. 2013).

Antibiotic Use

It is well established that antibiotics can cause perturbations in the gut microbiota. Infants can be exposed to antibiotics prenatally, at birth, or postnatally. Some infants may have multiple exposures over time, when their microbiome is still being shaped. A link between antibiotic use in early life and food allergies has been demonstrated although the relationship, including timing and frequency of exposure, needs further exploration (NASEM, 2017).

Prebiotics and Probiotics

Considering the importance of the microbiome in immune system regulation, the role of prebiotics and probiotics in allergy prevention continues to be an exploding area of investigation. A **prebiotic** is a substrate that is selectively utilized by host microorganisms conferring a health benefit (Hill et al, 2014). Breastmilk contains human milk oligosaccharides (HMO), which are nondigestible carbohydrates with prebiotic properties that provide the substrate for specific early microbial colonization. Prebiotics have been added to infant formulas, which were previously devoid of oligosaccharides, as they may decrease the incidence of atopic dermatitis. The role of HMO remains an active area of investigation (Heine, 2018).

Probiotics are live microorganisms that, when administered in adequate amounts, confer a health benefit on the host (Hill et al, 2014). Infants with allergies have been shown to have a microbial composition with lower numbers of *Bifidobacteria* compared with healthy infants (Heine, 2018). The administration of probiotics in the last weeks of pregnancy and to infants during the first few months of life is associated with a significant reduction in atopic eczema. However, the effect of the individual probiotic strain, dose, timing, food matrix, and environmental factors that affect colonization need to be explored further since results have been varied (International Scientific Association for Probiotics and Prebiotics, 2016).

The Synergy in Microbiota Research (SyMBIOTA) project is one of the largest infant microbiome studies in the world (CHILD study, 2018). It examines relationships between the infant microbiome and variations in this internal ecosystem such as antibiotic use, presence of pets, and food sensitization, that affect health and disease (Kozyrskyj, 2015; NASEM, 2017). The data suggest that lower species richness in microbiota of infants might be a predictor of food sensitization (i.e., milk, egg, peanut) even when adjustments for delivery mode, antibiotic use, and breastfeeding are considered (Azad et al, 2015). They also found that sensitization occurred after changes in microbiota diversity and richness and that this ratio could be a potential predictor of food sensitization.

Allergen Avoidance Hypothesis

Allergen exposure at conception and during pregnancy and lactation continues to be a focus of research since this is the time of the origin of the infant's immune system development. Maternal diet during pregnancy and lactation has a profound influence on the child's health (Venter et al, 2017). Avoidance of allergenic foods during pregnancy and the early postnatal period was a traditional approach for allergy prevention. However, high-quality studies on maternal diets conclude that the evidence is not strong enough to recommend changing the diet of pregnant and breastfeeding women to prevent food allergies in infants at normal or high risk of food allergies (NASEM, 2017). Thus elimination diets during pregnancy and lactation for the purpose of allergy prevention are not warranted.

Breastfeeding

Breastfeeding is one of the main influences on the infant gut microbiota development. Human milk is a nutritional matrix with a host of bioactive compounds, including growth factors and maternal antibodies that impact immune responses. There are many well-documented benefits of breastfeeding including protection against infections, obesity, and chronic diseases, and it is associated with a fecal microbiota high in beneficial *Bifidobacteria*. Many studies have examined the association between breastfeeding and the development of food allergy and the data is inconsistent. Infants who are exclusively breastfed can express clinical manifestations of food allergy, including FPIES as already described, and multiple food intolerances of infancy (Heine, 2018). The use of a hypoallergenic maternal elimination diet that

eliminates allergens such as cow's milk can be helpful if allergic symptoms are present in the infant. However, maternal dietary restrictions during pregnancy and lactation for the sole purpose of allergy prevention are not recommended (Heine, 2018). The exact role of breastfeeding in allergy prevention remains unclear, and it appears that it may not reliably confer a protective effect against food allergies, although more research is needed. At least 6 months of exclusive breastfeeding is recommended for all infants regardless of family allergy risk (see Box 25.9).

Infant Formulas

The use of infant formulas to prevent allergy in high-risk infants who are unable to exclusively breastfeed is being explored. A systematic review and meta-analysis was conducted by Boyle et al. to determine whether use of a hydrolyzed formula reduces the risk of allergic disease in high-risk infants (Boyle et al, 2016). Their conclusion, along with other systematic reviews, found that there is not sufficient evidence to support the use of hydrolyzed cow's milk formulas—partially hydrolyzed formulas (PHF) or EHF—over breastmilk for the prevention of food allergy and food sensitization. In addition, the evidence is not strong enough to conclude that hydrolyzed formulas reduce the risk of food allergy and food sensitization compared with standard formulas (NASEM, 2017).

Dual Allergen Hypothesis

The **dual allergen hypothesis** proposes that allergic sensitization to foods may occur from a disrupted skin barrier early in life, as occurs in infantile eczema. The loss of skin barrier integrity increases environmental exposure to low doses of food allergens through the skin. Data suggests that loss of function of flaggrin, a protein important for epithelial structure, along with a compromised skin barrier, increases the risk for food sensitization from the environment (Renz et al, 2018).

The hypothesis also postulates that oral exposure to these same allergens through consumption of the allergenic foods early in life leads to oral tolerance and prevents the development of sensitization and allergy even with subsequent exposures (Renz et al, 2018). This hypothesis is also thought to explain the **"atopic march,"** a pattern that describes a process in which atopic disorders progress over time from eczema (i.e., atopic dermatitis) to asthma to multiple allergic disorders including food allergy (NASEM, 2017).

The dual allergen hypothesis was born out of the observation that infants with eczema have a high risk of developing IgE-mediated food allergies. Supporting this hypothesis are data suggesting that early dietary introduction of peanut products may confer protection against peanut allergy.

However, many questions remain about the mechanisms by which sensitization and tolerance occur, and about the elements of the immune system that represent the most important contributors to the severity of food allergy or the establishment of tolerance.

Timing of Introduction of Solids and Infant Feeding

Earlier food allergy prevention strategies recommended delayed introduction of common allergenic foods into the infant's diet. There is now direct evidence from randomized controlled trials that the paradigm is shifting from avoidance to controlled exposure (West, 2017). Although the "optimal" period for introduction of complementary foods for allergy prevention is not known, a "window period" between 4 to 6 months of age when solids are introduced is recommended by most international guidelines for the induction of tolerance (Heine, 2018; West, 2017). The Australian HealthNuts study, the Learning Early About Peanut (LEAP), and Enquiring About Tolerance (EAT) are some of the key studies that assess early versus late introduction of

complementary foods for allergy prevention and provide insights on the best timing of the dietary introduction of food allergens in high-risk infants (Fleischer et al, 2015; Heine, 2018; West, 2017; DuToit et al, 2015) (see Box 25.9).

The pivotal LEAP trial provides strong evidence that early introduction of peanuts (from 4 to 11 months of age) increases protection against peanut allergy in infants who are at high risk (defined by early-onset eczema and/or egg allergy) (NASEM, 2017; West, 2017; Heine, 2018; Togias et al, 2017).

The role of diet diversity in early life feeding practices may be another influential factor in food allergy prevention. Increased diversity of complementary foods, increased vegetables and fruit, and more home-prepared meals in the first year of life have been associated with a reduced risk of food allergy (NASEM, 2017; Du Toit et al, 2018).

Many questions remain on the best strategies to optimize infant feeding regimens and support the most favorable “tolerogenic” microenvironment in the gut during the period of food allergen introduction, since the immunomodulatory capacity of the GI tract is influenced by multiple factors (West, 2017; Renz et al, 2017).

Nutritional Immunomodulation

A balanced immune system is essential to health, and nutrition is a major factor that impacts immunocompetence. The immunoregulatory network is orchestrated by a variety of nutrients such as vitamin D, folate, and omega-3 fatty acids, and is influenced not only by dietary intake but also by digestive dynamics and microbial interplay.

Vitamin D

Vitamin D has received increased recognition for its role in immune regulation, as several studies have provided evidence that vitamin D deficiency is associated with food allergy. Evidence suggests vitamin D helps promote immunoregulation through induction of T_{reg} cells and T-cell differentiation. A shift to Th2 responses occurs with low or vitamin D–deficient conditions (Renz et al, 2018). A few studies have also examined the effect of maternal vitamin D status, cord blood, 25(OH) D₃ levels, and the development of food allergy, with conflicting reports. Multiple genes are involved in vitamin D metabolism and regulatory pathways, and future studies that consider genetic polymorphisms will help clarify the relationship between vitamin D and food allergy (Jones et al, 2015; NASEM, 2017).

Fatty Acids

The role of dietary fats in allergy development has been the subject of investigation, with the omega-3 fatty acids being the most extensively studied. The amount of omega 3-fatty acids in the U.S. diet has decreased over time along with a corresponding increase in omega-6 fatty acids intake, and this imbalance is thought to be a critical nutrition factor in the prevalence of chronic disease, including allergic disorders (Heine, 2018).

Omega-3 fatty acids have antiinflammatory and immunomodulatory effects. Some studies suggest that maternal consumption of fish oil (a source of omega-3 fatty acids) in pregnancy protects against the development of asthma, eczema, and allergic sensitization in the infant, whereas others do not show these results (Palmer et al, 2013). Controversy and questions remain regarding the relationship between omega-3 fatty acid content of the maternal diet and whether this confers a protective effect against development of childhood food allergy. Further studies are needed to elucidate the role of fatty acids in allergy prevention and their role in the inflammatory cascade (see Chapter 7).

Folate

There is renewed interest in folate as a dietary methyl donor that alters gene expression and impacts immune function through epigenetic

mechanisms (Brown et al, 2014). Folate exposure in utero can affect DNA methylation during fetal development and influence transcriptional activity and may be involved in T-cell differentiation. Most studies to date have focused on asthma, with a very limited number examining the relationship of folate to food allergy and food sensitization. The significant role that folate plays in methylation of key regulatory genes and its potential in allergic predisposition warrants further investigation.

Other Nutrients

Few studies have examined the relationship between maternal dietary antioxidant intake (beta-carotene, vitamins C and E, copper, and zinc) during pregnancy and the risk of developing food allergy. In addition, nutrient assessment of individuals with food allergies and intolerances has not been thoroughly examined in research and is an avenue ripe for exploration (NASEM, 2017).

Future Directions

There are a number of areas that are being intensely studied as potential therapeutics for food allergy.

Immunotherapy

The concept of **allergen immunotherapy (AIT)**, which aims to provide desensitization in a systematic stepwise process, was first described in the early 1900s. It is a procedure inducing tolerance to a specific allergen by repetitive administration of small amounts of an allergen, and it has been effective in respiratory allergy and venom hypersensitivity. Three main clinical immunotherapy concepts have emerged since then, including oral immune therapy (OIT), sublingual immune therapy (SLIT) and epicutaneous immunotherapy (EPIT). Ongoing studies of these methods have identified benefits and limitations of each, including side effects and adverse reactions.

The effectiveness of the therapies in food allergy remains under investigation, including the potential of combination therapies such as OIT plus immune modulation with probiotics or traditional Chinese medicine (Sicherer and Sampson, 2018). A growing body of evidence supports the use of AIT for subsets of patients with food allergies; however, biomarkers that are predictive of favorable outcomes and strategies to improve the safety and efficacy of AIT are needed (Feuille and Nowak-Węgrzyn, 2018).

Genetics and Omics

The potential of genetic data and “omics” technologies such as epigenomics, proteomics, transcriptomics, metabolomics, microbiomics, and exposomics is now being recognized (see Chapter 6). For example, metabolomics can provide data on the metabolic pathway activity associated with egg and peanut allergy, whereas microbiomics can identify microbial risk factors that are influencing gut physiology. Other “omics” approaches can provide measurements of proteins involved in food allergy immune responses and environmental exposures (exposomics) contributing to food allergy prevalence. Data derived from “omics” approaches will provide robust sets of biological and environmental data that will be used to better inform our understanding of food allergy, and open new avenues for both the prevention and treatment of this disease (Dhondalay et al, 2018).

Future Innovations

Innovative approaches such as modification of relevant food allergens (to make them less allergenic while maintaining their immunogenicity) or combining other therapies (e.g., probiotic supplementation during food challenges) to increase efficacy and/or safety will continue to dominate the food allergy landscape (Neerven and Savelkoul, 2017).

Medical Nutrition Therapy for Upper Gastrointestinal Tract Disorders

DeeAnna Wales VanReken, MS, RDN, CD, IFNCP

KEY TERMS

achalasia	esophagitis	mucosa-associated lymphoid tissue (MALT)
achlorhydria	esophagogastroduodenoscopy (EGD)	Nissen fundoplication
achylia gastrica	functional dyspepsia	odynophagia
acid pocket	gastrectomy	parietal cells
atrophic gastritis	gastric pull-up	parietal cell vagotomy
Barrett's esophagus (BE)	gastric ulcer	peptic ulcer disease
bezoar	gastritis	pyloroplasty
Billroth I (gastroduodenostomy)	gastroesophageal reflux (GER)	Rome IV criteria
Billroth II (gastrojejunostomy)	gastroesophageal reflux disease (GERD)	Roux-en-Y
cannabinoid hyperemesis syndrome	gastroparesis	scintigraphy
dumping syndrome	heartburn	stress ulcer
duodenal ulcer	<i>Helicobacter pylori</i>	upper esophageal sphincter (UES)
dyspepsia	hematemesis	vagotomy
dysphagia	hiatal hernia	vagotomy, truncal
endoscopy	lower esophageal sphincter (LES)	vagus nerve
esophagectomy	melena	

The upper gastrointestinal tract is the portion of the alimentary canal containing the esophagus, stomach, and duodenum. Along with those segments, the oral cavity will also be included as relevant in this chapter.

Digestive disorders of both the upper and lower gastrointestinal (GI) tract, are among the most common problems in health care (see Chapter 27). Between 60 and 70 million people are affected by all digestive diseases, with over 48 million ambulatory care visits made annually in the United States alone (National Institutes of Health [NIH], 2014). As digestive disorders are the leading cause of all emergency department visits, 8.8% or more than 12,000 patients presented with stomach and abdominal pain, cramps, and spasms in 2015 alone (Centers for Disease Control and Prevention [CDC], 2015). More than 20 million diagnostic and surgical procedures involving the GI tract are performed each year (CDC, 2015). Dietary habits and specific foods can play an important role in the onset, treatment, and prevention of many GI disorders. Medical nutrition therapy is integral in the prevention and treatment of malnutrition and deficiencies that can develop from a GI tract disorder. Diet and lifestyle modifications can improve a patient's quality of life by alleviating GI symptoms and decreasing the number of health care visits and costs associated with GI disease.

Gail Cresci, PhD, RDN, LD, CNSC and Arlene Escuro, MS, RDN, CNSC were the authors of this chapter for the 14th edition.

THE ESOPHAGUS

The esophagus is a muscular tube with an average length of 25 cm in adults (Fig. 26.1), with the single but important function of delivering solids and liquids from the mouth to the stomach. It is lined with nonkeratinized stratified squamous epithelium, and submucosal glands secrete mucin, bicarbonate, epidermal growth factor, and prostaglandin E₂, which protect the mucosa from gastric acid.

The top of the esophagus is connected to the pharynx, and the bottom of the esophagus is connected to the stomach at the cardia. It is highly muscular, with muscles arranged in a way to facilitate the passage of food. As a bolus of food is moved voluntarily from the mouth to the pharynx, the **upper esophageal sphincter (UES)** relaxes, the food moves into the esophagus, and peristaltic waves move the bolus down the esophagus; the **lower esophageal sphincter (LES)** relaxes to allow the food bolus to pass into the stomach. The esophageal transit time takes an average of 5 seconds when in an upright position, and up to 30 seconds when in a supine position (la Roca-Chiapas and Cordova-Fraga, 2011).

The normal esophagus has a multitiered defense system that prevents tissue damage from exposure to gastric contents, including LES contraction, normal gastric motility, esophageal mucus, tight cellular junctions, and cellular pH regulators. Musculoskeletal disorders and motility disorders may result in dysphagia. For example, **achalasia** is characterized by a failure of esophageal neurons, resulting in a loss of ability to relax the LES and have normal peristalsis.

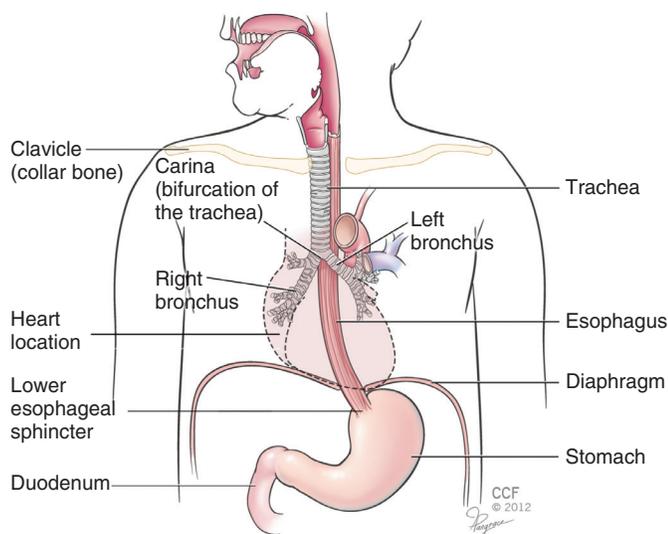

Fig. 26.1 Normal esophagus. (Cleveland Clinic, Cleveland, Ohio.)

Gastroesophageal Reflux Disease (GERD) and Esophagitis

Etiology

Gastroesophageal reflux (GER) is considered a normal physiologic process that occurs several times a day in healthy infants, children, and adults. GER generally is associated with transient relaxation of the LES independent of swallowing, which permits gastric contents to enter the esophagus. Limited information is known about the normal physiology of GER in infants, but regurgitation and spitting up, as the most visible symptom, is reported to occur daily in 50% of all infants (Lightdale and Gremse, 2013).

Gastroesophageal reflux disease (GERD) is a more serious, chronic form of GER, with symptoms or complications resulting from the reflux of gastric contents into the esophagus or beyond, and even into the oral cavity (including larynx) or lung. Symptoms are defined to include **heartburn** (painful, burning sensation that radiates up behind the sternum of fairly short duration) and/or regurgitation, at least once a week. Prevalence is worldwide, may be increasing over time, and varies by geographic location. The following prevalence estimates were published in a 2014 review of existing epidemiologic studies: North America 18% to 28%; Europe 9% to 26%; Middle East 9% to 33%; Australia 12%; East Asia 3% to 8% (El-Serag et al, 2014).

Esophagogastroduodenoscopy (EGD) uses a fiberoptic endoscope to directly visualize and examine the esophagus, stomach, and duodenum to classify severity of disease (see Focus On: Endoscopy and Capsules). GERD can be classified as nonerosive disease (NERD), indicating the presence of symptoms without abnormalities or erosions, or erosive disease (ERD), with symptoms and erosions present. ERD generally is associated with more severe and prolonged symptoms compared with NERD (Katz et al, 2013).

Some patients experience GERD symptoms primarily in the evening (nocturnal GERD), which has a greater impact on quality of life compared with daytime symptoms. Nocturnal GERD is associated significantly with severe **esophagitis** (inflammation of the esophagus) and Barrett's esophagus (an intestinal metaplasia described in further detail later in this chapter) and can lead to sleep disturbance. Patients with ERD are more likely to be men, and women are more likely to have NERD. There is a definite relationship between GERD and obesity. Several meta-analyses suggest an association between body

mass index (BMI), waist circumference, weight gain, and the presence of symptoms and complications of GERD. GERD is frequent during pregnancy, usually manifesting as heartburn, and may begin in any trimester. Significant predictors of heartburn during pregnancy are increasing gestational age, heartburn before pregnancy, and parity (Katz et al, 2013) (see Chapter 14). One Korean study also found a significant association between degree of psychosocial stress and reflux esophagitis severity (Song et al, 2013).

Chest pain may be a symptom of GERD, and distinguishing cardiac from noncardiac chest pain is required before considering GERD as a cause of chest pain. Although the symptoms of dysphagia can be associated with uncomplicated GERD, its presence warrants investigation for a potential complication, including an underlying motility disorder, stricture, or malignancy. Patients with disruptive GERD (daily or more than weekly symptoms) have an increase in time off work and decrease in work productivity, and a decrease in physical functioning (Katz et al, 2013).

Pathophysiology

The pathophysiology of GERD is complex. **Box 26.1** describes possible mechanisms involved in GERD. Three components make up the esophagogastric junction: the LES, the crural diaphragm, and the anatomic flap valve. This junction acts as an antireflux barrier. The LES is a 3- to 4-cm segment of circular smooth muscle at the distal end of the esophagus. The resting tone of this muscle can vary among healthy individuals, ranging from 10 mm Hg to 35 mm Hg relative to the intragastric pressure. The most common mechanism for reflux is transient LES relaxations, which are triggered by gastric distention and serve to enable gas venting from the stomach. On average, transient LES relaxations persist for about 20 seconds, which is significantly longer than the typical swallow-induced relaxation (Bredenoord et al, 2013).

For reflux to take place, pressure in the proximal stomach must be greater than the pressure in the esophagus. Patients with chronic respiratory disorders, such as chronic obstructive pulmonary disease (COPD), are at risk for GERD because of frequent increases in intraabdominal pressure. A chronically increased pressure also is seen during pregnancy and in overweight and obese people.

Hypersensitivity to acid can occur in people with erosive esophagitis and in those with normal mucosa. A factor contributing to increased esophageal sensitivity to acid is impaired mucosal barrier function. In a systematic review, the overall rate of gastric emptying

BOX 26.1 Possible Mechanisms Involved in Gastroesophageal Reflux Disease (GERD)

- Decreased salivation
- Transient lower esophageal sphincter (LES) relaxation
- Reduced LES pressure
- Impaired esophageal acid clearance
- Increased esophageal sensitivity
- Acid pocket
- Increased intraabdominal pressure
- Delayed gastric emptying

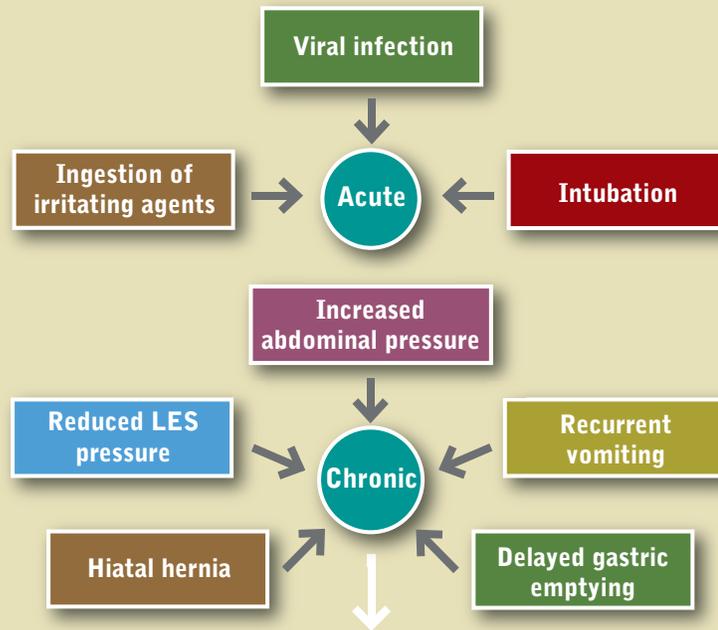

Data from Beaumont H et al: The position of the acid pocket as a major risk factor for acidic reflux in healthy subjects and patients with GORD, *Gut* 59:441, 2010; Bredenoord AJ et al: Gastroesophageal reflux disease, *Lancet* 381:1933, 2013; Penagini R, Bravi I: The role of delayed gastric emptying and impaired esophageal motility, *Best Pract Res Clin Gastroenterol* 24:831, 2010.

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Esophagitis

ETIOLOGY

PATHOPHYSIOLOGY

Reflux of gastric acid and/or intestinal contents through the lower esophageal sphincter (LES) and into the esophagus

MANAGEMENT

Behavioral Modification

- Avoid:**
- Eating within 3-4 hours of bedtime
 - Lying down after meals
 - Tight-fitting clothing
 - Cigarette smoking
 - Excess stress

Medical/Surgical Management

- Proton pump inhibitors
- Histamine-2 receptor antagonists
- Antacids
- Prokinetic agents
- Fundoplication

Nutrition Management

- Goal:**
Decrease exposure of esophagus to gastric contents
- Avoid:**
- Large meals
 - Excess intake of dietary fat
 - Alcohol, mint, coffee, and chocolate

- Goal:**
Decrease acidity of gastric secretions
- Avoid:**
- Coffee
 - Alcohol

- Goal:**
Prevent pain and irritation
- Avoid:**
- Any food that the patient feels exacerbates symptoms, especially hot and spicy foods

was delayed in patients with GERD (Penagini and Bravi, 2010). However, a relationship between delayed gastric emptying and increased reflux could not be seen in this study, suggesting that impaired emptying of the stomach as a whole is not an important determinant of GER.

Good peristaltic function is an important defense mechanism against GERD, as prolonged acid clearance correlates with the severity of esophagitis and the presence of complications such as Barrett's esophagus. An occurrence during the postprandial period known as **acid pocket** is a layer of unbuffered, highly acidic gastric juice at the esophago-gastric junction, ready to reflux due to the absence of peristaltic contraction in the proximal stomach.

Prolonged acid exposure can result in esophagitis, esophageal erosions, ulceration, scarring, stricture, and in some cases dysphagia (see *Pathophysiology and Care Management Algorithm: Esophagitis*). Acute esophagitis may be caused by reflux, ingestion of a corrosive agent, viral or bacterial infection, intubation, radiation, or eosinophilic infiltration. Eosinophilic esophagitis (EoE) is characterized by an isolated, severe eosinophilic infiltration of the esophagus manifested by GERD-like symptoms that may be caused by an immune response (see Chapter 25).

The severity of the esophagitis resulting from the GER is influenced by the composition, frequency, and volume of the gastric reflux; the health of the mucosal barrier; length of exposure of the esophagus to the gastric reflux; and the rate of gastric emptying. Symptoms of esophagitis and GERD may impair the ability to consume an adequate diet and interfere with sleep, work, social events, and the overall quality of life (Table 26.1).

Barrett's esophagus (BE) is a precancerous condition in which the normal squamous epithelium of the esophagus is replaced by an abnormal columnar-lined epithelium known as specialized intestinal metaplasia (tissue that is similar to the intestinal lining). The exact cause of BE is unknown, but GERD is a risk factor for the condition. The prevalence of BE is between 0.5% and 2% but is estimated to affect 1.6% to 6.8% of the general population (Runge et al, 2015). People with BE are at increased risk for a cancer called esophageal adenocarcinoma, with incidence rising dramatically over the past 40 years and speculated to continue to rise during coming decades (Thrift and Whitman, 2012). Risk factors for BE include prolonged history of

TABLE 26.1 Clinical Symptoms Associated with Gastroesophageal Reflux Disease (GERD)

Dental corrosion	Slow, progressive tooth surface loss associated with acid regurgitation
Dysphagia	Difficulty initiating a swallow (oropharyngeal dysphagia) or sensation of food being hindered or "sticks" after swallowed (esophageal dysphagia)
Heartburn (pyrosis)	Painful, burning sensation that radiates up behind the sternum of fairly short duration
Odynophagia	Painful swallowing
Regurgitation	Backflow of gastric content into the mouth not associated with nausea or retching
Noncardiac chest pain	Unexplained substernal chest pain resembling a myocardial infarction without evidence of coronary artery disease
Extraesophageal symptoms	Chronic cough, hoarseness, reflux-induced laryngitis, or asthma

Data from Bredenoord AJ et al: Gastro-esophageal reflux disease, *Lancet* 381:1933, 2013; Katz PO et al: Guidelines for the diagnosis and management of gastroesophageal reflux disease, *Am J Gastroenterol* 108:308, 2013.

TABLE 26.2 Types of Hiatal Hernia

Type 1 (sliding hiatal hernia)	Most common type; gastroesophageal junction is pushed above the diaphragm, causing a symmetric herniation of the proximal stomach
Type 2 (true paraesophageal hernia)	Fundus slides upward and moves above the gastroesophageal junction
Type 3 (mixed paraesophageal hernia)	Combined sliding and paraesophageal herniation
Type 4 (complex paraesophageal hernia)	Less common form; intrathoracic herniation of other organs, such as the colon, and small bowel into the hernia sac

GERD-related symptoms (more than 5 years), middle age, white male, obesity, smoking, and family history of BE or adenocarcinoma of the esophagus. Estrogen may be protective and account for the lower incidence of BE in females (Asanuma et al, 2016).

Abnormalities in the body such as **hiatal hernia** may also contribute to GER and esophagitis. The esophagus passes through the diaphragm by way of the esophageal hiatus or ring. The attachment of the esophagus to the hiatal ring may become compromised, allowing a portion of the upper stomach to move above the diaphragm. Table 26.2 describes the four types of hiatal hernia in greater detail. The most common symptom of hiatal hernia is heartburn. When acid reflux occurs with a hiatal hernia, the gastric contents remain above the hiatus longer than normal. The prolonged acid exposure increases the risk of developing more serious esophagitis. Fig. 26.2 illustrates a hiatal hernia (A), and postsurgical reduction (B). As the hiatal hernia enlarges, regurgitation may be more prominent, especially when lying down or when bending over. Epigastric pain occurs in the upper middle region of the abdomen after large, energy-dense meals. Weight reduction and decreasing meal size can reduce the negative consequences of hiatal hernia.

Patients with type 3 (mixed paraesophageal) hiatal hernia may present with severe chest pain, retching, vomiting, and **hematemesis** (vomiting of blood), as these hernias can twist and cause strangulation in the chest, resulting in a surgical emergency. Some patients can present with iron deficiency anemia without acute bleeding because the diaphragm becomes so irritated that the patient may develop chronic blood loss.

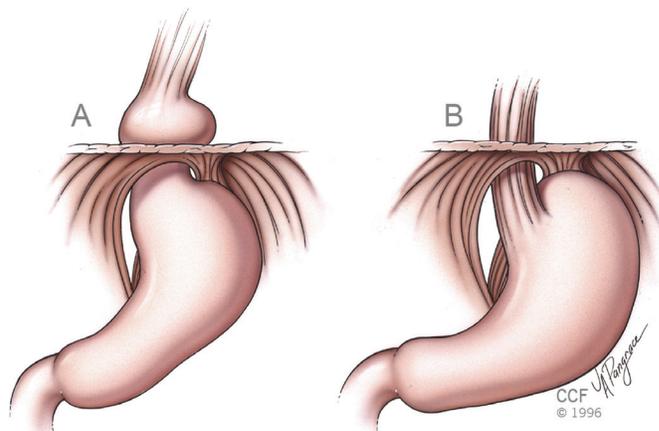

Fig. 26.2 A, Hiatal hernia. **B**, Postsurgical reduction of hiatal hernia. (Cleveland Clinic, Cleveland, Ohio.)

Medical and Surgical Management

The primary medical treatment of esophageal reflux is suppression of acid secretion. The aim in acid-suppression therapy is to raise the gastric pH above 4 during periods when reflux is most likely to occur. Proton pump inhibitors (PPIs), which decrease acid production by the gastric parietal cell, have been associated with superior healing rates and decreased relapses (Katz et al, 2013). Milder forms of reflux are managed by H₂ receptor (a type of histamine receptor on the gastric parietal cell) antagonists and antacids, which buffer gastric acid in the esophagus or stomach to reduce heartburn. Prokinetic agents, which increase propulsive contractions of the stomach, may be used in persons with delayed gastric emptying. A trial of baclofen, a gamma-amino butyric acid (GABA) agonist, can be considered in patients with objective documentation of continued symptomatic reflux despite optimal PPI therapy (Katz et al, 2013). However, there have not been long-term data published regarding efficacy of baclofen in GERD. Refer to Table 26.3 for medications commonly used

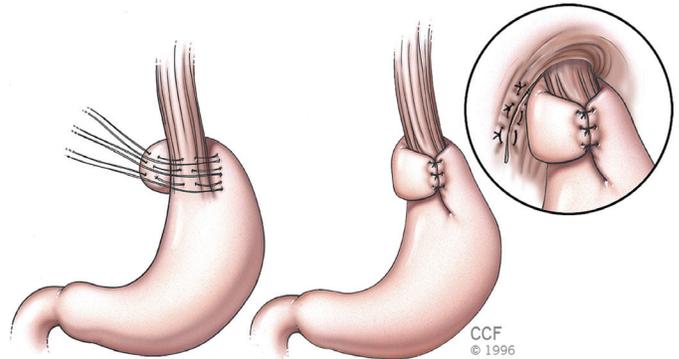

Fig. 26.3 Nissen fundoplication. (Cleveland Clinic, Cleveland, Ohio.)

TABLE 26.3 Common Medications Used in the Treatment of Upper Gastrointestinal Tract Disorders

Type of Medication	Common Names	Medication Function
Antacids	Magnesium, calcium, or aluminum bound to carbonate, hydroxide, or phosphate	Buffers gastric acid
Antigas	Simethicone	Lowers surface tension of gas bubbles
Antidiarrheal	Diphenoxylate Loperamide Opium preparations	Decreased gastrointestinal (GI) tract motility to induce lower stool volume output
Antidumping	Acarbose	Delays carbohydrate digestion by inhibiting alpha-glycoside hydrolase, which interferes with conversion of starch to monosaccharides
Antisecretory	Octreotide (somatostatin analog) Somatostatin	Inhibits release of insulin and other gut hormones; slows rate of gastric emptying and small intestine transit time; and increases intestinal water and sodium absorption
H ₂ blocker	Cimetidine Ranitidine Famotidine Nizatidine	Blocks the action of histamine on parietal cells, decreasing the production of acid
Prokinetic	Metoclopramide Erythromycin Domperidone	Increases contractility of the stomach and shortens gastric emptying time
Proton pump inhibitor (PPI)	Omeprazole Lansoprazole Esomeprazole Pantoprazole Dexlansoprazole Rabeprazole	Inhibits acid secretion

in upper GI disorders. See Appendix 13 for more information about these medications.

Of patients with severe GERD, 5% to 10% do not respond to medical therapy. The **Nissen fundoplication** was first described as a treatment for severe reflux esophagitis in 1956 and is still the most commonly performed antireflux surgery (Fig. 26.3). During this procedure, which can be done using either open or a laparoscopic technique, the fundus or top portion of the stomach is wrapped 360 degrees around the lower esophagus and sutured in place to limit reflux (see Fig. 26.3). Surgical therapy is considered for individuals for whom medical management has been unsuccessful, those who opt for surgery to avoid lifelong need for medication to control symptoms, those experiencing more serious complications (BE, peptic stricture), and those who have extraesophageal manifestations that include both laryngeal and pulmonary symptoms (throat-clearing, hoarseness, postnasal drip, cough, shortness of breath, asthma) (Yates and Oelschlager, 2015). As many as 18% of those undergoing surgery will need a repeat operation due to fundoplication failure. Unfortunately, for these patients, quality of life scores decrease and there is less improvement of dysphagia with the second procedure, leading surgeons to consider more invasive surgeries such as Roux-en-Y or short colon interposition (Wilshire et al, 2016). Surgical approaches in children are reserved for those who have intractable symptoms unresponsive to medical therapy or who are at risk for life-threatening complications of GERD (Lightdale and Gremse, 2013). Refer to Box 26.2 for dietary guidelines after Nissen fundoplication.

Lifestyle Modifications and Medical Nutrition Therapy

The first step in symptom management of GERD should consist of changes in lifestyle, including diet. A recent small clinical trial found improvements in NERD participants with the addition of psyllium fiber into the diet three times daily for a total of 12.5 grams soluble fiber per day. Those enrolled in the study were selected if they previously ate a low (<20 g/day) fiber diet at baseline. During the study, no other dietary changes were made, and PPIs, H₂ blockers, or prokinetics were not allowed. The result demonstrated that dietary fiber increased the LES pressure and decreased total reflux episodes in participants (Morozov et al, 2018). Besides diet, other important factors that trigger reflux symptoms are caffeine, alcohol, tobacco, and stress. Initial recommendations should focus on meal size and content. Eating small rather than large meals reduces the probability that gastric contents will reflux into the esophagus.

Certain foods can lower LES pressure, including coffee and carminatives such as peppermint, but more research is needed to

BOX 26.2 Dietary Guidelines After a Nissen Fundoplication

1. Start clear liquid diet after surgery.
2. Advance oral diet to soft, moist, solid foods. Starting solids could be before leaving the hospital or written in hospital discharge instructions.
3. Follow soft, moist foods diet for about 2 months. Foods must be soft to pass through the esophagus.
4. Consume small, frequent meals.
5. Swallow small bites of food and chew thoroughly to allow an easy passage through the esophagus and avoid use of straw to consume liquids. Drink slowly.
6. Avoid foods and beverages that may cause backflow of stomach contents. This consists of citrus fruits and juices, tomato, pineapple, alcohol, caffeine, chocolate, carbonated beverages, peppermint or spearmint, fatty or fried foods, spicy foods, vinegar or vinegar-containing foods.
7. Avoid dry foods that are hard to pass through the esophagus, such as bread, steak, raw vegetables, rolls, dry chicken, raw fruits, peanut butter, other dry meats, or anything with skin, seeds, or nuts.
8. Avoid any food that may cause discomfort.
9. After 2 months, start to incorporate new foods into the diet. Try one new food item or beverage at a time. By 3–6 months, patient should be able to tolerate most foods.
10. Consult doctor or dietitian if having difficulty eating or losing weight.

establish their clinical significance in GERD when used in normal or small amounts (Jarosz and Taraszewska, 2014; Dossett et al, 2017). Fermented alcoholic beverages (such as beer and wine) stimulate the secretion of gastric acid and should be limited. Carbonated beverages enhance gastric distention, which increases transient LES relaxations. Highly acidic foods such as citrus juices and tomatoes should be avoided because they cause pain when the esophagus is already inflamed.

The role of spices in the pathological conditions related to upper GI disorders is not clear. When study participants with GERD were initially exposed to a capsaicin-containing red pepper sauce, an increase in both heartburn sensation and an enhancement of secondary peristalsis (triggered by esophageal distention on intake of food or beverage) occurred. However, repeating the same exposure led to a reversal of these effects, and may indicate lowered protection for the esophagus due to delayed acid clearance in those with GERD (Yi et al, 2016). Chewing gum has been shown to increase salivary secretions, which help raise esophageal pH, but studies have not demonstrated its efficacy compared with other lifestyle measures. Limiting or avoiding aggravating foods may improve symptoms in some individuals. Thus recommendations are to have a generally healthy diet and to avoid food items that, in the experience of the patient, trigger symptoms.

Obesity is a contributing factor to GERD and hiatal hernia because it increases intragastric pressure, and weight reduction may reduce acid contact time in the esophagus, leading to decreased reflux symptoms. Advising patients who have reflux episodes at night to elevate the head of the bed by 6 to 8 inches using blocks under bed posts is recommended. Further, frequent bending over should be avoided. Use of loose-fitting garments in the waist area is also thought to decrease the risk of reflux.

A few recent studies have shown an improvement of GERD symptoms with a low sugar and/or low carbohydrate diet. One small study conducted in Taiwan found statistical differences in symptoms of GERD patients based on whether a 500 mL liquid meal provided

BOX 26.3 Nutrition Care Guidelines for Reducing Gastroesophageal Reflux and Esophagitis

1. Nutrition Recommendations:
 - Avoid large, high-fat meals and decrease greasy foods.
 - Avoid eating 2 to 3 hours before lying down.
 - Avoid chocolate, mint, tomatoes, and tomato products.
 - Avoid caffeine-containing foods and beverages.
 - Avoid alcoholic beverages.
 - Avoid acidic and highly spiced foods.
 - Consume a well-balanced diet with adequate fiber.
 - Consider weight loss if overweight or obese.
 - Choose smaller, more frequent meals rather than three larger meals each day.
2. Lifestyle Recommendations:
 - Elevate the head of bed by 6 to 8 inches for individuals who have reflux episodes at night.
 - Quit smoking and avoid secondhand smoke and alcoholic beverages.
 - Reduce overall stress levels when possible.
 - Wear loose-fitting clothing around the stomach area, as tight or constricting clothing can worsen reflux.

Data from National Digestive Diseases Information Clearinghouse: *Gastroesophageal Reflux (GER) and Gastroesophageal Reflux Disease (GERD) in Adults* (website): <http://digestive.niddk.nih.gov/>; Song et al, 2013.

84.8 grams versus 178.8 grams of carbohydrates, while both contained equal amounts of protein and fat. Acid-reducing medications were prohibited during the study period. Endoscopy examinations, 24-hour pH monitoring, and reflux symptoms were recorded and included but were not limited to heartburn, acid regurgitation, and abdominal discomfort. For the participants in the low-carbohydrate group, shorter acid reflux periods and fewer acid-reflux symptoms were demonstrated (Wu et al, 2018). Although there are limited studies exploring the impact of the low-carbohydrate diet on resolution of GERD symptoms, promising results such as these warrant further research.

Use of tobacco products is contraindicated with reflux. Cigarette smoking should be stopped because it is associated with decreased LES pressure and decreased salivation, thus causing prolonged acid clearance. Smoking tobacco products also compromises GI integrity and increases the risk of esophageal and other cancers. Lifestyle changes to treat GERD in infants may involve a combination of feeding changes and positioning therapy. Modifying the maternal diet if infants are breastfed, changing formulas, and reducing the feeding volume while increasing the frequency of feedings may be effective strategies to address GERD in infants. Thickened feedings appear to decrease observed regurgitation rather than the actual number of reflux episodes. Little is known about the effect of thickening formula on the history of infantile reflux or the potential allergenicity of commercial thickening agents (Lightdale and Gremse, 2013).

Identification and treatment of the mechanism underlying the GERD is the first line of therapy. A combined approach of lifestyle changes, nutrition, exercise, and stress reduction can be effective in reducing symptoms in some patients. Boxes 26.3 and 26.4 contain information about diet and lifestyle modifications and integrative approaches to help reduce symptoms of GERD.

BOX 26.4 Integrative Approaches to GI Conditions, Including Acid Reflux/Heartburn

According to the National Health Interview Survey (NHIS), which is published every 5 years, complementary and integrative medicine (CIM) use is more prevalent in those with gastrointestinal (GI) conditions versus those without. A follow-up study to the most recent report found that 42% of respondents with GI conditions saw a practitioner for or used CIM within the previous year, while only 28% of those without GI conditions used CIM. Of those who reported having GI conditions, 3% used at least one CIM modality to address the problem. GI conditions, as defined by the NHIS, were limited to one or more of the following: abdominal pain, nausea and/or vomiting, liver conditions, digestive allergies, stomach or intestinal illness, and acid reflux/heartburn. The most common CIM modalities used were paired into groups as follows (Dossett et al, 2014):

- Herbs and nonvitamin nonmineral supplements, including zinc, glutamine, deglycyrrhizinated licorice, and aloe gel
- Manipulative therapies: chiropractic, osteopathic, massage, craniosacral therapy
- Mind-body therapies: hypnosis, biofeedback, meditation, imagery, progressive relaxation
- Mind-body exercise: yoga, tai chi, qi gong
- Special diets: vegetarian or vegan, macrobiotic, Atkins, Pritikin, Ornish, or dietary counseling
- Movement therapy: Feldenkrais, Alexander technique, Pilates, Trager psychological integration
- Other: acupuncture, Ayurveda, chelation, energy healing, homeopathy, naturopathy, traditional healers

Among these, herbs and supplements, mind-body therapies, and manipulative therapies were the top three respondents reported using to address a GI condition, and 47% used 3 or more modalities. Overwhelmingly, 80% reported that they perceived CIM therapy to be helpful, but only 70% informed their medical provider about using CIM. While the NHIS acknowledges some important details about the use of CIM and GI conditions, the data are self-reported, and the conditions were limited to those included in the survey. The follow-up study is important because it reveals a significant number of individuals who are integrating CIM modalities with traditional treatment for GI disorders (Dossett et al, 2014).

With many patients using integrative medicine to treat upper GI conditions, including acid reflux/heartburn, it is important for the nutrition professional to be aware of the most common modalities being used. Acupuncture, mind-body therapies, herbs and dietary supplements, and nutrition and lifestyle interventions are all popular and have varying degrees of evidence to support their use. While acupuncture, weight loss, and elevating the head of the bed have good evidence, there is also reasonable evidence to support mind-body modalities and dietary modifications (Dossett et al, 2017; Eherer et al, 2012; Jarosz and Taraszewska, 2014; Maradey-Romero et al, 2014). Further study is needed, and specific recommendations should be tailored to the individual by a well-trained professional using evidence-based data from reliable sources, as many patients may look to anecdotal evidence that is not founded in scientific research (Cowan, 2014).

Surgery of the Esophagus

The primary indication for an **esophagectomy** is esophageal cancer or BE with high-grade dysplasia. A patient undergoing esophagectomy often presents with dysphagia, decreased appetite, side effects from chemotherapy, and weight loss. Esophagectomy requires that there be another conduit in place to transport food from the oropharynx to the rest of the GI tract for digestion and absorption. Placement of an enteral feeding tube preoperatively, or at the time of surgery, provides enteral access for patients who will experience eating challenges and a

slow transition back to a normal diet. The enteral route of nutrition is preferred; however, if the GI tract is not functional, parenteral nutrition (PN) must be provided (see Chapter 12).

Medical Nutrition Therapy

Nutrition assessment of an esophagectomy candidate includes evaluation of treatment plans, history of weight loss, and the ability to swallow solid foods and liquids. Generally, the only esophagectomy patients screened at low nutrition risk preoperatively are those with BE with high-grade dysplasia, or those who are asymptomatic.

Preoperative phase. Swallowing difficulty (**dysphagia**) is the commonly identified problem in patients awaiting an esophagectomy. Dietary modifications may range from regular food with adequate chewing and slow eating to soft foods or to pureed or blenderized foods. Patients may also benefit from the addition of nutrient-dense, high-protein smoothies and nutritive beverages made from whole foods and healthy fats to maximize energy and protein intake before surgery. If the oral dietary modifications do not prevent further weight loss, nutrition support from a nasogastric feeding tube inserted in the preoperative patient may be necessary.

Postoperative phase. A **gastric pull-up** procedure (Fig. 26.4) involves removal of a segment of or the entire esophageal tract and replacing it with the stomach tissue. Complications after this procedure include increased risk of aspiration, dysphagia, anastomosis leak, wound infection, and stricture at the anastomosis site. A jejunostomy feeding tube may be placed at surgery to provide postoperative nutrition until adequate oral intake is achieved. The tube feeding schedule is changed eventually from continuous to cyclical feedings at night as the patient is transitioned to an oral diet during the day.

Transition to oral intake postoperatively proceeds from clear liquids to a soft, moist foods diet. The patient is advised to eat small frequent meals with limited fluids at mealtimes. Some patients may experience dumping syndrome if food passes into the small intestine too quickly. The symptoms of dumping syndrome include abdominal pain, nausea, diarrhea, weakness, and dizziness. Box 26.5 lists dietary guidelines after esophageal surgery to prevent dumping syndrome (see Dumping Syndrome later in this chapter for more details).

Head and Neck Cancer

Pathophysiology

Cancers of the upper aerodigestive tract, collectively referred to as head and neck cancers, comprise malignancies of the oral cavity (lips and

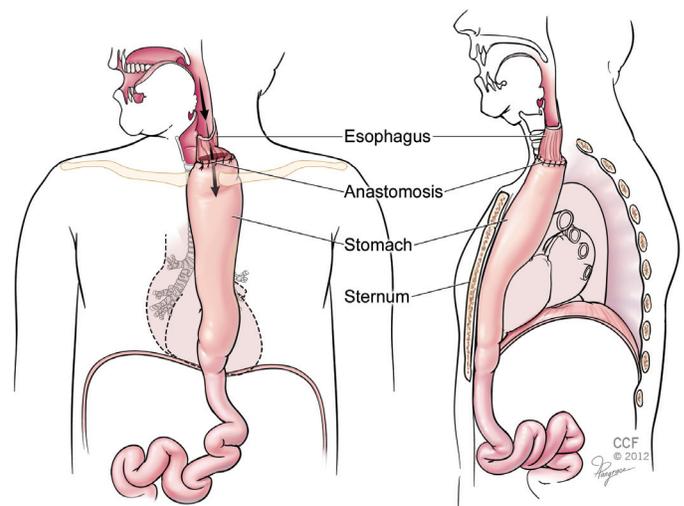

Fig. 26.4 Gastric pull-up. (Cleveland Clinic, Cleveland, Ohio.)

BOX 26.5 Nutrition Guidelines After Esophagectomy

1. Enteral nutrition is provided through a jejunostomy feeding tube after esophagectomy.
2. A patient cannot eat or drink anything by mouth until instructed by the doctor.
3. Once an oral diet is allowed, patient is provided with specific guidelines on how to taper the tube feedings and advance the oral diet (from sips of clear liquids to very moist, tender foods).
4. It may take several weeks to taper the tube feedings and adjust to oral diet. When tube feeding is discontinued, the patient should continue to flush the jejunostomy tube daily. A patient will continue to adjust to oral feedings for about 3 months.
5. During the 3-month transition:
 - Eat six small meals per day and include sources of protein and fat at every small meal.
 - Choose very tender, moist foods that can be easily cut with the side of fork or spoon and use sauces or gravies to moisten food.
 - Gradually increase the volume and variety of foods at each meal.
 - Avoid skins, seeds, nuts, tough or dry meats, breads and rolls, peanut butter, fried and greasy foods, raw vegetables, cooked corn and peas, and raw fruits.
 - Avoid items that can cause heartburn and stomach reflux such as caffeine, citrus fruits, pineapples, tomatoes, carbonated beverages, mints, and alcohol.
 - Drink no more than 4 fluid ounces of water or other liquids with meals. Drink fluids about 30 minutes before or after the meal and sip slowly.
 - Avoid concentrated sweets and sugars.
 - Eat slowly and chew foods thoroughly.
6. After 3 months, more food should be added back into the diet. Try one new food or beverage at a time.
7. After 6 months, a patient should be eating normally. It is still advised to eat frequent small meals.

inside of the mouth, including the front portion of the tongue and the roof and floor of the mouth), the oropharynx (back portion of the tongue and the part of the throat behind the oral cavity), the larynx, and the esophagus. The patient diagnosed with head and neck cancer faces unique challenges in maintaining adequate nutrition. The disease and the treatments, especially surgery and chemo- and radiation therapy, have significant impact on upper digestive tract function, and oral intake is often insufficient during and after therapy. Approximately 35% to 60% of all patients with head and neck cancer are malnourished at the time of diagnosis due to intake difficulties, tumor burden, and cachexia (Alshadwi and Nadershah, 2013). Dysphagia is a hallmark of head and neck cancer; it occurs as a result of mechanical obstruction, sensory impairment, or **odynophagia** (painful swallowing). In these patients there is a high prevalence of alcohol abuse and long-term tobacco use, which are also associated with chronic malnutrition (Schoeff et al, 2013).

Medical Nutrition Therapy

Depending on the tumor site, the surgical procedure may significantly alter the anatomy and lead to scarring that can negatively affect swallowing. The patient is likely to be restricted from oral intake while healing from the surgery. Placement of a gastrostomy tube is the most common approach to ensure safe delivery of adequate nutrition, but the optimal timing is not defined. Many clinicians may place them prophylactically before the start of radiation or surgical resection to prevent complications from malnutrition (Marian et al, 2017).

Although the goal is eventual transition to oral feeding, some patients will require additional enteral nutrition (EN) because of structural and sensory deficits.

Aggressive prophylactic swallowing therapy is a recent development in the treatment of dysphagia in patients with head and neck cancer. This approach focuses on maintaining or regaining function rather than simply accommodating dysfunction (reliance on feeding tube) and empowers patients to progress carefully with oral intake despite imperfect swallowing (Schoeff et al, 2013).

THE STOMACH

The stomach accommodates and stores meals, mixes food with gastric secretions, and controls emptying into the duodenum. Gastric volume is approximately 50 mL when empty but can expand to approximately 4 L. Gastric **parietal cells** (acid-producing cells) produce 1.5 to 2 L of acid daily, resulting in a pH between 1 and 2 (see Chapter 1 for a detailed discussion of normal stomach function).

The mucosa of the stomach and duodenum is protected from proteolytic actions of gastric acid and pepsin by a coating of mucus secreted by glands in the epithelial walls from the lower esophagus to the upper duodenum. The mucosa also is protected from bacterial invasion by the digestive actions of pepsin and hydrochloric acid (HCl). Prostaglandins play an important role in protecting the gastroduodenal mucosa by stimulating the secretion of mucus and bicarbonate and maintaining blood flow during periods of potential injury.

Dyspepsia and Functional Dyspepsia

Pathophysiology

Dyspepsia (indigestion) refers to nonspecific, persistent upper abdominal discomfort or pain. It affects an estimated 20% to 40% of the general population and significantly reduces quality of life (Ford and Moayyedi, 2013). The underlying causes of dyspepsia may include GERD, peptic ulcer disease, gastritis, gallbladder disease, or other identifiable pathologic conditions.

Functional gastrointestinal disorders (FGIDs), now known as disorders of gut-brain interaction (DGBI), have been diagnosed and classified using standards defined by the Rome criteria since its inception in the late 1980s. The most recent update using current scientific data was released in May 2016 and is known as the **Rome IV criteria**. According to these criteria, **functional dyspepsia** (FD) is defined as an umbrella term to include patients with postprandial distress syndrome (PDS) and epigastric pain syndrome (EPS) (Schmulson and Drossman, 2017). Symptoms can include postprandial fullness and early satiety, but also may cause patients to perceive epigastric discomfort and/or burning after meals. The syndromes can overlap and are considered gastroduodenal disorders that occur in the absence of any organic, systemic, or metabolic disease likely to explain the symptoms (Talley and Ford, 2015). The word discomfort is important to emphasize, as many patients will not complain of pain but rather of burning and pressure or fullness in the epigastric area, with a frequent complaint of early satiety. Belching, abdominal bloating, and nausea can also be present in both syndromes, but vomiting is considered an unusual occurrence (Schmulson and Drossman, 2017).

Medical Nutrition Therapy

Current treatments for FD have generally ignored the potential role of diet. The possible effect of specific foods and macronutrients and other dietary habits to induce or exacerbate FD symptoms has

been poorly studied, and often there are conflicting results (Lacy et al, 2012). However, one more recent study demonstrated spicy, pickled, and high-fat foods as catalysts, inducing symptoms the most in patients with this condition (Akhondi-Meybodi et al, 2015). Using a food and symptom diary during a clinical evaluation of a patient with FD and assessing symptoms associated with eating patterns is useful. Dietary modifications such as consuming smaller meals with a reduction in dietary fat may be promising in FD therapy. Helping the patient identify problematic foods also can be helpful.

Gastritis and Peptic Ulcers

Pathophysiology

Gastritis is a nonspecific term literally meaning inflammation of the stomach. It can be used to describe symptoms relating to the stomach, an endoscopic appearance of the gastric mucosa, or a histologic change characterized by infiltration of the epithelium with inflammatory cells such as polymorphonuclear cells (PMNs). Acute gastritis refers to rapid onset of inflammation and symptoms. Chronic gastritis may occur over a period of months to decades, with reoccurring symptoms. Symptoms include nausea, vomiting, malaise, anorexia, hemorrhage, and epigastric pain. Prolonged gastritis may result in atrophy and loss of stomach parietal cells, with a loss of HCl secretion (achlorhydria) and intrinsic factor, resulting in pernicious anemia (see Chapter 31).

Helicobacter pylori Gastritis

Helicobacter pylori is a gram-negative bacteria that is somewhat resistant to the acidic environment in the stomach. *H. pylori* infection is responsible for most cases of chronic inflammation of the gastric mucosa and peptic ulcer, gastric cancer, and **atrophic gastritis** (chronic inflammation with deterioration of the mucous membrane and glands), resulting in achlorhydria and loss of intrinsic factor (Dos Santos and Carvalho, 2015).

H. pylori is a known underlying cause of noncardia gastric cancer and responsible for deaths from peptic ulcer (Axon, 2014). An updated classification of gastric cancers was adopted in part because of the role of *H. pylori*, which is a strong risk factor for noncardia gastric cancer. Traditionally, gastric cancer was considered a single disease, but scientists now classify it by its location in either the top inch of the stomach near the esophagus (gastric cardia) or the rest of the stomach (noncardia).

Developed countries have seen a decrease in *H. pylori* infections in recent years because of increased information, testing, and effective treatment. Risk factors for this infection are higher in less-developed countries with lower standard of living, poor education, and reduced lifespan. In these communities, the prevalence of reinfection is also higher, leading to an ongoing public health problem. The revelation that treating *H. pylori* infection decreases the risk for some cancers but may increase the risk of other cancers (esophageal) is also prompting more research and knowledge that treatment must be more widespread (Axon, 2014).

While prevalence of *H. pylori* infection correlates with geography and socioeconomic status of the population and begins during childhood, it is often not diagnosed until adulthood. *H. pylori* is spread through contaminated food and water and is correlated with lower levels of hygiene. More than half of the world population is infected and prevalence ranges from as low as 18.9% in Switzerland, to 24.6%–35.6% in the United States and Australia, to as high as 87.7% in Nigeria (Hooi et al, 2017). *H. pylori* infection does not resolve spontaneously, and risks of complications increase with the duration of the infection. Other risk factors contributing to pathology and disease severity include patient age at onset, specific strain and concentration of the

organism, genetic factors related to the host, and the patient's lifestyle and overall health.

In the first week after *H. pylori* infection, many PMNs and a few eosinophils infiltrate the gastric mucosa. These are replaced gradually with the mononuclear cells. The presence of lymphoid follicles is called **mucosa-associated lymphoid tissue (MALT)**. MALT may become autonomous to form a low-grade, B-cell lymphoma called MALT lymphoma. *H. pylori* can cause duodenitis if it colonizes gastric tissue that may be present in the duodenum.

Treating *H. pylori* with antibiotics can cause PMNs to disappear within a week or two, but a mild gastritis can persist for several years, as the reduction in mononuclear cells is slow. In countries where *H. pylori* is common, so is gastric cancer. Because *H. pylori* can cause peptic ulcer and gastric cancer, antibiotic treatment is favored when it is diagnosed. **Box 26.6** includes information about integrative approaches for *H. pylori*.

BOX 26.6 Integrative Approaches to *Helicobacter Pylori* and Associated GI Disease

Typical medical treatment for *H. pylori* is with “triple therapy” (TT) that combines two antimicrobial drugs (clarithromycin and amoxicillin or metronidazole) with proton pump inhibitor (PPI) for 1 to 2 weeks with an 80% to 85% success rate (Sarkar et al, 2016; Oh et al, 2016). Unfortunately, adverse events such as *Clostridium difficile* infection (CDI) or pseudomembranous colitis can occur with the change in gut flora due to TT treatment. One small randomized controlled trial (RCT) employed a 4-week comparison of standard medical treatment alone versus standard medical treatment with a probiotic added to demonstrate an eradication rate of 100% in the probiotic group versus 90% in the control. The effect was thought to be due to lowered imbalance of microbiota during treatment, thus leading to better tolerated treatment completion (Oh et al, 2016). Whereas this particular study was very small, a much larger meta-analysis reviewed similar comparison data from 6997 participants from 45 RCTs to find eradication rates of 82.31% in the probiotic group versus 72.08% in the control group (Zhang et al, 2015). Probiotics species (*Lactobacillus*, *Bifidobacterium*) have been studied for prevention, management, and eradication of *H. pylori* (Zhu et al, 2014). Further study on specific strains and larger clinical trials is warranted to investigate the role of probiotic therapy and whether it should be included as a standard of care in medical treatment moving forward.

Food also provides an interesting alternative to standard therapy. Emerging research on the synergy of food combinations that may inhibit the growth of *H. pylori* suggests that green tea, broccoli sprouts, black currant oil, and kimchi (fermented cabbage) help with *H. pylori* eradication (Kennan et al, 2010). Recent studies have also demonstrated anti-*H. pylori* potential and significant inhibition of the bacteria's growth by n-3 polyunsaturated fatty acids (PUFAs) in both in vitro and in vivo models. A decrease in growth and associated inflammation of *H. pylori* has been shown with administration of docosahexaenoic acid (DHA). Although some results showed fish oil as less effective than aspects of TT treatment, and omega-3s would not be a standalone therapy, data suggests, when combined with standard TT treatment, that PUFAs and DHA could have potential to dampen recurrence rates (Park et al, 2015).

Because of the known relationship between *H. pylori* and peptic ulcers, eradication of the bacteria is a primary focus of treatment for those who test positive for it. Dietary polyphenols are being reviewed in a variety of studies to determine efficacy in combination with conventional treatment for peptic ulcers. Piper betel, curcumin, gallic acid, apple, grape, pomegranate and green tea polyphenols, and quercetin represent only a few compounds being investigated. These bioactive compounds are only a starting point for the direction of future research and clinical trials needed to determine the role of food as a part of the treatment for peptic ulcer disease (Farzaei et al, 2015).

Non-*Helicobacter pylori* Gastritis

Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) are corrosive; both inhibit prostaglandin synthesis, which is essential for maintaining the mucus and bicarbonate barrier in the stomach. Thus chronic use of aspirin or other NSAIDs, steroids, alcohol, erosive substances, tobacco, or any combination of these factors may compromise mucosal integrity and increase the chance for acquiring acute or chronic gastritis. Eosinophilic gastroenteritis (EGE) also may contribute to some cases of gastritis. Poor nutrition and general poor health may contribute to the onset and severity of the symptoms and can delay the healing process.

Medical Treatment

Treatment for gastritis involves removing the inciting agent (e.g., pathogenic organism, NSAIDs). Noninvasive methods for diagnosing *H. pylori* include a blood test for *H. pylori* antibodies, a urea breath test, or a stool antigen test. **Endoscopy** is a common invasive diagnostic tool (see *Focus On: Endoscopy and Capsules* for more details about this procedure). Antibiotics and PPIs are the primary medical treatments.

Side effects of chronic acid suppression either from disease or chronic use of PPIs are a current topic of interest in medical research. First approved in 1989, PPIs reduce gastric acid production by binding irreversibly to the hydrogen/potassium ATPase enzyme on gastric parietal cells and are now one of the most commonly prescribed medications in the United States. While they are generally well-tolerated medications and are considered safe, there have been some emerging concerns regarding long-term use over the past several years. This is especially true for those taking the medication for longer than intended, or when no longer indicated, as they are now widely available over the counter. A Mayo Clinic review found that the association between each of the health concerns and long-term PPI use varies between likely causative, unlikely causative, and unclear association. For hypomagnesemia, vitamin B₁₂ deficiency, and small intestinal bacterial overgrowth (SIBO) the association is *likely causative*, whereas community acquired pneumonia (CAD) is *unlikely causative*, and bone fractures, *Clostridium difficile* infection, chronic kidney disease, and dementia have an *unclear association* (Nehra et al, 2018). See Appendix 13 for nutrients of concern for those taking these medications.

Peptic Ulcers

Etiology

Normal gastric and duodenal mucosa is protected from the digestive actions of acid and pepsin by the secretion of mucus, the production of bicarbonate, the removal of excess acid by normal blood flow, and the rapid renewal and repair of epithelial cell injury. **Peptic ulcer disease** occurs when open sores (peptic ulcers) form as a result of the breakdown of the normal defense and repair mechanisms, and are differentiated as either gastric or duodenal, depending on location. Typically, more than one of the mechanisms must be malfunctioning for symptomatic peptic ulcers to develop. Peptic ulcers typically show evidence of chronic inflammation and repair processes surrounding the lesion.

The primary causes of peptic ulcers are *H. pylori* infection, gastritis, use of aspirin, other NSAIDs and corticosteroids, and severe illness (see Stress Ulcers later in this chapter and *Pathophysiology and Care Management Algorithm: Peptic Ulcer*). Life stress may lead to behaviors that increase peptic ulcer risk. Although excessive use of concentrated forms of ethanol can damage gastric mucosa, worsen symptoms of peptic ulcers, and interfere with ulcer healing, alcohol consumption in moderation does not cause peptic ulcers in healthy people. Use of

tobacco products also is linked with peptic ulcer risk because tobacco decreases bicarbonate secretion and mucosal blood flow, exacerbates inflammation, and is associated with additional complications of *H. pylori* infection. Other risk factors include gastrinoma and Zollinger-Ellison's syndrome (see Chapter 28).

FOCUS ON

Endoscopy and Capsules

The esophagogastroduodenoscopy (EGD) procedure allows the mucosa of the upper gastrointestinal (GI) tract to be viewed, photographed, and biopsied. Also known as an endoscopy, the procedure involves insertion of a flexible tube into the esophagus with a light and camera on the distal end. It can be passed through the esophagus and into the stomach or upper small bowel. Inflammation, erosions, ulcerations, changes in the blood vessels, and destruction of surface cells can be identified. These changes can then be correlated with chemical, histologic, and clinical findings to formulate a diagnosis. This may be useful when physicians suspect certain conditions, such as complicated gastroesophageal reflux disease (GERD) strictures, Barrett's esophagus (BE), esophageal varices, or gastroduodenal ulcers or celiac disease.

EGD also can be used for a number of therapeutic purposes, such as cauterization at ulcer sites, dilation or deployment of stents in areas of stricture, and placement of percutaneous feeding tubes. Endoscopy may be used in long-term monitoring of patients with chronic esophagitis and gastritis because of the possibility that they will develop premalignant lesions or carcinoma.

Capsule endoscopy can be used to view segments of the GI tract that are not accessible by standard EGD, to screen for abnormalities or bleeding, check pH, and measure the time it takes to pass through different segments of the GI tract. In this procedure, capsules containing a miniaturized video camera, light, and radio transmitter that can be swallowed and the signal transmitted to a receiver worn on the waist of the patient, allowing wireless capsule endoscopy. The procedure is less invasive than normal endoscopy and provides the advantage of being able to observe, record, and measure GI function as the patient is ambulatory.

Unfortunately, the images from capsule endoscopy can be blurred by rapid intestinal transit or limited in number after battery failure in cases of slow transit. In addition, reviewing the thousands of images obtained after each capsule endoscopy can be very time consuming. Prototypes of the newest generation of capsule endoscopy allow the physician to magnetically guide the capsule to a specific location by having the patient lie on a special table. Future generations of capsule endoscopy are on the drawing boards to hopefully allow therapeutic measures to be accomplished in the small bowel via capsule endoscopy.

The incidence and number of surgical procedures related to peptic ulcers has decreased markedly in the past 3 decades because of recognition of symptoms and risk factors, and earlier screening for *H. pylori*. Uncomplicated peptic ulcers in either the gastric or duodenal region may present with signs similar to those associated with dyspepsia and gastritis.

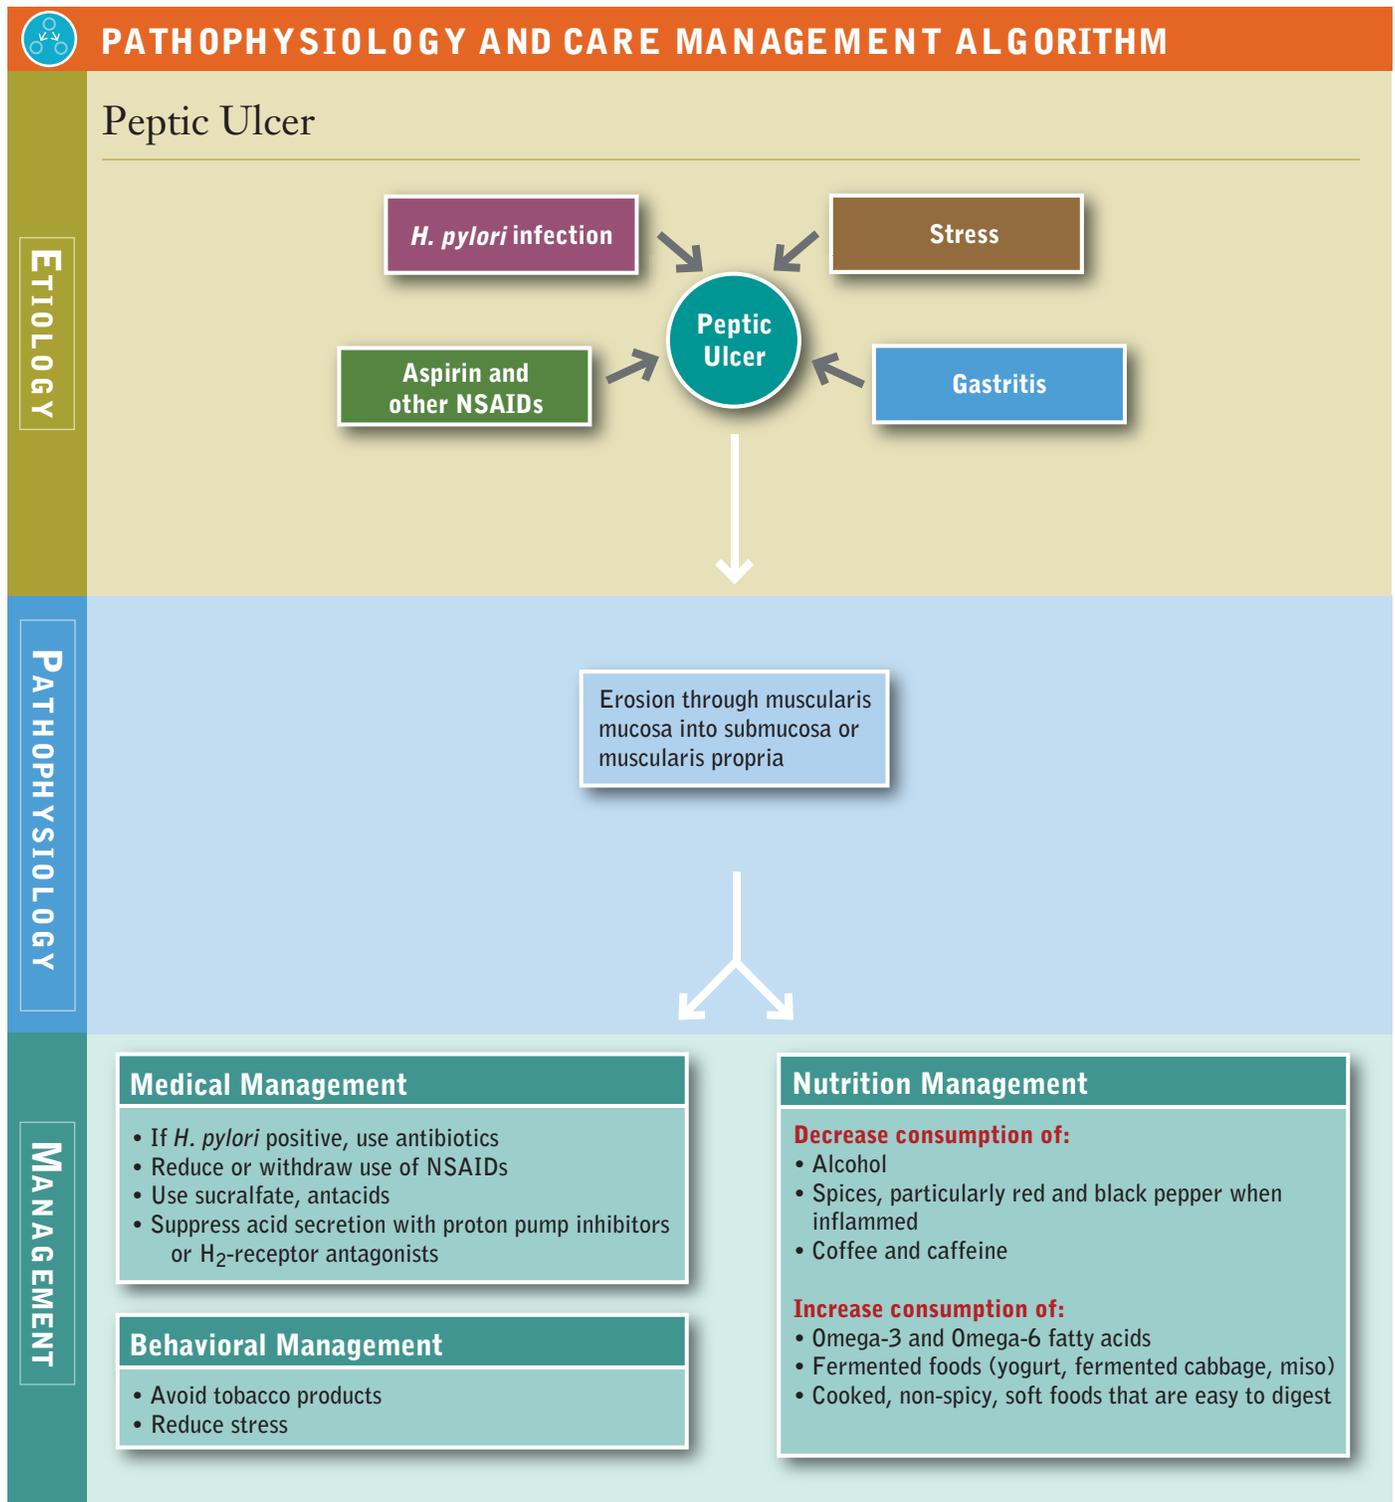

Abdominal discomfort is the most common symptom of peptic ulcers and can be felt anywhere between the navel and the breastbone. This discomfort is usually described as a dull or burning pain that occurs when the stomach is empty (between meals or during the night), and may be briefly relieved by eating food, in the case of duodenal ulcers, or by taking antacids. In both types of peptic ulcers, the symptoms last for minutes to hours and come and go for several days or weeks. Other symptoms include bloating, burping, nausea, vomiting, poor appetite, and weight loss. Some people experience only mild symptoms or none at all.

Peptic ulcers also may have “emergency symptoms,” in which medical assistance should be sought immediately. These include sharp, sudden, persistent, and severe stomach pain, bloody or black stools (**melen**), bloody vomit (hematemesis), or vomit that looks like coffee grounds. These symptoms could be signs of a serious problem, such as:

- Acute or chronic GI bleed: when acid or a peptic ulcer breaks a blood vessel.

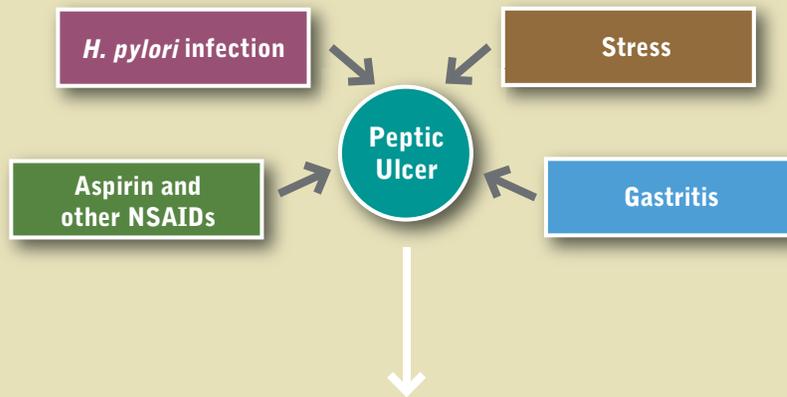

- GI perforation: when a peptic ulcer burrows completely through the stomach or duodenal wall, potentially penetrating an adjacent organ (e.g., pancreas)
- GI obstruction: when a peptic ulcer blocks the path of food trying to leave the stomach.

If or when these problems occur, immediate medical attention is necessary, as complications of hemorrhage and perforation contribute significantly to the morbidity and mortality of peptic ulcers.

Peptic Ulcer

ETIOLOGY

PATHOPHYSIOLOGY

Erosion through muscularis mucosa into submucosa or muscularis propria

MANAGEMENT

- Medical Management**
- If *H. pylori* positive, use antibiotics
 - Reduce or withdraw use of NSAIDs
 - Use sucralfate, antacids
 - Suppress acid secretion with proton pump inhibitors or H₂-receptor antagonists
- Behavioral Management**
- Avoid tobacco products
 - Reduce stress

- Nutrition Management**
- Decrease consumption of:**
- Alcohol
 - Spices, particularly red and black pepper when inflamed
 - Coffee and caffeine
- Increase consumption of:**
- Omega-3 and Omega-6 fatty acids
 - Fermented foods (yogurt, fermented cabbage, miso)
 - Cooked, non-spicy, soft foods that are easy to digest

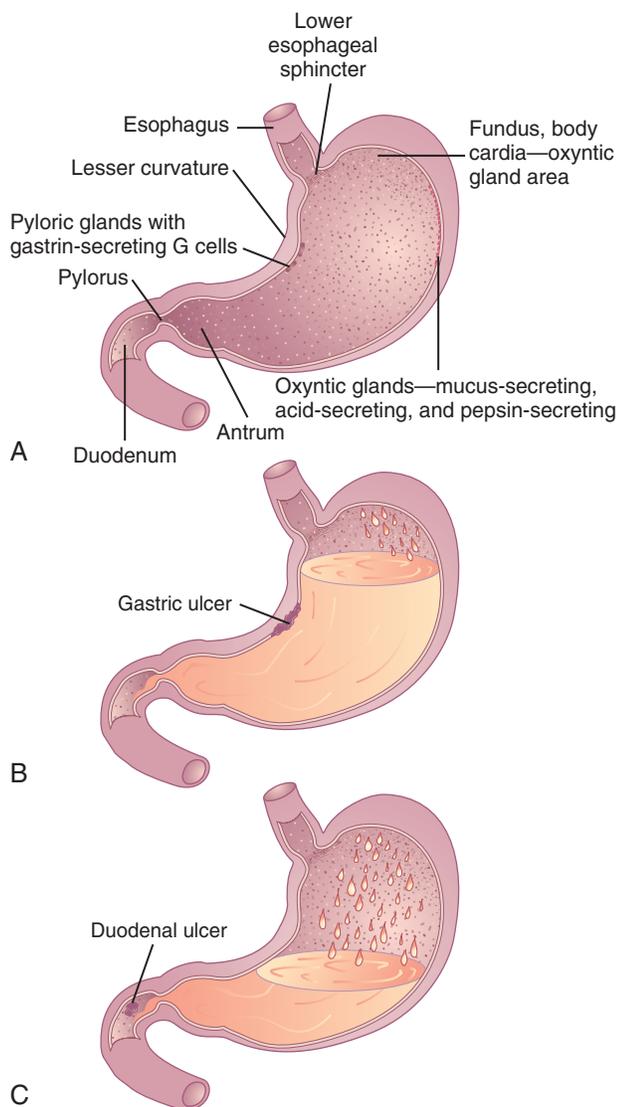

Fig. 26.5 **A**, Diagram showing a normal stomach and duodenum; **B**, a gastric ulcer; **C**, a duodenal ulcer.

Gastric versus Duodenal Ulcers

Pathophysiology

Although gastric ulcers can occur anywhere in the stomach, most occur along the lesser curvature (Fig. 26.5). **Gastric ulcers** typically are associated with widespread gastritis, inflammatory involvement of parietal cells, and atrophy of acid- and pepsin-producing cells occurring with advancing age. In some cases, gastric ulceration develops despite relatively low acid output. Antral hypomotility, gastric stasis, and increased duodenal reflux are associated commonly with gastric ulcers, and when present, may increase the severity of the gastric injury. The incidence of hemorrhage and overall mortality is higher with a gastric ulcer than a duodenal ulcer.

A **duodenal ulcer** is characterized by increased acid secretion throughout the entire day accompanied with decreased bicarbonate secretion. Most duodenal ulcers occur within the first few centimeters of the duodenal bulb, in an area immediately below the pylorus. Gastric outlet obstruction occurs more commonly with duodenal ulcers than with gastric ulcers, and gastric metaplasia (e.g., replacement of duodenal villous cells with gastric-type mucosal cells) may occur with duodenal ulcer related to *H. pylori*.

Medical and Surgical Management of Ulcers

Regardless of the type of ulcer, the first intervention is to evaluate the patient endoscopically and resuscitate as needed. Control acute bleeding if present.

Peptic ulcers. *H. pylori* is the primary cause of gastritis and peptic ulcers, thus its diagnosis if present, and treatment, should be the first medical intervention. At the first endoscopy, diagnostic biopsies should be taken for *H. pylori*. Treatment of *H. pylori* infection entails eradication of this organism with the appropriate antibiotic and acid-suppressive regimen. Although surgical intervention is less prevalent, emergent and elective procedures and surgeries are still required for peptic ulcer complications. Interventions can range from endoscopic, open, and laparoscopic procedures to treat individual lesions, to partial gastrectomy and occasionally selective vagotomies.

Stress ulcers. **Stress ulcers** may occur as a complication of metabolic stress caused by trauma, burns, surgery, shock, renal failure, or radiation therapy. A primary concern with stress ulceration is the potential for significant GI hemorrhage. Gastric ischemia associated with GI hypoperfusion, oxidative injury, reflux of bile salts and pancreatic enzymes, microbial colonization, and mucosal barrier changes also have been implicated. Although stress ulcerations usually occur in the fundus and body of the stomach, they also may develop in the antrum, duodenum, or distal esophagus. Typically shallow, and causing oozing of blood from superficial capillary beds, stress ulcer lesions also may occur deeper, eroding into the submucosa, causing massive hemorrhage or perforation.

Stress ulcers that bleed can be a significant cause of morbidity in the critically ill patient (see Chapter 37). Although current prevention and treatment include sucralfate, acid suppressants, and antibiotics as needed, high-quality evidence to guide clinical practice in effective treatments is limited. Efforts to prevent gastric ulcers in stressed patients have focused on preventing or limiting conditions leading to hypotension and ischemia and coagulopathies. Avoiding NSAIDs and large doses of corticosteroids is also beneficial.

Providing oral or enteral feeding, when possible, increases GI vascular perfusion and stimulates secretion and motility. A meta-analysis of studies in critically ill patients that received an H_2 -receptor antagonist for stress ulcer prevention found this therapy to be preventative only in patients who did not receive enteral feeding. In fact, for patients receiving enteral feeding, H_2 -receptor antagonist therapy may increase the risk of pneumonia and death (Chanpura and Yende, 2012). Further research is needed to prospectively test the effect of enteral feeding on the risk of stress ulcer prophylaxis.

Medical Nutrition Therapy

In persons with atrophic gastritis, vitamin B_{12} status should be evaluated because lack of intrinsic factor and gastric acid results in malabsorption of this vitamin (see Chapter 31). Low acid states may influence absorption of iron, calcium, and other nutrients because gastric acid enhances bioavailability. In the case of refractory iron deficiency anemia, other causes may be the presence of *H. pylori* and gastritis. Eradication of *H. pylori* has resulted in improved absorption of iron and increased ferritin levels (Hershko and Camaschella, 2014).

For several decades dietary factors have gained or lost favor as a significant component in the cause and treatment of dyspepsia, gastritis, and peptic ulcer disease. There is little evidence that specific dietary factors cause or exacerbate gastritis or peptic ulcer disease. Protein foods temporarily buffer gastric secretions, but they also stimulate secretion of gastrin, acid, and pepsin. Milk or

cream, which in the early days of peptic ulcer management was considered important in coating the stomach, is no longer considered medicinal.

The pH of a food has little therapeutic importance, except for patients with existing lesions of the mouth or the esophagus. Most foods are considerably less acidic than the normal gastric pH of 1 to 3. The pH of orange juice and grapefruit is 3.2 to 3.6, and the pH of commonly used soft drinks ranges from approximately 2.8 to 3.5. On the basis of their intrinsic acidity and the amount consumed, fruit juices and soft drinks are not likely to cause peptic ulcers or appreciably interfere with healing. Some patients express discomfort with ingestion of acidic foods, but the response is not consistent among patients, and in some, symptoms may be related to heartburn. The dietary inclusion of “acidic foods” should be individualized based on the patient’s perception of their effect.

Consumption of large amounts of alcohol may cause at least superficial mucosal damage and may worsen existing disease or interfere with treatment of the peptic ulcer. Modest consumption of alcohol does not appear to be pathogenic for peptic ulcers unless coexisting risk factors are also present. On the other hand, beers and wines significantly increase gastric secretions and should be avoided in symptomatic disease.

Coffee and caffeine stimulate acid secretion and also may decrease LES pressure; however, neither has been strongly implicated as a cause of peptic ulcers outside of the increased acid secretion and discomfort associated with their consumption.

When very large doses of certain spices are fed orally or placed intragastrically without other foods, they increase acid secretion and cause small, transient superficial erosions, inflammation of the mucosal lining, and altered GI permeability or motility. Small amounts of chili pepper or its active component, capsaicin, may increase mucosal protection by increasing production of mucus. The burning sensation in the gut when capsaicin is consumed is due to transient receptor potential vanilloid-1 (TRPV1) receptors throughout the GI tract, and repeated exposure can desensitize the receptor. Larger amounts of capsaicin may not be as well tolerated and could cause superficial mucosal damage, especially when consumed with alcohol, as TRPV1 receptors can also be stimulated by ethanol (Patcharatrakul and Gonlachanvit, 2016). Another spice, curcumin, through its antiinflammatory activity that inhibits the NF- κ B pathway activation may be a chemopreventive candidate against *H. pylori*-related cancer (Sarkar et al, 2016) (see Chapter 12).

Overall, a high-quality diet without nutrient deficiencies may offer some protection and may promote healing. Persons being treated for gastritis and peptic ulcer disease should be advised to avoid foods that exacerbate their symptoms and to consume a nutritionally complete diet with adequate dietary fiber from fruits and vegetables.

Carcinoma of the Stomach

Although the incidence and mortality have fallen dramatically over the last 50 years in many regions, gastric cancer is still the second most common cause of cancer death worldwide, with varying incidence in different parts of the world and among various ethnic groups (Nagini, 2012). Despite advances in diagnosis and treatment, the 5-year survival rate of stomach cancer is only 20%.

Etiology

The cause of gastric cancer is multifactorial, but more than 80% of cases have been attributed to *H. pylori* infection. In addition, diet, lifestyle, genetic, socioeconomic, and other factors contribute to

gastric carcinogenesis. A Western diet, high in processed meats, fat, starches, and simple sugars, is associated with an increased risk of gastric cancer compared with a diet high in fruits and vegetables (Bertuccio et al, 2013). Other factors that may increase the risk of gastric cancer include alcohol consumption, excess body weight, smoking, intake of highly salted or pickled foods, or inadequate amounts of micronutrients. Certain cooking practices also are associated with increased risk of gastric cancer, including broiling of meats, roasting, grilling, baking, and deep frying in open furnaces, sun drying, salting, curing, and pickling, all of which increase the formation of carcinogenic N-nitroso compounds. Polycyclic aromatic hydrocarbons such as benzo[a]pyrene formed in smoked food have been incriminated in many areas of the world (Nagini, 2012).

Pathophysiology

Stomach cancer refers to any malignant neoplasm that arises from the region extending between the gastroesophageal junction and the pylorus. Because symptoms are slow to manifest themselves and the growth of the tumor is rapid, carcinoma of the stomach frequently is overlooked until it is too late for a cure. Loss of appetite, strength, and weight frequently precede other symptoms. In some cases, **achylia gastrica** (absence of HCl and pepsin) or **achlorhydria** (absence of HCl in gastric secretions) may exist for years before the onset of gastric carcinoma. Malignant gastric neoplasms can lead to malnutrition as a result of excessive blood and protein losses or, more commonly, because of obstruction and mechanical interference with food intake.

Medical and Surgical Management

Most cancers of the stomach are treated by surgical resection; thus, part of the nutritional considerations includes partial or total **gastrectomy**, a resection or removal of the stomach. Some patients may experience difficulties with nutrition after surgery.

Medical Nutrition Therapy

The dietary regimen for carcinoma of the stomach is determined by the location of the cancer, the nature of the functional disturbance, and the stage of the disease. The patient with advanced, inoperable cancer should receive a diet that is adjusted according to tolerance, preference, and comfort. Anorexia is almost always present from the early stages of disease. In the later stages of the disease, the patient may tolerate only a liquid diet. If a patient is unable to tolerate oral feeding, consideration should be given to using an alternate route, such as a gastric or intestinal enteral tube feeding, or if this is not tolerated or feasible, parenteral feeding. The nutritional support for the patient should be in accordance with the patient’s goals of care (see Chapter 12).

Gastric Surgeries

Because of increased recognition and treatment for *H. pylori* and acid secretion, gastric surgeries are performed less frequently. However, partial or total gastrectomy may still be necessary for patients with ulcer disease that does not respond to therapy, or for those with malignancy. Gastric surgeries performed for weight loss or bariatric surgeries are more common. These surgeries, such as Roux-en-Y gastric bypass, gastric banding, sleeve gastrectomy, vertical banding gastroplasty, and jejunioileal bypass are designed to induce weight loss through volume restriction, malabsorption, or both (see Chapter 20).

Types of Surgeries

A total gastrectomy involves removal of the entire stomach, whereas only a portion of the stomach is removed with a subtotal or partial

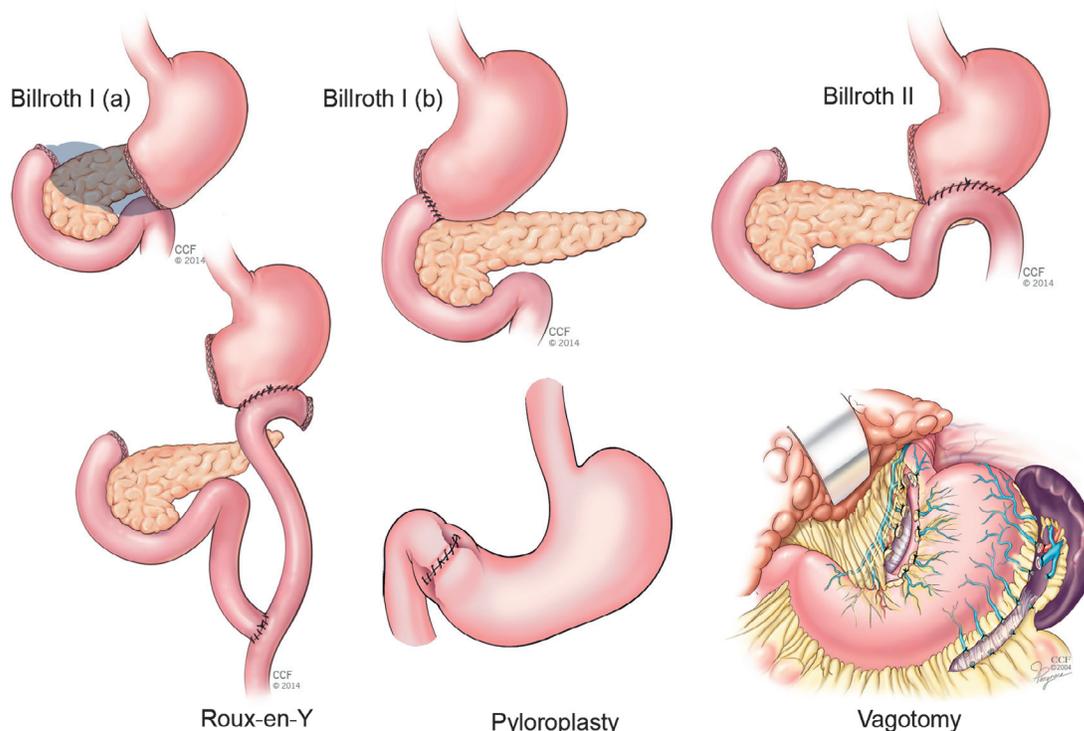

Fig. 26.6 Gastric surgical procedures [Billroth I (A: preoperative and B: postoperative), Billroth II, Roux en Y, pyloroplasty, vagotomy].

gastrectomy. A gastrectomy is accompanied by a reconstructive procedure. A total gastrectomy is performed for malignancies that affect the middle or upper stomach. The total stomach is removed, and a Roux-en-Y reconstruction is performed to maintain GI tract continuity. With a **Roux-en-Y**, the jejunum is pulled up and anastomosed to the esophagus. The duodenum is then connected to the small bowel so that bile and pancreatic secretions can flow into the intestine. **Billroth I (gastroduodenostomy)** involves removal of the pylorus and/or antrum, and an anastomosis of the proximal end of the duodenum to the distal end of the remnant stomach. A **Billroth II (gastrojejunostomy)** involves removal of the stomach antrum and an anastomosis of the remnant stomach to the side of the jejunum, which creates a blind duodenal loop (Fig. 26.6).

The **vagus nerve** is responsible for not only motility, but also stimulation of parietal cells in the proximal stomach, therefore a **vagotomy** often is performed to eliminate gastric acid secretion. **Truncal vagotomy**, complete severing of the vagus nerve on the distal esophagus, decreases acid secretion by parietal cells in the stomach and decreases their response to the hormone gastrin. A **parietal cell vagotomy** (partial or selective) divides and severs only the vagus nerve branches that affect the proximal stomach where gastric acid secretion occurs, whereas the antrum and pylorus remain innervated. Vagotomy at certain levels can alter the normal physiologic function of the stomach, small intestine, pancreas, and biliary system. Vagotomy procedures commonly are accompanied by a drainage procedure (antrectomy or **pyloroplasty**) that aids with gastric emptying.

Postoperative Medical Nutrition Therapy

Oral intake of fluids and foods is initiated as soon as GI tract function returns (typically 24 to 72 hours postoperatively). Small frequent feedings of ice or water are normally initiated, followed by liquids and

easily digested solid foods, after which the patient can progress to a regular diet. Although this is the common postoperative diet intervention, there is limited evidence supporting this practice. In fact, some studies suggest beginning a regular diet of tolerated foods as the first diet to improve patient tolerance (Warren et al, 2011). If the patient is unable to tolerate an oral diet for an extended period of time (e.g., 5 to 7 days), then enteral feeding should be considered if appropriate feeding access is available, and if not, PN should be considered.

Understanding the surgery performed and the patient's resulting anatomy is paramount to providing proper nutritional care. Nutritional complications after gastric surgeries are varied (Table 26.4). Complications such as obstruction, dumping, abdominal discomfort, diarrhea, and weight loss may occur, depending on the nature and extent of the disease and surgical interventions (see Fig. 26.6). Patients may have difficulty regaining normal preoperative weight because of inadequate food intake related to (1) early satiety, (2) symptoms of dumping syndrome (see later in this chapter), or (3) nutrient malabsorption.

Patients with certain gastric surgeries, such as Billroth II, result in a mismatch in timing of food entry into the small intestine and the release and interaction with bile and pancreatic enzymes, contributing to impaired nutrient digestion and absorption. Patients who are lactose tolerant before gastric surgery may experience relative lactase deficiency, either because food enters the small intestine further downstream from adequate lactase presence, or because the rate of transit through the proximal small intestine is increased. Because of the complications of reflux or dumping syndrome associated with traditional gastrectomies, other procedures are used, including truncal, selective, or parietal cell vagotomy; pyloromyotomy; antrectomy; Roux-en-Y esophagojejunostomy; loop esophagojejunostomy; and pouches or reservoirs made from jejunal or ileocecal segments.

TABLE 26.4 Gastric Surgery–Related Nutrition Complications

Surgical Procedure	Potential Complications
Vagotomy	Impairs motor function of stomach
Total gastric and truncal vagotomy	Gastric stasis and poor gastric emptying
Total gastrectomy	Early satiety, nausea, vomiting Weight loss Inadequate bile acids and pancreatic enzymes available because of anastomotic changes Malabsorption Protein-energy malnutrition Anemia Dumping syndrome Bezoar formation Vitamin B ₁₂ deficiency Metabolic bone disease
Subtotal gastrectomy with vagotomy	Early satiety Delayed gastric emptying Rapid emptying of hypertonic fluids

Cresci G et al: *Nutrition essentials of general surgery*, ed 5, Lippincott Williams & Wilkins, 2013, Table 3–13, p 72; Rollins, CJ (2015): Chapter 23, Drug-Nutrient Interactions with Gastrointestinal Drugs. In *The Health Professional's Guide to Gastrointestinal Nutrition* (pp. 296–311). Chicago IL: Cathy Immartino.

Some chronic nutritional complications that can occur after gastric surgery include anemia, osteoporosis, and select vitamin and mineral deficiencies resulting from inadequate intake and or malabsorption. Iron deficiency may be attributed to loss of acid secretion because gastric acid normally facilitates the reduction of iron compounds, allowing their absorption. Rapid transit and diminished contact of dietary iron with sites of iron absorption can also lead to iron deficiency.

Vitamin B₁₂ deficiency may cause a megaloblastic anemia (see Chapter 31). If the amount of gastric mucosa is reduced, intrinsic factor may not be produced in quantities adequate to allow for complete vitamin B₁₂ absorption, and pernicious anemia may result. Bacterial overgrowth in the proximal small bowel or the afferent loop contributes to vitamin B₁₂ depletion because bacteria compete with the host for use of the vitamin. Therefore after gastrectomy patients should receive prophylactic vitamin B₁₂ supplementation (injections) or take synthetic oral supplementation.

Dumping Syndrome

Etiology

The **dumping syndrome** is a complex GI and vasomotor response to the presence of large quantities of hypertonic foods and liquids in the proximal small intestine. Dumping syndrome usually occurs as a result of surgical procedures that allow excessive amounts of liquid or solid foods to enter the small intestine in a concentrated form. Milder forms of dumping may occur to varying degrees in persons without surgical procedures, and most of the symptoms can be reproduced in normal individuals by infusing a loading dose of glucose into the jejunum. Dumping may occur as a result of total or partial gastrectomy, manipulation of the pylorus, fundoplication, vagotomy, and some gastric bypass procedures for obesity. As a result of better medical management of peptic ulcers, use of selective vagotomies, and newer surgical

procedures to avoid complications, classic dumping is encountered less frequently in clinical practice.

Pathophysiology

Symptoms can be divided into two types or stages of dumping of solids and liquids into the small intestine, and characteristics and symptom severity vary between patients:

- Early dumping (within 10 to 30 minutes postprandially) is characterized by GI and vasomotor symptoms, which include abdominal pain, bloating, nausea, vomiting, diarrhea, headache, flushing, fatigue, and hypotension. These symptoms likely occur because of the rapid influx of hyperosmolar contents into the duodenum or small intestine. A subsequent fluid shift from the intravascular compartment to the intestinal lumen occurs, resulting in small intestine distention, potentially causing cramps and bloating.
- Late dumping (1 to 3 hours postprandially) results in symptoms that are predominantly vasomotor and include perspiration, weakness, confusion, shakiness, hunger, and hypoglycemia. Late dumping is likely the result of reactive hypoglycemia. Rapid delivery, as well as hydrolysis and absorption of carbohydrates, produces an exaggerated rise in insulin level and a subsequent decline in blood glucose. The rapid changes in blood glucose and the secretion of gut peptides, glucose insulinotropic polypeptide, and glucagon-like polypeptide-1 appear to be at least partly responsible for the late symptoms (Deloose et al, 2014).

Medical Management

Medical intervention typically involves dietary changes as the initial treatment, and they are usually effective. However, in 3% to 5% of patients, severe dumping persists despite dietary change. In these patients, medications may be used to slow gastric emptying and delay transit of food through the GI tract. Some, such as acarbose, inhibit alpha glycoside hydrolase and interfere with carbohydrate absorption, and octreotide, a somatostatin analog, inhibits insulin release (see Table 26.3 for common medications). Rarely, surgical intervention is used to treat dumping syndrome.

Medical Nutrition Therapy

Patients with dumping syndrome may experience weight loss and malnutrition caused by inadequate intake, malabsorption, or a combination of both. The prime objective of nutrition therapy is to restore nutrition status and quality of life. Because they are digested more slowly, proteins and fats are better tolerated than carbohydrates, particularly simple carbohydrates. Simple carbohydrates such as lactose, sucrose, fructose, glucose, and dextrose are hydrolyzed rapidly and should be limited, but complex carbohydrates (starches) can be included in the diet.

Liquids leave the stomach and enter the jejunum rapidly; thus, some patients have trouble tolerating liquids with meals. Patients with severe dumping may benefit from limiting the amount of liquids taken with meals and drinking liquids between meals without solid food. Reclining (approximately 30 degrees) after meals may also minimize severity of symptoms.

The use of soluble fiber supplements, particularly pectin or gums (e.g., guar) can be beneficial in managing dumping syndrome because of fiber's ability to form gels with carbohydrates and fluids and delay GI transit. Patients may need to be taught about portion sizes of foods, especially of carbohydrate foods such as juices, soft drinks, desserts, and milk. The exchange list given in Appendix 18 can be used to calculate carbohydrate intake and teach about carbohydrate control.

BOX 26.7 Basic Guidelines for Dumping Syndrome

1. Eat six to eight small meals throughout the day.
2. Limit fluids to 4 ounces (½ cup) at a meal, just enough to rinse food down.
3. Drink remaining fluids at least 30 to 40 minutes before and after meals.
4. Eat slowly and chew foods thoroughly. Some may benefit from soft, ground, or pureed foods, or those that are already broken down, such as ground meats.
5. Avoid extreme temperatures of foods (very hot or very cold).
6. Use seasonings and spices as tolerated (may want to avoid pepper, hot sauce).
7. Lie down or recline for at least 30 minutes after eating.
8. Limit simple carbohydrate foods and liquids with more than 12 grams of sugar per serving. Examples: fruit juice, Gatorade, Powerade, Kool Aid, sweet tea, sucrose, honey, jelly, corn syrup, cookies, pie, doughnuts. Increase complex carbohydrate foods such as whole grains and foods made with them, and potatoes.
9. Choose foods that are higher in soluble fiber. Some examples of these foods include apples, oats, beets, carrots, and beans.
10. Include a protein-containing food at each meal.
11. Add a serving of fat such as olive oil, nut butter, or avocado to meals as tolerated to encourage slower gastric emptying. Minimize fried foods, chips, cookies, hot dogs, and other greasy foods.
12. Milk and dairy products may not be tolerated in the lactose intolerant. Introduce these slowly in the diet if they were tolerated preoperatively.
13. Avoid sugar alcohols such as sorbitol, xylitol, mannitol, and maltitol, as these may exacerbate symptoms.

University of Virginia Health System. Anti-Dumping Diet, <https://uvahealth.com/services/digestive-health/images-and-docs/dumping-syndrome.pdf>; Cresci GA (2015): Chapter 14, Gastrointestinal Tract Surgery. In *The Health Professional's Guide to Gastrointestinal Nutrition* (pp.168–181). Chicago IL: Cathy Immartino.

Postgastrectomy patients often do not tolerate lactose, but small amounts (e.g., 6 g or less per meal) may be tolerated at one time. Patients typically do better with cheeses or unsweetened yogurt than with fluid milk. Nondairy milks are also useful when necessary. Vitamin D and calcium supplements may be needed when intake is inadequate. Commercial lactase-containing products are available for those with significant lactose malabsorption (see Chapter 27 for further discussion of lactose intolerance and its management).

When steatorrhea (greater than 7% of dietary fat in the stool) exists, reduced-fat formulas or pancreatic enzymes may be beneficial. **Box 26.7** provides general nutrition guidelines for patients with dumping syndrome after gastric surgery; however, each diet must be adjusted based on a careful dietary and social history from the patient.

GASTROPARESIS

Etiology

Gastroparesis is a syndrome of delayed gastric emptying without evidence of mechanical obstruction and is a complex and potentially debilitating condition. The nature of gastroparesis is complex in part because gastric motility is orchestrated by a variety of chemical and neurologic factors. Viral infection, diabetes, and surgeries are the most common causes for gastroparesis; however, more than 30% of cases are idiopathic. Numerous classes of clinical conditions are associated with gastroparesis, including acid-peptic diseases, gastritis, postgastric

surgery, disorder of gastric smooth muscle, psychogenic disorders, long-term uncontrolled diabetes, and neuropathic disorders.

Pathophysiology

Clinical symptoms may include abdominal bloating, decreased appetite and anorexia, nausea and vomiting, fullness, early satiety, halitosis, and postprandial hypoglycemia. The gold-standard measure of gastric emptying rate is **scintigraphy**, a nuclear test of gastric emptying. This consists of the patient ingesting a radionuclide-labeled meal (such as an egg labeled ^{90m}technetium), and scintigraphic images are taken over time (generally 4 hours) to assess the rate of gastric emptying. Gastric emptying is abnormal when greater than 50% of the meal is retained after 2 hours of study or when greater than 10% of the meal is retained after 4 hours.

Medical Management

Numerous symptoms of gastroparesis can affect oral intake, and the management of these symptoms generally improves nutrition status. Treatment of nausea and vomiting is perhaps the most vital, and prokinetics and antiemetics are the primary medical therapies (see Table 26.3). Metoclopramide and erythromycin are medications that may be used to promote gastric motility. SIBO, appetite, ileal brake (the slowing effect of intestinal transit of undigested food, often fat, reaching the ileum), or formation of a **bezoar** (concentration of undigested material in the stomach) are other factors that may affect nutritional status. In a select patient population, implantation of gastric pacemakers may be advantageous to improve gastric emptying (Ross et al, 2014).

Bezoar formation may be related to undigested food such as cellulose, hemicellulose, lignin and fruit tannins (phytoezoars), or medications (pharmacoezoars) such as cholestyramine, sucralfate, enteric-coated aspirin, aluminum-containing antacids, and bulk-forming laxatives. Treatment of bezoars includes enzyme therapy (such as papain, bromelain, or cellulase), lavage, and sometimes endoscopic therapy to mechanically break up the bezoar. Most patients respond to some combination of medication and dietary intervention; however, unresponsive and more severe cases may benefit from placement of an enteral tube into the small intestine, such as a nasenteric small bowel feeding tube (for less than 4-week need) or percutaneous endoscopic gastrostomy with jejunal extension (PEG/J) (for more than 4-week need). The latter allows for nutrition to bypass the stomach while providing an alternative route for venting of gastric secretions, which may relieve nausea and vomiting.

Medical Nutrition Therapy

The primary dietary factors that affect gastric emptying include volume, liquids versus solids, hyperglycemia, fiber, fat, and osmolality. Generally, patients benefit from smaller, more frequent meals, as larger volumes of food that create stomach distention could delay gastric emptying and increase satiety. Patients with gastroparesis often continue to empty liquids, as they empty, in part, by gravity and do not require antral contraction.

Shifting the diet to more pureed and liquefied foods is often useful. A number of medications (such as narcotics and anticholinergics) slow gastric emptying and should be avoided if possible. Moderate to severe hyperglycemia (serum blood glucose more than 200 mg/dL) may acutely slow gastric motility, with long-term detrimental effects on gastric nerves and motility. Laboratory data considered in initial assessment include glycosylated hemoglobin A1C (if diabetes is present), ferritin, vitamin B₁₂, and 25-OH vitamin D (see Chapter 29).

Fiber, particularly pectin, can slow gastric emptying and increase risk of bezoar formation in patients who are susceptible. It is prudent to advise patients to avoid high-fiber foods and fiber supplements.

The size of the fibrous particles, not the amount of fiber, is more important in bezoar risk (e.g., potato skins versus bran). This and the resistance to chewing are factors in bezoar formation. Examination of the patient's dentition is very important because patients who have missing teeth, a poor bite, or are edentulous are at greater risk. Even people with good dentition have swallowed and passed food

particles up to 5 to 6 cm in diameter (potato skins, seeds, tomato skins, peanuts).

Although fat is a powerful inhibitor of stomach emptying primarily mediated by cholecystokinin, many patients tolerate fat well in liquid form. Fat should not be restricted in patients who are struggling to meet their daily caloric needs.

FOCUS ON

New GI Disorders Classified by Rome IV Criteria

With the updated Rome criteria, some important additions have been included, as they fit the new definition of disorders of gut-brain interaction (DGBIs) due to their effect on the central nervous system (CNS). These conditions are of important note given the ongoing use of opioids for pain management, and also given the more recent legalization and increased use of marijuana in some states. The new diagnoses include:

- **Narcotic bowel syndrome (NBS)** or opioid-induced gastrointestinal (GI) hyperalgesia is classified as a centrally mediated disorder of GI pain. Ironically, narcotics can lead to more discomfort in those with functional GI disorders, who present with chronic or frequent pain, nausea, bloating, periodic

vomiting, abdominal distention, and constipation. Over time, pain can worsen or incompletely resolve with increased doses of narcotics.

- **Opioid-induced constipation** is classified as a bowel disorder and considered the most common adverse side effect of chronic opioid use, and is treated with medications when severe.
- **Cannabinoid hyperemesis syndrome** is classified as a gastroduodenal disorder and included with other nausea and vomiting disorders. It is a syndrome of cyclic vomiting associated with cannabis use, with a common report of symptom improvement with hot bathing, and relief of symptoms with cessation of cannabis use.

International Foundation for Functional Gastrointestinal Disorders: *Narcotic Bowel Syndrome* (website), 2018. <https://www.iffgd.org/other-disorders/narcotic-bowel-syndrome.html>. CLINICAL CASE STUDY

Suzie is a 55-year-old female who is referred to the outpatient clinic with dumping syndrome that has started to interfere with her daily life. She travels for work, and keeping up with her busy schedule has become more difficult with symptoms at unpredictable times when she needs to be driving or in a meeting. A nutrition consultation with a registered dietitian specializing in gastrointestinal disorders is requested by her thoracic surgeon to help with relief of symptoms.

Nutrition Assessment

- **Medical History:** a short bout with dumping syndrome in 2014 after a Nissen fundoplication for a hiatal hernia that resolved a short period after surgery. After a minor hernia repair surgery to redo the fundoplication in early 2018, she began experiencing it again but with more severity. Symptoms include sudden weakness, shakiness, and hunger. She has occasional nausea during episodes, but no vomiting. Suzie also has a new diagnosis of gastroparesis, discovered before her second fundoplication. Upon discovering this, her surgeon also did a pyloroplasty during her second fundoplication surgery to try and help with gastroparesis, and she will have another gastric emptying study in 3 months. Other history includes elevated blood pressure that she reports controlling with diet, heartburn, and blood glucose levels within normal limits unless she is having a dumping episode, when it dips as low as 30 mg/dL. She also reports occasional numbness and tingling in her hands and feet.
- **Medications:** Reglan, Tums, and Omeprazole.
- **Nutrition History:** Suzie travels for work as a sales manager and is on the road constantly, eating mostly packaged and prepared foods on the go, and frozen dinners at home since she lives alone and does not enjoy cooking. Immediately after her fundoplication surgery she ate only soft foods but has recently graduated to some more-normal texture foods after ok from her surgeon to do so. She is unable to determine any food triggers for her dumping with her food journal and has not documented how soon an episode happens after eating. She tries to eat 6 smaller meals per day because her doctor told her

this would be better. She also stays well hydrated, drinking at least one 24-ounce water bottle with each meal. She met with a registered dietitian once but says the dietitian did not specialize in this condition, so it was not as helpful as she would have hoped. She is mostly vegetarian but occasionally has fish or chicken. She says she is not opposed to eating meat but mostly avoids cooking it. She is open to nutrition recommendations and arrives at the appointment ready to learn.

- **Dietary recall:**
 - **Breakfast:** She has coffee with cream and one slice of toast with butter or jam before leaving to drive to an adjacent city for a few hours for meetings.
 - **Snack:** In the car, she has a cooler packed with applesauce, peach cups, or a banana, of which she selects one or two for a snack midmorning.
 - **Lunch:** She stops at a grocery store deli and has her favorite on-the-go meal, a large plate of macaroni and cheese, or sometimes has a chef salad now that her doctor has allowed her to eat regular-texture foods again. She eats the meal in her car most days.
 - **Snack:** In the afternoon she eats another of her cooler items, and occasionally has a string cheese that she picked up at the grocery store deli.
 - **Dinner:** Frozen meal of Michelina's fettuccine Alfredo, which she describes as high protein. She may alternate out with another frozen pasta meal if she wants some variety, but the nutrition is about the same, according to her.
- **Anthropometrics:** Height: 170.2 cm (67 inches); Weight: 66.4 kg (146 lb); body mass index (BMI): 22.9 kg/m²
- **Usual Body Weight:** 68.2 kg (150 lbs); weight change: 2.6% decrease in 3 months (clinically insignificant)
- **Nutrition Focused Physical Assessment:** No evidence of muscle or fat loss; no lower or upper extremity edema. Tongue is sore and inflamed. Her nails are brittle and her skin is very pale.
- **Functional Capacity:** Unable to exercise over the past few months due to fatigue and low energy. She is feeling more forgetful lately as well and has to write everything down.

Continued

CLINICAL CASE STUDY—cont'd

- **Laboratory Data:** Blood glucose: 70–100 mg/dL at fasting laboratory draws, only drops low temporarily during dumping episodes; blood pressure: 144/92 (H); gastric emptying study results: 78% of gastric contents left in the stomach after 4 hours.

Nutrition Diagnostic Statements

- Food- and nutrition-related knowledge deficit (P) related to lack of prior relevant nutrition-related education (E) as evidenced by (S) intake of many refined carbohydrate foods in the setting of dumping syndrome
- Undesirable food choices (P) related to lack of prior exposure to nutrition-related information (E) as evidenced by (S) elevated blood pressure, intake of high-sodium foods

Nutrition Care Questions

1. What dietary changes would you recommend for Suzie?
2. What changes would recommend for Suzie about her eating pattern?
3. Would you recommend any micronutrient testing or supplementation? If so, which ones?
4. How would you prioritize education needs for Suzie?
5. Would you do any coordination of care with Suzie's doctor about anything you learned?

Monitoring and Evaluation

- What would you monitor at a 1-month follow up with Suzie?
- What would you measure at a 3-month follow up with Suzie?
- What would you evaluate at a 6-month follow up with Suzie?

diverticulitis	insoluble fiber	small intestinal bacterial overgrowth (SIBO)
diverticulosis	intestinal ostomy	soluble fiber
enterocutaneous fistula (ECF)	irritable bowel syndrome (IBS)	S-pouch
eructation	Koch pouch	steatorrhea
fecal microbiota transplant (FMT)	lactase intolerance	stimulant laxatives
fistula	medium-chain triglycerides (MCTs)	stool softeners
flatulence	microbiota	synbiotics
flatus	neurogenic bowel	tropical sprue
FODMAPs	oral rehydration solution (ORS)	ulcerative colitis (UC)
	osmotic agents	W-pouch

The lower gastrointestinal (GI) tract is defined as the portion of the alimentary canal including the jejunum and ileum of the small intestine, as well as the entire large intestine. Dietary interventions for diseases of this part of the digestive system have typically been focused on methods to alleviate symptoms and to correct nutrient deficiencies. A comprehensive nutritional assessment should be performed to determine the nature and severity of the GI problem to determine the best approach for each individual. Information obtained should include a history of weight trends, medications and supplements, presence of GI and other symptoms that may affect oral intake or fluid loss, and potential signs and symptoms of micronutrient deficiencies.

COMMON INTESTINAL PROBLEMS

It is important to understand some of the common GI processes that occur in healthy people before discussing diseases relating to the lower

GI tract. Dietary ramifications such as intestinal gas, flatulence, constipation, and diarrhea are often considered in the management of more serious GI disorders.

Intestinal Gas and Flatulence

Pathophysiology

The daily volume of human intestinal gas is about 200 mL, and it is derived from complex physiologic processes, including **aerophagia** (swallowed air) and bacterial fermentation by the intestinal tract. Intestinal gases include carbon dioxide (CO₂), oxygen (O₂), nitrogen (N₂), hydrogen (H₂), and sometimes methane (CH₄), and are either expelled through **eructation** (belching) or passed rectally as **flatus**. Detectable levels of CH₄ produced via anaerobic fermentation by human enteric microflora of both endogenous and exogenous carbohydrates have been found in 30% to 62% of healthy adult individuals (Sahakian et al, 2010). This remains compelling, as abnormal CH₄ production has been considered in the pathogenesis of several intestinal disorders, including colon cancer, inflammatory bowel disease (IBD), irritable bowel syndrome (IBS), and diverticulosis (Triantafyllou et al, 2014).

Portions of this chapter were written by Gail Cresci, PhD, RDN, LD, CNSC and Arlene Escuro, MS, RDN, CNSC.

When patients complain about “excessive gas” or **flatulence**, they may be referring to increased volume or frequency of belching or passage of rectal gas. They may also complain of abdominal distention or cramping associated with the accumulation of gases in the upper or lower GI tract. The amount of air swallowed increases with eating or drinking too fast, smoking, chewing gum, sucking on hard candy, using a straw, drinking carbonated drinks, and wearing loose-fitting dentures. Foods that produce gas in one person may not cause gas in someone else, depending on the mix of microorganisms in the individual’s colon. Inactivity, decreased motility, aerophagia, dietary components, and certain GI disorders can alter the amount of intestinal gas and individual symptoms.

Normally, the concentration of bacteria in the small intestine is significantly lower than that found in the colon. Various conditions can lead to overgrowth of bacteria in the small intestine, causing bloating, distention, nausea, diarrhea, or other symptoms. In a normally functioning bowel, factors such as gastric acid, intestinal peristalsis, the ileocecal valve, bile acids, the enteric immune system, and pancreatic enzyme secretion all work in concert to prevent the overgrowth of bacteria within the small intestine.

Medical Nutrition Therapy

When evaluating a patient, clinicians must investigate and differentiate between increased production of gas and gas that is not being passed. It is also important to consider why a patient may have new or increased symptoms or if gas is accompanied by other symptoms such as constipation, diarrhea, or weight loss. Keeping a food diary to track eating habits and symptoms may help identify specific foods or behaviors that may be contributing to gas production. Careful review of the diet and the amount of burping or gas passed may help relate specific foods to symptoms and determine the severity of the problem. Eating behaviors to consider could include whether a patient is chewing food well, eating slowly or under stressful conditions, and eating large amounts of raw foods that could be contributing to excess gas.

If milk or milk products are causing gas, a patient is evaluated for lactose intolerance (see detailed discussion later in this chapter for more in-depth discussion on this condition) and advised to avoid milk products for a short time to see if symptoms improve. Recent viral or GI infection may induce temporary or even permanent impairment in the ability to digest lactose. If intake is desired or difficult to avoid for some reason, lactase tablets, drops, and lactose-free milk products are available to help digest lactose and reduce gas.

Inactivity, constipation, intestinal dysmotility, or partial bowel obstruction may contribute to the inability to move normal amounts of gas produced. Further, a sudden change in diet, such as a drastic increase in fiber intake, also can alter gas production. Specific foods that contain raffinose (a complex sugar resistant to digestion), such as beans, cabbage, broccoli, Brussels sprouts, asparagus, and some whole grains can increase gas production. Changes in the intestinal flora occur over time after an increase in dietary fiber. A gradual introduction of fiber with adequate fluid consumption appears to reduce complaints of gas. **Box 27.1** outlines foods that may cause increase in gas production.

Constipation

Constipation is a major problem worldwide. In the United States, chronic constipation leads to 8 million visits to medical providers per year (Wald, 2016). Its exact prevalence is difficult to ascertain because only a minority of patients suffering from constipation seek health care. Reports of its prevalence have varied widely, ranging from 0.7% to 29% in children and from 2.5% to 79% in adults (Ferootan et al, 2018; Rajindrajith et al, 2016). This worldwide variation in prevalence

BOX 27.1 Foods That May Increase Intestinal Gas Production

1. Beans (legumes)
2. Vegetables such as broccoli, cauliflower, cabbage, Brussels sprouts, onions, mushrooms, artichokes, and asparagus
3. Fruits such as pears, apples, and peaches
4. Whole grains such as whole wheat and bran
5. Sodas: fruit drinks especially apple juice and pear juice; and other drinks that contain high-fructose corn syrup, a sweetener made from corn
6. Milk and milk products as well as soft cheese, ice cream, and yogurt
7. Packaged foods such as bread, cereal, and salad dressing that contain small amounts of lactose (milk sugar).
8. Sugar-free candies and gums that contain sugar alcohols such as sorbitol, mannitol, erythritol, and xylitol

From National Institute of Diabetes and Digestive and Kidney Diseases: *Digestive Diseases A-Z* (website): <http://digestive.niddk.nih.gov/>.

rates arises from factors such as cultural diversity; genetic, environmental, and socioeconomic conditions; and different health care systems. Constipation has a significant impact on quality of life, and it contributes to health care financial burden. Female gender in adults, advancing age, high body mass index, and low socioeconomic status seem to be associated with a higher prevalence of constipation (Ferootan et al, 2018).

Etiology

Constipation is defined as difficulty with defecation characterized by infrequent bowel movements or dyschezia (painful, hard, or incomplete evacuations). Normal bowel movement frequency can range from three times per day to three times per week. Stool weight is used most frequently in medical practice and clinical descriptions as an objective measure of the amount or volume of stool. A volume of as little as 200 g daily is considered normal in healthy children and adults. The Bristol Stool Scale (Fig. 27.1) was first developed in Bristol, England, in the 1990s and has been modified over time but remains a useful reference for clinicians and patients to identify stool form or consistency (Lewis and Heaton, 1997).

The causes of constipation are varied and may be multifactorial. Inadequate fiber intake has been cited as the primary culprit since the early 1970s, but treatment of the underlying disorder should always be the primary course of action. It is also important to understand symptom patterns and classification of constipation to tailor therapy based on the underlying pathophysiology. **Box 27.2** outlines factors and conditions known to cause constipation.

Pathophysiology

Constipation is categorized as either primary or secondary. **Primary constipation**, also known as idiopathic or functional constipation, is caused by physical or functional problems when no underlying disorder can be identified (Barco et al, 2015). The different subtypes of primary constipation can be categorized as follows (Andrews and Storr, 2011):

- Normal-transit constipation: This is most common form of chronic constipation seen by clinicians and is also known as functional constipation. Stool passes through the colon at a rate of about 5 days in persons with normal-transit constipation. In functional constipation, patients report symptoms they believe to be consistent with constipation such as the presence of hard stools or a perceived difficulty with defecation. However, on testing, stool transit is not delayed, and the stool frequency is often within the

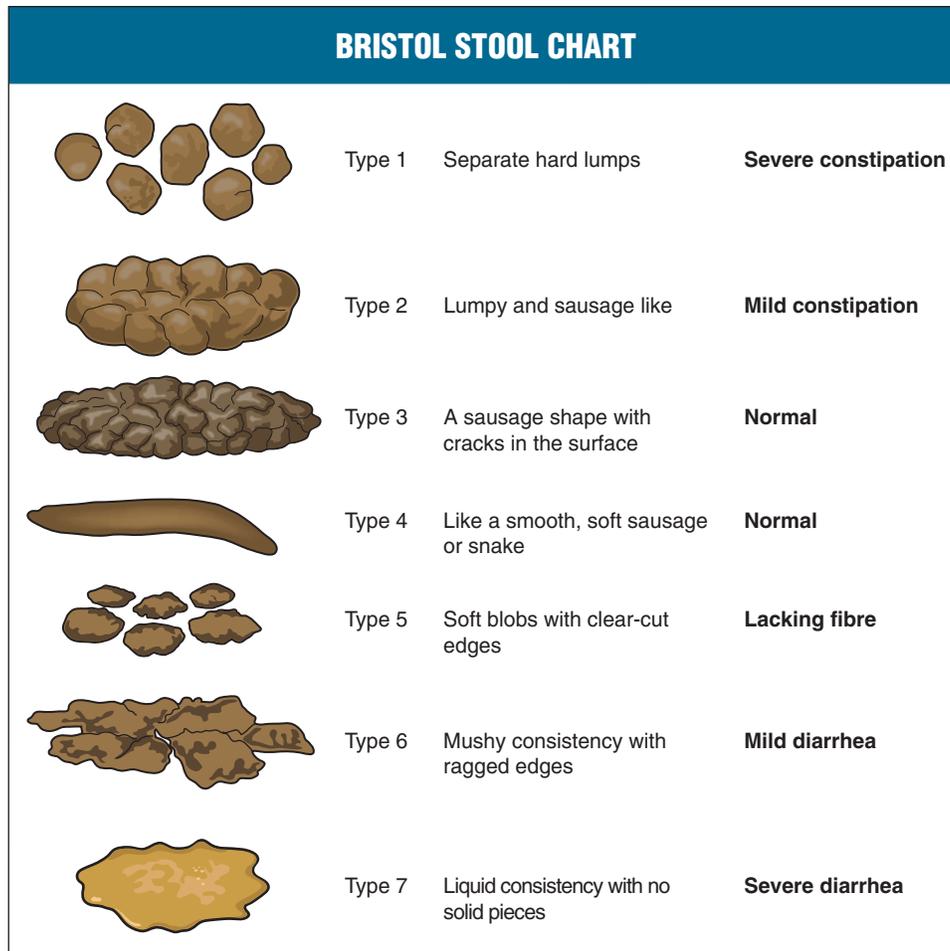

Fig. 27.1 Bristol Stool Scale (Wikimedia Commons: File: BristolStoolChart.png (website), <https://commons.wikimedia.org/wiki/File:BristolStoolChart.png>, Updated June 18, 2018).

BOX 27.2 Causes of Constipation

Lifestyle and Diet

Lack of fiber in diet
 Low total calorie and fluid intake
 Iron and calcium supplements
 Lack of exercise
 Immobility
 Laxative abuse
 Postponing urge to defecate

Dysmotility Disorders

Chronic intestinal pseudoobstruction
 Hypothyroidism
 Colonic inertia
 Gastroparesis
 Hirschsprung disease
 Chagas disease
 Metabolic and endocrine abnormalities such as diabetes

Neurologic Diseases

Amyotrophic lateral sclerosis
 Multiple sclerosis
 Muscular dystrophy
 Parkinson's disease

Friedrich ataxia
 Cerebral palsy
 Para- or quadriplegia
 Spinal cord injury
 Cerebrovascular disease
 Brain trauma

Pelvic Floor Disorders

Pregnancy
 Dyssynergic defecation

Chronic Use of Opiates

Oncology patients
 Chronic pain patients
 Narcotic bowel syndrome

Other Gastrointestinal Disorders

Diseases of the upper gastrointestinal tract
 Diseases of the large bowel resulting in:
 Failure of propulsion along the colon (colonic inertia)
 Anorectal malformations or outlet obstruction
 Irritable bowel syndrome (IBS) Small Intestinal Bacteria Overgrowth (SIBO)
 Anal fissure

BOX 27.3 Rome IV Diagnostic Criteria for Functional Constipation

Criteria fulfilled for the last 3 months, with symptom onset at least 6 months before diagnosis

1. Must include two or more of the following:
 - a. Straining during more than 25% of defecations
 - b. Lumpy or hard stools (Bristol stool scale 1 to 2) in more than 25% of defecations
 - c. Sensation of incomplete evacuation for more than 25% of defecations
 - d. Sensation of anorectal obstruction/blockage for more than 25% of defecations
 - e. Manual maneuvers to facilitate more than 25% of defecations (i.e., digital evacuation, support of the pelvic floor)
 - f. Fewer than three defecations per week
2. Loose stools are rarely present without the use of laxatives.
3. There are insufficient criteria for irritable bowel syndrome.

Sood R, Ford AC: Diagnosis: rome IV criteria for FGID's – an improvement or more of the same? *Nat Rev Gastroenterol Hepatol* 13:501–502, 2016.

normal range. Patients may experience bloating and abdominal pain or discomfort. Symptoms of functional constipation typically respond with dietary fiber alone or with the addition of an osmotic agent. The Rome IV criteria for the diagnosis of functional constipation is outlined in **Box 27.3** (Sood and Ford, 2016).

- **Slow transit constipation:** This subtype causes infrequent bowel movements (typically less than once per week). Often patients do not feel the urge to defecate but may complain of associated bloating and abdominal discomfort. Slowing of intestinal contents occurs more commonly in the rectosigmoid colon and results in decreased water content in the stool and reduced propulsive action. Treatment typically uses an aggressive laxative regimen. When severe and not resolved by other less invasive treatment options, select patients with slow transit constipation may also be considered for surgical procedures such as subtotal colectomy and ileorectal anastomosis.
- **Anorectal dysfunction:** This subtype is a result of pelvic floor muscle laxity, impaired rectal sensation, and decreased luminal pressure in the anal canal. Frequently, laxatives are highly ineffective in anorectal dysfunction. The use of biofeedback therapy to retrain the muscles can be used by patients with constipation caused by problems in the anorectal muscles. It uses a combination of diaphragmatic muscle training, simulated defecation, and manometric or electromyogram (EMG) guided anal sphincter and pelvic muscle relaxation, with a goal of improving recto-anal coordination and sensory awareness (Lee et al, 2014). The measurements are displayed on a video screen as line graphs, and sounds indicate when the patient is using the correct muscles.

Secondary constipation can result from a wide variety of factors. The most common of these are lack of dietary fiber, inactivity, or low fluid intake. Other causes can include but are not limited to medications, lifestyle, mechanical blockages caused by cancers, adhesions, and strictures, psychogenic factors such as anxiety, depression, dementia, or eating disorders, or metabolic abnormalities such as electrolyte imbalance and diabetes. Conditions such as obesity, pregnancy, irritable bowel syndrome (IBS), small intestinal bacteria overgrowth (SIBO), or celiac disease can also contribute to secondary constipation and should be considered in clinicians addressing the problem (Barco et al, 2015). **Neurogenic bowel** is a type of bowel dysfunction caused by nerve malfunction after spinal cord injury or nerve diseases including but not limited to multiple sclerosis (MS) or amyotrophic lateral sclerosis (ALS) that damages nerves associated with controlling the lower colon. The two main types of neurogenic bowel include reflex (spastic) bowel or flaccid bowel, which both lead to constipation for various reasons (Cedars Sinai, 2018)

IBS may also be associated with chronic constipation. A low FODMAP diet is often helpful. More information on IBS and a low FODMAP diet is found later in this chapter.

Medical Management for Adults

A thorough and meticulous history is most helpful in ruling out constipation secondary to medications or other underlying medical illness. After this is done, the first approach to treat mild and functional constipation is to ensure adequate dietary fiber and fluid intake, exercise, and heeding the urge to defecate. Patients who depend on laxatives are encouraged to work with a medical professional and consider a transition to something milder such as magnesium citrate when medically appropriate and reducing the laxative dose until withdrawal is complete.

When constipation persists despite lifestyle and dietary modifications, medications that promote regular bowel movements may be prescribed. Agents used in the treatment of constipation are categorized broadly as either stool softeners or stimulants.

- **Stool softeners** (i.e., docusate sodium) are anionic surfactants with an emulsifying detergent-like property that increases the water content in stool to make bowel movements easier to pass.
- **Osmotic agents** such as magnesium hydroxide, sorbitol, lactulose, and polyethylene glycol contain poorly absorbed or nonabsorbable sugars and work by pulling fluid into the intestinal lumen.
- **Stimulant laxatives** such as bisacodyl and senna increase peristaltic contraction and bowel motility and act to prevent water absorption. Chronic use of laxatives is associated with abdominal cramping and fluid imbalance.

Lubiprostone (Amitiza) is a medication that has been approved by the FDA for idiopathic constipation and to treat IBS with constipation in adults. The drug is a chloride channel activator that increases intestinal fluid secretion and mobility without altering sodium or potassium electrolytes (Bailes and Reeve, 2013). It increases spontaneous bowel movements but is contraindicated in patients with suspected or known mechanical GI obstruction. It is recommended that patients take 1500 to 2000 mL of fluids per day and a high-fiber diet in addition to the medication (Pronsky et al, 2015). Further data on efficacy of any medication should be evaluated as nutrition intervention, positioning for defecation, and physical therapy may be equally as effective.

Medical Management for Infants and Children

Constipation is often especially troubling in infants and young children. Approximately 3% to 5% of all pediatric visits are related to chronic constipation. Some patients have symptoms that persist for 6 months or more. Constipation in this life stage may be related to inadequate intake of fiber or fluid, side effects of medication, inactivity, or disordered bowel motility. Historically, a high-fiber diet has been recommended for children with constipation, but few studies document benefit (Kranz et al, 2012). A thorough history and physical examination, parent-child education, behavioral and nutritional intervention, and appropriate use of laxatives often lead to dramatic improvement.

Medical Nutrition Therapy

Primary nutrition therapy for constipation in otherwise healthy people is consumption of adequate amounts of fluids and dietary fiber, soluble and insoluble. Fiber increases colonic fecal fluid, microbial mass (which accounts for 60% to 70% of stool weight), stool weight and frequency, and the rate of colonic transit. With adequate intake of fluid, fiber may soften stools and make them easier to pass. Dietary reference intakes (DRIs) recommend consumption of 14 g dietary fiber per 1000 kcal, or 25 g for adult women and 38 g for adult men. Typical intake of dietary fiber in the United States is only about 16.2 g/day (Grooms et al, 2013).

BOX 27.4 Guidelines for High-Fiber Diets

1. Increase consumption of whole-grain breads and cereals to 6 to 11 servings daily.
2. Increase consumption of vegetables, legumes, fruits, nuts, and seeds to 5 to 8 servings daily.
3. Consume high-fiber cereals, granolas, and legumes to bring fiber intake to 25 g in women or 38 g in men or more daily.
4. Increase consumption of fluids to at least 2 L (or about 2 qt) daily.

Note: Following these guidelines may cause an increase in stool weight, fecal water, and gas. The amount that causes clinical symptoms varies among individuals, depending on age and presence of gastrointestinal (GI) disease, malnutrition, or resection of the GI tract.

Dietary fiber refers to edible plant materials not digested by the enzymes in the GI tract and is categorized as soluble or insoluble. **Soluble fiber** forms a gel, acting to slow digestion and does not generally have a laxative effect. **Insoluble fiber** absorbs water to add bulk to stool and accelerate fecal transit through the intestines (Barco et al, 2015). Fiber consists of cellulose, hemicellulose, pectins, gums, lignins, starchy materials, and oligosaccharides that are partially resistant to digestive enzymes. Both types of fiber are readily available in a whole foods diet that includes a variety of whole grains, fruits, vegetables, legumes, seeds, and nuts.

A high-fiber therapeutic diet may have to exceed 25 to 38 g/day. The **high-fiber diet** in Box 27.4 provides more than the amount of fiber typically recommended. It is important to assess dietary fiber intake before making recommendations for fiber supplementation. If a patient is already taking 25 to 30 g of dietary fiber daily, fiber supplementation is unlikely to be helpful. If less than this amount is being consumed, fiber should be added slowly in graduated doses to eventually reach 25 to 30 g per day. Amounts greater than 50 g/day are not necessary and may increase abdominal distention and excessive flatulence due to fermentation by the colonic flora.

Bran and fiber supplements may be helpful in persons who cannot or will not eat sufficient amounts of fiber-containing foods. Several of these commercial fiber supplements can be added to cereals, yogurts, fruit sauces, juices, or soups. Cooking does not destroy fiber, but the structure may change. Recommending the consumption of adequate daily fluid intake is also very important in facilitating the effectiveness of a high-fiber intake. Gastric obstruction and fecal impaction may occur when boluses of fibrous gels or bran are not consumed with sufficient fluid to disperse the fiber.

Increasing dietary fiber for laxation is unlikely to provide relief for patients with serious dysmotility syndromes, neuromuscular disorders, chronic opioid use, pelvic floor disorders, or other serious GI disease. In conditions such as neuromuscular disorders or with chronic opioid use, a specific laxative medication regimen or gut motility stimulator medication (i.e. methylnaltrexone) may be a necessary part of disease management.

Diarrhea

Diarrhea is defined by the World Health Organization as the passage of three or more loose or liquid stools per day. Diarrhea occurs when there is accelerated transit of intestinal contents through the small intestine, decreased enzymatic digestion of foodstuffs, decreased absorption of fluids and nutrients, increased secretion of fluids into the GI tract, or exudative losses.

Pathophysiology

- Diarrhea may be related to inflammatory disease; infections with fungal, bacterial, or viral agents; medications; overconsumption of sugars or other osmotic substances; an allergic response to a food;

or insufficient or damaged mucosal absorptive surface. There are many different subtypes of diarrhea associated with various medical conditions and/or surgeries.

- Exudative diarrheas are always associated with mucosal damage, leading to an outpouring of mucus, fluid, blood, and plasma proteins, with a net accumulation of electrolytes and water in the gut. Prostaglandin and cytokine release may be involved. Diarrhea associated with Crohn's disease, ulcerative colitis (UC), and radiation enteritis is often exudative.
- Osmotic diarrheas occur when osmotically active solutes are present in the intestinal tract and are poorly absorbed. An example is the diarrhea that accompanies dumping syndrome in someone that consumes a beverage containing simple sugars after having various GI-tract resections such as a Billroth II procedure (gastrojejunostomy).
- Secretory diarrheas are the result of active intestinal secretion of electrolytes and water by the intestinal epithelium, resulting from bacterial exotoxins, viruses, and increased intestinal hormone secretion. Unlike osmotic diarrhea, fasting does not relieve secretory diarrhea.
- Malabsorptive diarrheas result when a disease process impairs digestion or absorption to the point that nutrients, such as fat, appear in the stool in increased amounts. Excess fat in the stool is called **steatorrhea**. Diarrhea occurs because of the osmotic action of these nutrients and the action of the bacteria on the nutrients that pass into the colon. Malabsorptive diarrhea occurs when there is not enough healthy absorptive area or inadequate production or interrupted flow of bile and pancreatic enzymes, or there is rapid transit, such as in IBD or after extensive bowel resection. Box 27.5 lists diseases and conditions associated with malabsorption and diarrhea.
- Medication-induced diarrheas are frequent in hospitalized and long-term care patients. Medications that cause diarrhea do so by different mechanisms. For example, medications such as lactulose (used in the management of hepatic encephalopathy) and sodium polystyrene sulfonate with sorbitol (used to treat hyperkalemia) create increased bowel movements as part of their mechanism of action. Some antibiotics have direct effects on GI function. Examples include erythromycin, which acts as a motilin agonist and increases lower GI motility, as well as clarithromycin and clindamycin, which increase GI secretions.

In those with underlying illnesses such as human immunodeficiency virus (HIV) and other immune deficiency states, the causes of diarrhea are often multifactorial and can include side effects of medications, proliferation of opportunistic organisms, and GI manifestations of the disease itself (Pavie et al, 2012) (see Chapter 36). Increased risk of opportunistic infection is also associated with use of antineoplastic agents (such as chemotherapy) or in those with malnutrition.

Antibiotic-Associated Diarrhea

The human intestinal tract is home for trillions of bacteria **microbiota** (Fig. 27.2). In the normal GI tract, commensal gut microbiota ferment sloughed intestinal cells and undigested foodstuffs to gases and short-chain fatty acids (SCFAs). Absorption of SCFAs facilitates absorption of electrolytes and water from the colon. Broad-spectrum antibiotics decrease the number of commensal bacteria in the bowel and may result in decreased fermentation byproducts, reducing the absorption of electrolytes and water, thereby causing diarrhea.

Some antibiotics allow proliferation of opportunistic pathogenic microorganisms normally suppressed by competitive microorganisms in the GI tract. The toxins produced by some opportunistic microorganisms can cause colitis and increased secretion of fluid and

BOX 27.5 Diseases and Conditions Associated With Malabsorption**Inadequate Digestion**

Pancreatic insufficiency
Gastric acid hypersecretion
Gastric resection

Altered Bile Salt Metabolism with Impaired Micelle Formation

Hepatobiliary disease
Interrupted enterohepatic circulation of bile salts
Bacterial overgrowth
Drugs that precipitate bile salts

Genetic Abnormalities of Mucosal Cell Transport

Disaccharidase deficiency
Monosaccharide malabsorption
Specific disorders of amino acid malabsorption
Abetalipoproteinemia
Vitamin B₁₂ malabsorption
Celiac disease

Inflammatory or Infiltrative Disorders

Crohn's disease
Amyloidosis
Scleroderma
Tropical sprue
Gastrointestinal allergy
Infectious enteritis
Whipple disease
Intestinal lymphoma
Radiation enteritis
Drug-induced enteritis
Endocrine and metabolic disorders
Short-bowel syndrome (SBS)

Abnormalities of Intestinal Lymphatics and Vascular System

Intestinal lymphangiectasia
Mesenteric vascular insufficiency
Chronic congestive heart failure

Data from Beyer PL: Short bowel syndrome. In Coulston AM et al, editors: *Nutrition in the prevention and treatment of disease*, ed 1, San Diego, 2001, Academic Press; Branski D et al: Chronic diarrhea and malabsorption, *Pediatr Clin North Am* 43:307, 1996; Fine KD: Diarrhea. electrolytes. A rise in antibiotic use has led to an increase in **antibiotic-associated diarrhea (AAD)** and overgrowth of *Clostridium difficile* with resultant ***Clostridium Difficile* (*C. Difficile*) infection (CDI)**.

C. difficile is a spore-forming organism, and the spores are resistant to common disinfectant agents. The spore-forming ability of *C. difficile* allows the organism to be spread inadvertently to other patients by health care providers (iatrogenic infection) if strict infection control procedures are not followed. The presence of this infection is detected

by analysis of a stool sample for the presence of the toxin produced by the organisms. Clindamycin, penicillin, and cephalosporins are associated most often with the development of *C. difficile* infection. Its occurrence depends on the number of antibiotics used, the duration of exposure to antibiotics, and the patient's age and overall health. Chronic suppression of stomach acid with proton pump inhibitor medications during broad-spectrum antibiotic therapy also may increase susceptibility to CDI (Tarig et al, 2017; Trifan et al, 2017).

C. difficile was historically considered a nosocomial (hospital-acquired) diarrheal infection associated with antibiotic exposure. More recently, its prevalence has increased to include a higher incidence in populations previously considered at low risk (DePestel and Aronoff, 2013). *C. difficile* may cause colitis, secretory diarrhea, severe dilation of the colon (toxic megacolon), perforation of the bowel wall, peritonitis, or even death (Pattani et al, 2013). Adding further complication to eradicating CDI, resistant strains are less susceptible to treatment with antimicrobials and cause a more severe form of the disease with increased health care costs and higher mortality (O’Keefe, 2010).

According to the Centers for Disease Control and Prevention (CDC), *C. difficile* was estimated to cause almost 500,000 infections in the United States in 2011 alone. Of those, 83,000 patients presented with at least one recurrence, and almost 29,000 died within 30 days of the initial diagnosis. Prescribing unnecessary or incorrect antibiotics occurs in 30% to 50% of hospitalized patients who receive them. This oversight is thought to be an important contributor to increased risk for this life-threatening infection (CDC, 2015). Fortunately, with increased infection risk protocols, greater precautions with antibiotic use, and clinician awareness, there was an 8% decrease in CDI from 2011 to 2014 (CDC, 2018). See Fig. 27.3 infographic reviewing important details.

Medical Management

Because diarrhea is a symptom, not a disease, the first step in medical treatment is to identify and treat the underlying problem. The next

goal is to manage fluid and electrolyte replacement. In cases of severe diarrhea, restoring fluid and electrolytes is first priority. Electrolyte losses, especially potassium and sodium, should be corrected early by using oral glucose electrolyte solutions with added potassium. Oral rehydration solutions (ORS) work because they contain concentrations of sodium and glucose that are optimal for interaction with the sodium-glucose transport (SGLT) proteins in the intestinal epithelial cells (see Chapter 1).

With intractable diarrhea, especially in an infant or young child, parenteral feeding may be required. Parenteral nutrition (PN) may even be necessary if exploratory surgery is anticipated, or if the patient is not expected to resume full oral intake within 5 to 7 days (see Chapter 12).

Supplementation with probiotics, defined below, shows some promise to prevent AAD and CDI and research is ongoing, but there are inadequate data to recommend probiotics as a primary treatment for CDIs (Pattani et al, 2013) (see *Focus On: Probiotics and Prebiotics and the Gut Microbiota*). Currently, the best treatment for refractory CDI is to employ **fecal microbiota transplant (FMT)**. With the concept of the human gut microbiota as an organ, FMT may be considered an organ transplant. In this procedure, the gut microbiota of the person infected with *C. difficile* is replaced with healthy donor stool, typically from a family member with similar dietary and living habits. A recent study found a >90% success rate in participants receiving FMT for eradication of CDI, with no disease recurrence after procedure (Konturek et al, 2016).

FOCUS ON

Probiotics and Prebiotics and the Gut Microbiota

Some gastrointestinal conditions such as *Clostridium difficile* infection (CDI), small intestinal bacterial overgrowth (SIBO), antibiotic-associated diarrhea, and perhaps inflammatory bowel disease may result or have exacerbated symptoms when there are alterations to the colonies of microorganisms that exist in the small or large intestines. Exposure to broad-spectrum antibiotics causes dramatic alterations to gut microbiota, placing the patient at risk for overgrowth of potentially pathogenic microbes and opportunistic gastrointestinal (GI) infections.

A **probiotic** is defined by the Food and Agriculture Organization of the United Nations and the World Health Organization (FAO/WHO) as “live nonpathogenic organisms (bacteria or yeast) which when administered in adequate amounts confer a health benefit on the host.” To be a probiotic, meaning “for life,” a live microbial strain must meet very stringent criteria. According to the FAO/WHO, these criteria include being safe for human consumption, being a live and viable organism with strain identification, being of human origin, being resistant to acid and bile, being able to survive the upper intestinal tract environment and reach the distal intestine (ileum and colon) to attach to the intestinal epithelium, and being able to colonize the distal intestine, confer health benefit to the host, and have scientifically proven health benefits (Cresci and Izzo, 2017). Unfortunately, such a regulatory framework does not exist in the United States at present. Therefore because of these strict criteria, some supplements termed “probiotics” are not truly probiotics and their use may be misleading to clinicians and consumers.

Certain strains of bacteria have been identified as probiotics. These may be available in supplement form (e.g., capsules, powders) or included in fermented food products (e.g., yogurts, kefir). The exact dose, means for delivery, or the duration of viability are uncertain, probably vary for different probiotic strains, and may depend on the condition to be treated. It has been suggested that probiotics may restore the balance of intestinal microbes and improve symptoms and prevent or treat conditions in which a gut dysbiosis has occurred, such as antibiotic-associated diarrhea (Pattani et al, 2013). *Saccharomyces boulardii*, a probiotic yeast, has been shown to reduce recurrence in those with CDI when

high-dose oral vancomycin was also used (Cresci and Izzo, 2017). Certain types of probiotics may be effective in reducing the duration of enterovirus-induced acute infectious diarrhea in pediatric and adult patients and in those with inflammatory bowel disease (IBD).

Like probiotics, prebiotics have strict criteria for their classification. Prebiotics, undigested polysaccharides, and sloughed proteins are the food source for the commensal gut microbiota.

A **prebiotic** is defined as “a selectively fermented ingredient that allows specific changes, both in the composition and activity in the gut microbiota, that confer benefits upon host well-being and health” (Cresci and Izzo, 2017). Importantly, prebiotics must be resistant to gastric acidity, to hydrolysis by mammalian enzymes, and to GI absorption; must be fermented in the GI tract by the gut microbiota; and must be selective in the stimulation of the gut microbiota growth and activity that contribute to health and well-being. Prebiotics are naturally occurring or synthetic sugars and are not available to all gut microbial species. Upon reaching the distal intestine (ileum and colon), prebiotics are fermented by the gut microbiota to yield short-chain fatty acids (SCFAs) and gases (carbon dioxide, hydrogen, and methane). SCFAs (acetate, propionate, butyrate) serve many biologic roles, including aiding with water and electrolyte absorption, decreasing intraluminal pH, altering cell proliferation and differentiation, and modifying intestinal immune and inflammatory processes (Cresci and Izzo, 2017). Although probiotics have reported safety issues with select clinical conditions, prebiotics carry few safety concerns. However, like probiotics, prebiotics may also contribute to GI discomfort (bloating, gas) if introduced too rapidly into the diet.

Because there is promise in theory and in select studies for improving gut dysbiosis with supplements, further studies evaluating the optimal dose, timing, duration, and indications for probiotics, prebiotics, and their combinations, are warranted. Regular intake of food sources of prebiotics and probiotics can also encourage increased microbial diversity in the gut, reducing reliance on supplements when appropriate.

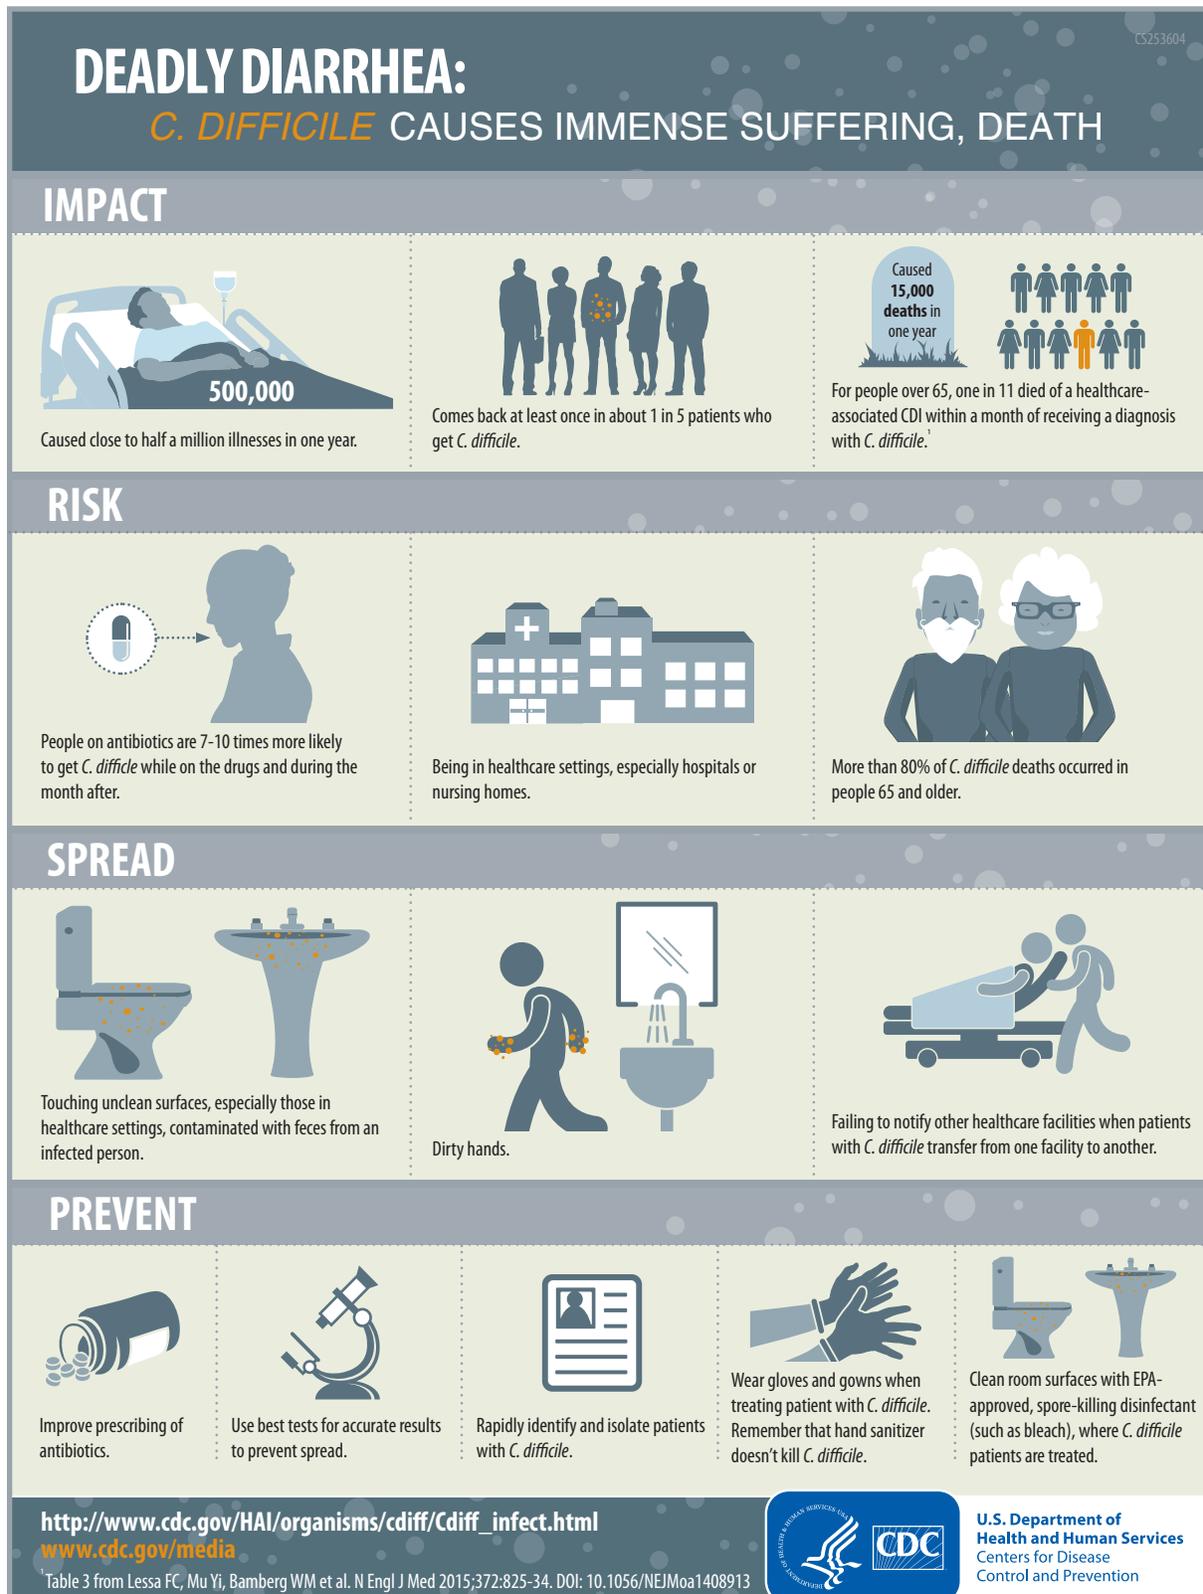

Fig. 27.3 Deadly Diarrhea: *C. Difficile* causes immense suffering, death (CDC, 2015).

Products that combine probiotic microorganisms and a prebiotic fiber source have been described as **synbiotics** for their synergistic effects. A recent review evaluated efficacy of probiotics, prebiotics, and synbiotics for improvements in the microbiota for a variety of disorders. Synbiotics were found effective for hepatic encephalopathy,

improved high-density lipoprotein (HDL) and fasting glucose, but also demonstrated positive results for treating infectious diarrhea in children (Patel and DuPont, 2015).

There is a long history of safe use of many strains of “live active cultures” in foods in healthy humans. However, the body of evidence

is limited on the use of large doses of concentrated probiotic supplements, especially of specific strains that exhibit greater resistance to gastric acid or have increased ability to proliferate in the GI tract. Limited safety data support the use of concentrated probiotic supplements in patients with immunocompromised states or critical illness, or when probiotics are administered directly into the small intestine, as with jejunal feeding tubes, but research in this area continues (Stavrou et al, 2015). A number of case reports exist of hospitalized patients receiving concentrated strains of probiotics that have become septic because of infection in the bloodstream with the very same strain of probiotic being administered. In a review of cases of adverse events related to probiotic administration in hospitalized patients, 25% of adverse events resulted in patient death (Whelan and Myers, 2010). Many of these case reports do indicate the culprit probiotic was a non-pathogenic yeast, and since then product label warnings against providing this supplement to critically ill patients have been instated to avoid such complications. In a large double-blind, randomized study of a high-dose multispecies probiotic administered via jejunal feeding tube in patients with severe acute pancreatitis, there were significantly more deaths in those who received probiotics compared with those receiving the inactive placebo, and a reduced risk of infectious complications was not demonstrated in the probiotic group (Besselink et al, 2008). Although this historical study was concerning and provides warning before administering live cultures to critically ill patients, there were study flaws and limitations, which lead to questions whether the increased mortality was solely the result of probiotic supplementation; further study is needed in this area.

Probiotic preparations hold promise as an adjunctive or primary treatment in several gastrointestinal conditions, but research is ongoing on modifying the microbiota and there remain inadequate data thus far to make large generalizations regarding probiotic safety for all populations (Bafeta et al, 2018). In contrast, as an emerging area of scientific research, there is also a movement to determine how manipulating the microbiota can confer benefit to the host (Walsh et al, 2014). To learn more and follow this exciting area of nutrition research, the International Scientific Association for Probiotics and Prebiotics (<https://isappscience.org/>) is an excellent resource.

Medical Nutrition Therapy

All nutrition interventions related to diarrhea must be viewed within the context of the underlying pathologic condition responsible for the diarrhea. Replacement of necessary fluids and electrolytes is the first step, using ORS, soups and broths, vegetable juices, and isotonic liquids. Restrictive diets, such as the BRAT diet made up of bananas, rice, applesauce, and toast, are nutrient poor; no evidence indicates that they are necessary during acute diarrheal illness. Although there is limited research to support doing so, some clinicians also recommend a progression of starchy carbohydrates such as cereals, breads, and low-fat meats, followed by small amounts of vegetables and fruits, followed by fats. The goal with this progression is to limit large amounts of hyperosmotic carbohydrates that may be maldigested or malabsorbed, foods that stimulate secretion of fluids, and foods that speed the rate of GI transit.

Sugar alcohols, lactose, fructose, and large amounts of sucrose may worsen osmotic diarrheas. IBS may also be associated with diarrhea or a mix of constipation and diarrhea. Several diet changes within the low FODMAP diet similar to the foods mentioned above may improve symptoms (see Irritable Bowel Syndrome in this chapter). Because the activity of the disaccharidases and transport mechanisms decrease during inflammatory and infectious intestinal disease, sugars may have to be limited, especially in children. Malabsorption is only one potential cause of diarrhea, and diarrhea may occur without significant

TABLE 27.1 Food to Limit in a Low-Fiber (Minimal-Residue) Diet

Food	Comments
Lactose (in lactose malabsorbers)	6 to 12 g is normally tolerated in healthy lactase-deficient individuals but may not be in some individuals.
Insoluble fiber (quantities >20 g)	Modest amounts (10 to 15 g) may help maintain normal consistency of gastrointestinal (GI) contents and normal colonic mucosa in healthy states and GI disease.
Sorbitol, mannitol, and xylitol (excess, >10 g/day)	Well tolerated in moderate amounts; large amounts may cause hyperosmolar diarrhea.
Fructose (excess, 20 to 25 g/meal)	
Sucrose (excess, >25 to 50 g/meal)	
Caffeine	Increases GI secretions, colonic motility
Alcoholic beverages (especially wine and beer)	Increase GI secretions

malabsorption of macronutrients (carbohydrate, fat, and protein). Absorption of most nutrients occurs in the small intestine; diarrhea related to colonic inflammation or disease preserves the absorption of most ingested nutrients.

Minimal fiber and low-residue diets are rarely indicated (Table 27.1). Patients are encouraged to resume a regular diet as tolerated that contains moderate amounts of soluble fiber. The metabolism of soluble fiber and resistant starches by colonic bacteria leads to production of **short-chain fatty acids (SCFAs)**, which in physiologic quantities serve as a substrate for colonocytes, facilitate the absorption of fluid and salts, and may help to regulate GI motility.

Fibrous material tends to slow gastric emptying, moderate overall GI transit, and pull water into the intestinal lumen. Providing fiber to patients with diarrhea does increase the volume of stool, and in some cases (such as small intestinal bacterial overgrowth [SIBO]) initially can increase gas and bloating. Modest intake of prebiotic components and soluble fibers such as pectin or gum slows transit through the GI tract.

Several probiotics have been studied for preventing AAD. Currently, of those tested, *Saccharomyces boulardii* and *Lactobacillus*-based formulations appear to be most effective in reducing AAD (Pattani et al, 2013). A more recent meta-analysis specifically found *Saccharomyces boulardii* to be effective in reducing risk of AAD in both children and adults without adverse side effects, but also encouraged caution in patients who are immunocompromised or with life-threatening illnesses managed in the intensive care unit (ICU) setting (Szajewska and Kotodziej, 2015). Studies are still needed to find the optimal combination of probiotics and/or prebiotics, testing for dosing schedules, and concentrations.

Severe and chronic diarrhea is accompanied by dehydration and electrolyte depletion. If also accompanied by prolonged infectious, immunodeficiency, or inflammatory disease, malabsorption of vitamins, minerals, and protein or fat also may occur, and nutrients may have to be replaced parenterally or enterally. In some forms of infectious diarrhea, loss of iron from GI bleeding may be severe enough to cause anemia. Nutrient deficiencies themselves cause mucosal changes such as decreased villi height and reduced enzyme secretion, further contributing to malabsorption. As the diarrhea begins to resolve, the addition

of more normal amounts of fiber to the diet may help to restore normal mucosal function, increase electrolyte and water absorption, and increase the firmness of the stool.

Food in the lumen is needed to restore the compromised GI tract after disease and periods of fasting. Early refeeding after rehydration reduces stool output and shortens the duration of illness. Micronutrient replacement or supplementation also may be useful for acute diarrhea, probably because it accelerates the normal regeneration of damaged mucosal epithelial cells.

Treating Diarrhea in Infants and Children

Acute diarrhea is most dangerous and a leading cause of mortality in infants and small children, who are easily dehydrated by large fluid losses. Provision of extra fluids, including breastmilk, can prevent dehydration, but in the most severe cases replacement of fluid and electrolytes must be aggressive and immediate. Since 1978, the World Health Organization (WHO) has recommended a standard **oral rehydration solution (ORS)** for this acute situation as a way for parents to be able to participate in their children's care at home with a reduced need for IV hydration or hospitalization. The standard WHO-recommended ORS historically had an osmolarity of 311 mOsm/L and contained specific concentrations of sodium (90 mEq), potassium (20 mEq/L), chloride (80 mEq/L), and glucose (20 g/L) (Suh et al, 2010).

For over 25 years, the standard solution was used, decreasing the mortality rate from 5 million to 1.3 million deaths annually (WHO, 2002). While incredibly effective at rehydrating, reducing fecal volume or duration of illness was still an important concern, leading to research and development of a new solution. The result of this work came to fruition in 2003, when the WHO made a change to recommend a new lower osmolality solution at 245 mOsm/L with decreased concentrations of both glucose (13.5 g/L) and sodium (75 mEq/L), as it was shown to result in greater water absorption in children with noncholera diarrhea (Suh et al, 2010; WHO 2002; WHO 2006).

Overall, when reduced-osmolality ORS is used for children with acute diarrhea, it results in decreased need for intravenous therapy, significant reduction in stool output, and decreased vomiting compared with standard WHO-recommended ORS (Atia and Buchman, 2009). Commercial solutions such as Pedialyte, Infalyte, Lytren, Equalyte, and Rehydralyte typically contain less glucose and slightly less salt than the WHO-ORS formulation and are available in pharmacies, often without a prescription. Oral rehydration therapy is less invasive and less expensive than intravenous rehydration and, when used with children, allows parents to assist with their children's recovery. However, close attention must be paid to the actual electrolyte content, as many so-called ORS are not useful for rehydration. See Table 27.2 for ORS recipes that can be used to create the formula at home. Commercial sports drinks (i.e., Gatorade) without the added salt are not recommended.

TABLE 27.2 Oral Rehydration Solution (ORS) Recipes*

2 cups Gatorade, 2 cups water, ³ / ₄ tsp salt	28 g glucose, 82 mEq Na, 1.5 mEq K
or	
1 quart water, ³ / ₄ tsp salt, 6 tsp sugar	24 g glucose, 76 mEq Na, 0 mEq K

*Each makes 1 liter and should be made fresh every 24 hours. Data from Krenitsky J, McCray S: *University of Virginia Health System Nutrition Support Traineeship Syllabus*, Charlottesville, VA, 2010, University of Virginia Health System; Recipes from Parrish CR: The clinician's guide to short bowel syndrome, *Pract Gastroenterol* 29:67, 2005.

A substantial proportion of children 9 to 20 months of age can maintain adequate intake when offered either a liquid or a semisolid diet continuously during bouts of acute diarrhea. Even during acute diarrhea, the intestine can absorb up to 60% of the food eaten. Some practitioners have been slow to adopt the practice of early refeeding after severe diarrhea in infants despite evidence that "resting the gut" is actually more damaging.

Gastrointestinal Strictures and Obstruction Pathophysiology

Patients with gastroparesis, adhesions, hernias, metastatic cancers, dysmotility, or volvulus are prone to obstruction, which can result in partial or complete blockage of movement of food or stool through the intestines. Obstructions may be partial or complete and may occur in the stomach (gastric outlet obstruction), small intestine, or large intestine. Symptoms include bloating, abdominal distention and pain, nausea, and vomiting.

Obstructions are not usually caused by foods in an otherwise healthy individual, and researchers have not found that eating, diet, and nutrition play a role in causing or preventing the frequency of obstructive symptoms in this population. However, when sections of the GI tract are partially obstructed or not moving normally, foods may contribute to obstruction. In these individuals with a compromised GI tract, it is believed that fibrous plant foods can contribute to obstruction because the fiber in the foods may not be completely chewed to pass through narrowed segments of the GI tract.

Medical Nutrition Therapy

Most clinicians would recommend patients prone to obstructions to chew food thoroughly and avoid excessive fiber intake, limiting intake to foods with less than 3 grams of fiber per serving or no more than 10 grams per day. A patient with a partial bowel obstruction may be able to tolerate a restricted-fiber diet and liquids, depending on the location of the stricture or obstruction in the GI tract. A more proximal (closer to the mouth) blockage may require a semisolid or liquid diet. However, the more distal (closer to the anus) the blockage, the less likely altering the consistency of the diet will help. Symptoms are more severe during complete obstruction. Patients may be intolerant of oral intake and of their own secretions leading to progressive dehydration, electrolyte imbalance, and systemic toxicity. Initial treatment consists of aggressive fluid resuscitation, nasogastric decompression, and administration of analgesics and antiemetics.

Patients with complete bowel obstruction may require surgical intervention. In some cases, enteral feeding beyond the point of obstruction may be feasible, but if enteral feeding is not possible for a prolonged period, PN may be needed. Working with the patient and physician is necessary to determine the nature, site, and duration of the obstruction so that nutrition therapy can be individualized.

DISEASES OF THE SMALL INTESTINE

Celiac Disease (Gluten-Sensitive Enteropathy)

The prevalence of **celiac disease (CD)** has been underestimated in the past and now is considered to affect 0.3% to 0.9% of the population in the United States and varies by race and ethnicity, with a marked predominance among non-Hispanic whites. Worldwide incidence of CD is about 1% (Leonard et al, 2017). The onset and first occurrence of symptoms may appear any time from infancy to adulthood. The disease may become apparent when an infant begins eating gluten-containing cereals. In some, it may not appear until adulthood, when it may be triggered or unmasked during GI surgery, stress, pregnancy, or viral infection. It may be discovered as a result of evaluation for

another suspected problem (such as constipation, abdominal pain, unexplained anemia).

Etiology

The presentation in young children is likely to include the more “classic” GI symptoms of diarrhea, steatorrhea, malodorous stools, abdominal bloating, fatigue, and poor weight gain. An increasing number of patients are being diagnosed with extraintestinal symptoms (such as headache, brain “fog,” anemia, reduced bone-mineral density, chronic fatigue, dental enamel hypoplasia, elevated liver enzymes). A recent study found that only 34% of pediatric patients presented with classic symptoms of CD and 43% of patients had nonclassic symptoms (Almallouhi et al, 2017). CD frequently is misdiagnosed as IBS, lactase deficiency, gallbladder disease, or other disorders not necessarily involving the GI tract, because the presentation and onset of symptoms vary so greatly.

Patients may present with one or more of a host of conditions associated with CD: anemias, generalized fatigue, weight loss or failure to thrive, osteoporosis, vitamin or mineral deficiencies, and (although rare) GI malignancy. **Dermatitis herpetiformis**, yet another manifestation of CD, presents as an itchy skin rash; its presence is diagnostic of CD. **Box 27.6** lists conditions associated with CD. Persons who are diagnosed late in life, who cannot or will not comply with the diet, or who were diagnosed as children but told they would grow out of it, are at a higher risk for experiencing long-term complications from CD (Nachman et al, 2010).

Pathophysiology

CD, or **gluten-sensitive enteropathy**, is characterized by a combination of four factors: (1) genetic susceptibility, (2) exposure to gluten,

(3) an environmental “trigger,” and (4) an autoimmune response. **Gluten** refers to specific peptide fractions of proteins (prolamins) found in wheat (glutenin and gliadin), rye (secalin), and barley (hordein). A small number of those with CD may also react to the avenin protein in oats (Pinto-Sanchez et al, 2017). These peptides are generally more resistant to complete digestion by GI enzymes and may reach the small intestine intact. In a normal, healthy intestine, these peptides are harmless, as the intestinal barrier is intact and prevents translocation from the intestine. However, in persons with CD these peptides travel from the intestinal lumen, across the intestinal epithelium, and into the lamina propria, where they can trigger an inflammatory response that results in flattening of intestinal villi and elongation of the crypt cells (secretory cells), along with a more general systemic immune response (Sams and Hawks, 2014) (Fig. 27.4). The “triggers” that cause a genetically predisposed individual to develop CD are not well understood, but stressors (e.g., illness, inflammation) are thought to play a role.

When CD remains untreated, the immune and inflammatory response eventually results in atrophy and flattening of villi. Over time, the process can cause enough damage to the intestinal mucosa to compromise normal secretory, digestive, and absorptive functions, leading to impaired micronutrient and macronutrient absorption (Kupfer and Jabri, 2012). Cells of the villi become deficient in the disaccharidases and peptidases needed for digestion and also in the carriers needed to transport nutrients into the bloodstream. The disease primarily affects the proximal and middle sections of the small bowel, although the more distal segments also may be involved (Sams and Hawks, 2014).

The term **gluten sensitivity** is used commonly to describe persons with nonspecific symptoms, without the immune response characteristic of CD or the consequential intestinal damage. **Gluten intolerance**,

BOX 27.6 Symptoms and Conditions Associated With Celiac Disease

Nutritional

Anemia (iron or folate, rarely B₁₂)
Osteomalacia, osteopenia, fractures (vitamin D deficiency, inadequate calcium absorption)
Coagulopathies (vitamin K deficiency)
Dental enamel hypoplasia
Delayed growth, delayed puberty, underweight
Lactase deficiency

Extraintestinal

Fatigue, malaise (sometimes despite lack of anemia)
Arthritis, arthralgia
Dermatitis herpetiformis
Infertility, increased risk of miscarriage
Hepatic steatosis, hepatitis
Neurologic symptoms (ataxia, polyneuropathy, seizures); may be partly nutrition related
Psychiatric syndromes

Associated Disorders

Autoimmune diseases: type 1 diabetes, thyroiditis, hepatitis, collagen vascular disease
Gastrointestinal malignancy
IgA deficiency

IgA, Immunoglobulin A.

Kupfer SS, Jabri B: Pathophysiology of celiac disease, *Gastrointest Endosc Clin N Am* 22:639, 2012.

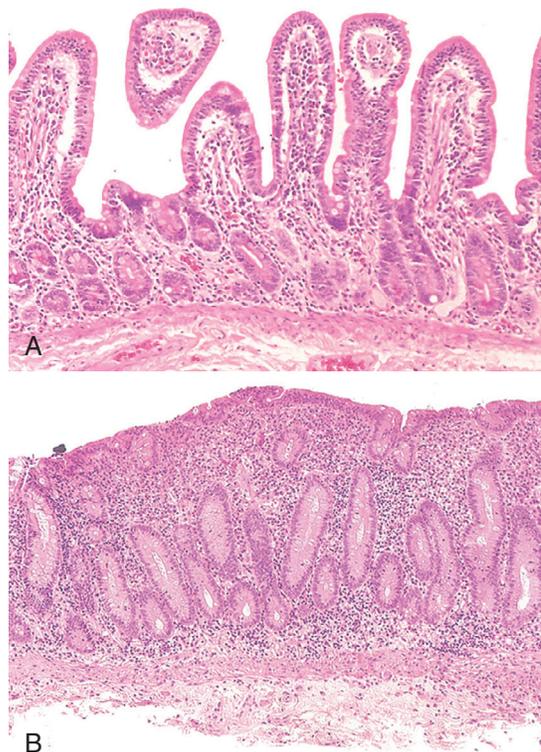

Fig. 27.4 CD (gluten-sensitive enteropathy). **A**, Peroral jejunal biopsy specimen of diseased mucosa shows severe atrophy and blunting of villi, with a chronic inflammatory infiltrate of the lamina propria. **B**, Normal mucosal biopsy. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

also called nonceliac gluten sensitivity, describes individuals who have symptoms after ingesting gluten-containing foods. Symptoms may be isolated in the gastrointestinal tract such as nausea, abdominal cramps, or diarrhea; or may be extraintestinal in nature such as brain fog or generalized pain. Patients who experience these symptoms should be advised against following a gluten-free (GF) diet without having a workup to exclude or confirm a diagnosis of CD because (1) testing to diagnose CD requires ongoing exposure to gluten in the diet, (2) there may be a different underlying medical condition for which a GF diet is not the treatment, and (3) a GF diet can be expensive and restrictive. Non-celiac gluten-sensitivity or wheat sensitivity includes a reaction to gluten as well as other components of wheat such as fructan (a FODMAP) (Gibson, 2017b).

Assessment

The diagnosis of CD is made from a combination of clinical, laboratory, and histologic evaluations. Persons suspected of having CD should be evaluated for the overall pattern of symptoms and family history. Blood screening for certain antibodies should be completed if symptoms and/or family history may indicate CD. If serology is positive, a biopsy of the small intestine is the gold standard for confirming diagnosis of CD. An intestinal biopsy positive for CD generally shows villous atrophy, increased intraepithelial lymphocytes, and crypt cell hyperplasia. However, biopsy is not used for initial screening because of its cost and invasiveness.

Elevated blood levels of certain autoantibodies are found in people with CD. To screen for CD several serologic tests are evaluated. These tests evaluate levels of serum immunoglobulin A (IgA) antibodies to tissue transglutaminase (tTG IgA), which has a sensitivity of 73.9% to 100% and specificity of 77.8% to 100% (Leonard et al, 2017). There is a higher incidence of IgA deficiency in patients with CD; thus physicians often measure total IgA levels when serologic findings are normal, but the overall clinical picture suggests CD (see *Clinical Insight: Antibody Testing for Celiac Disease and Gluten Sensitivity*). Because dietary change alters diagnostic results, initial evaluation should be done *before* the person has eliminated gluten-containing foods from his or her diet. Serologic tests also may be used to monitor the response of a newly diagnosed patient treated with a GF diet. Certain genetic testing is becoming increasingly more common to evaluate for HLA DQ2 or HLA DQ8 carrier status. It is important to know as clinicians that a positive result from these tests does not indicate

presence of CD, nor does it exclude it. Approximately 25% of the Caucasian population is positive for HLA DQ2, but less than 5% of these people develop CD (May-Ling Tjon et al, 2010).

Lifelong, strict adherence to a GF diet is the only known treatment for CD (see Box 27.7 for a list of safe, questionable, and unsafe choices on the GF diet). The GF diet diminishes the autoimmune process, and the intestinal mucosa usually reverts to normal or near normal. Within 2 to 8 weeks of starting the GF diet, most patients report that their clinical symptoms have abated. Histologic, immunologic, and functional improvements may take months to years, depending on the duration of the disease, age of the subject, and degree of dietary compliance. With strict dietary control, levels of the specific antibodies usually become undetectable within 6 to 12 months in most persons. Marked gut improvement and a return to normal histologic findings occurs in the majority of patients after an average of 2 years (Hutchinson et al, 2010). Patients who are able to follow the GF diet closely have a better overall response (see *Pathophysiology and Care Management Algorithm: Celiac Disease*).

In some individuals, recovery may be slow or incomplete. A small percentage of patients are “nonresponders” to diet therapy. Inadvertent gluten intake is the most common offender, but another coexisting disorder may be present (such as pancreatic insufficiency, IBS, bacterial overgrowth, fructose intolerance, other food allergies or GI maladies, or unknown causes). For nonresponders, intensive interviewing to identify a source of gluten contamination or treatment of another underlying disease may resolve the symptoms. Diagnosis of **refractory celiac disease** is made when patients do not respond or respond only temporarily to a GF diet, and all external causes have been ruled out, including inadvertent gluten ingestion. Patients with refractory celiac disease may respond to steroids, azathioprine, cyclosporine, or other medications classically used to suppress inflammatory or immunologic reactions.

Several novel treatments for CD are being studied for their potential as alternative therapies. Researchers seek to treat CD by reducing gluten exposure (by digestion with added enzymes), decreasing uptake of gluten (by tightening junctions between intestinal epithelial cells), altering the immune response to gluten, or repairing intestinal injury.

Medical Nutrition Therapy

Elimination of gluten peptides from the diet is the only treatment for CD presently. The diet omits all dietary forms of wheat, rye, and barley, which are the major sources of the prolamins.

CLINICAL INSIGHT

Antibody Testing for Celiac Disease and Gluten Sensitivity

There are two different types of antibodies considered in celiac disease diagnosis: those which are “antigluten,” and those which are “antiself” (autoimmune). “Antigluten” antibodies are the antigliadin immunoglobulin G (IgG) and immunoglobulin A (IgA). Ig stands for “immunoglobulin” or “antibody.” In celiac disease, the autoimmune antibodies are antiendomysial IgA and antitissue transglutaminase IgA (tTG IgA).

The tTG IgA test is highly sensitive and specific. It correlates well with biopsy, is inexpensive, not subjective, and can be performed on a single drop of blood. However, it can be falsely positive in a patient who has other autoimmune conditions, such as type 1 diabetes. For those with a negative tTG IgA test, IgA deficiency should be considered.

Antigliadin antibodies IgG and IgA recognize a small piece of the gluten protein called gliadin. Antigliadin IgG has good sensitivity, while antigliadin IgA has good specificity. Their combined use provides a screening test for celiac disease.

Many normal individuals without celiac disease will have an elevated antigliadin IgG. It is estimated that 0.2% to 0.4% of the general population has selective IgA deficiency, while 2% to 3% or more of people with celiac disease are IgA deficient.

If a celiac panel is only positive for antigliadin IgG, this is not highly suggestive for celiac disease if the patient has a normal total IgA level. An antigliadin IgG level three to four times the upper limit of normal for that laboratory is highly suggestive of a condition where the gut is abnormally permeable (“leaky”) to gluten. This can happen with food allergies, cystic fibrosis, parasitic infections, Crohn’s disease, and other types of autoimmune gastrointestinal (GI) diseases. These antibodies may also be slightly elevated in individuals with no obvious disease (Kelly et al, 2015).

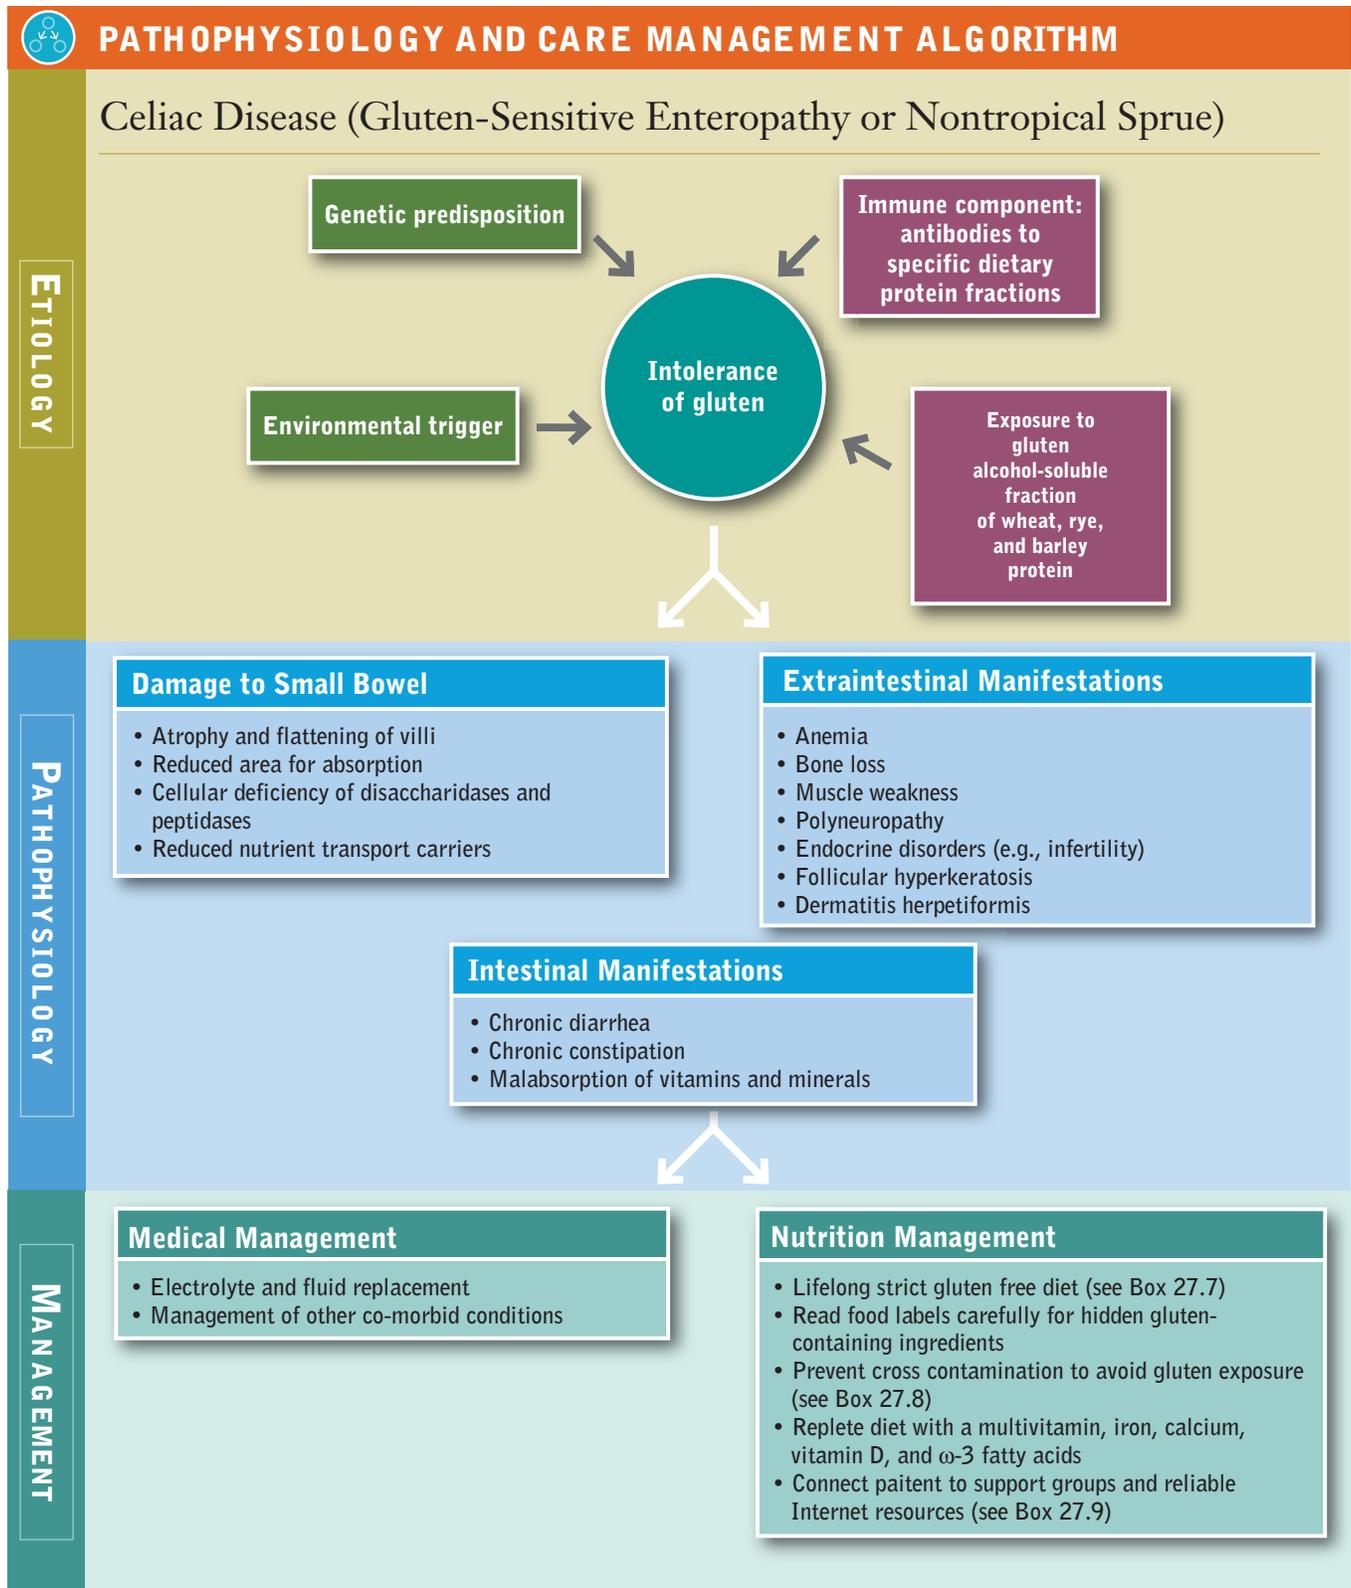

Ruth Leyse-Wallace, PhD, RDN

BOX 27.7 The Basic Gluten-Free Diet

Foods	Safe Choices	Avoid
Grains and flours	Amaranth, arrowroot, bean flours (such as garbanzo or fava bean), buckwheat, corn (maize) or cornstarch, flax, Job's tears, millet, potato, quinoa, ragi, rice, and wild rice sorghum, soybean (soya), tapioca, teff	Wheat (bulgur, couscous, durum, farina, graham, kamut, semolina, spelt, triticale, emmer, farro, wheat germ), rye, barley, oats (except pure, uncontaminated oats), low-gluten flour. Caution: "wheat free" does not necessarily mean "gluten free."
Cereals—hot or dry	Cream of rice, cream of buckwheat, hominy, gluten-free dry cereals, grits	Those with wheat, rye, oats (except gluten-free oats), barley, barley malt, malt flavoring, wheat germ, bran
Potatoes, rice, starch	Any plain potatoes, sweet potatoes and yams, all types of plain rice, rice noodles, 100% buckwheat soba noodles, gluten-free pasta, polenta, hominy, corn tortillas, parsnips, yucca, turnips	Battered or deep-fried French fries (unless no other foods have been fried in the same oil), pasta, noodles, wheat starch, stuffing, flour tortillas, croutons. Labels for commercial potato or rice products with seasonings should be reviewed.
Crackers, chips, popcorn	Rice wafers or other gluten-free crackers, rice cakes; plain corn chips, corn tortilla chips, potato chips, and other root (taro, beet, sweet potato, or vegetable, etc.) or grain (amaranth, quinoa) chips, plain popcorn	Gluten-free crackers, graham crackers, rye crisps, matzo, croutons, pretzels, some chips with flavorings
Desserts	Sorbet, popsicles, Italian ice, ice creams, puddings without gluten ingredients	Ice cream with bits of cookies, "crispiers," pretzels, pie crust, cookies, cakes, ice cream cones, and pastries made from gluten-containing flours
Milk and yogurt	Any plain, unflavored milk or yogurt, buttermilk, cream, half and half	Malted milk, yogurts with added "crunchies" or toppings. Some flavored milks and yogurts.
Cheese	Cheese (all styles including blue cheese and Gorgonzola), processed cheese (i.e., American), cottage cheese	Some cheese spreads or sauces
Eggs	All types of plain, cooked eggs	Eggs Benedict (sauce usually made with wheat flour)
Meat, fish, shellfish, poultry	Any fresh, plain untreated meat, fish, shellfish, or poultry; fish canned in brine, vegetable broth, or water	Breaded or battered meats. Some commercially treated, preserved, or marinated meats, luncheon meats, fish, shellfish; self-basting or cured poultry (check labels)
Beans and legumes	Any plain frozen, fresh, dried, or canned (no flavorings or sauces added) beans: garbanzo beans, kidney beans, lentils, pinto beans, edamame, lima, black beans, etc.	Those with added sauces
Soy products and meat analogs or alternatives	Plain tempeh, tofu, edamame, some miso	Seitan; 3-grain tempeh, traditional soy sauce (contains wheat), many meat analogs and imitation seafood, some miso
Nuts and seeds	Any plain (salted or unsalted) nuts, seeds or nut butters, coconut	Nut butters with gluten-containing ingredients
Fruits and juices	Any plain fresh, canned, frozen fruits or juices, plain dried fruit	Dried fruit dusted with flour, pie filling thickened with flour
Vegetables	Any plain, fresh, canned or frozen vegetables including corn, peas, lima beans, etc.	Vegetables in gluten-containing sauce or gravy
Soups	Homemade soups with known allowed ingredients	Check labels on all commercial soups
Condiments, jams, and syrups	Ketchup, mustard, salsa, wheat-free soy sauce, mayonnaise, vinegar (except malt vinegar), jam, jelly, honey, pure maple syrup, molasses	Malt vinegar, soy sauce, many gravies and sauces, marinades, some salad dressings
Seasonings and flavorings	Any plain herb or spice; salt; pepper; brown or white sugar; or artificial sweetener (i.e., Equal, Sweet-N-Low, Splenda)	Seasoning mixes and bouillon with gluten ingredients
Fats	Butter, margarine, all pure vegetable oils (including canola), mayonnaise, cream	Some salad dressings and sandwich spreads
Baking ingredients	Yeast, baking soda, baking powder, cream of tartar, regular chocolate baking chips	See grains and flours; Check label on grain sweetened, carob or vegan chocolate chips
Beverages	Coffee, tea, pure cocoa powder, sodas, some soy or rice milks	Malted beverages, some flavored instant coffee mixes, some herbal teas, some soy or rice milks
Alcohol	Wine, all distilled liquor, including vodka, tequila, gin, rum, whiskey, and pure liqueurs, gluten-free beers, hard ciders	Beer, ale, lager, gluten-removed beers, some drink mixes
Candies	Check labels—many are gluten-free	Candy from bulk food bins, licorice

CD, Celiac disease.

Adapted from Parrish CR et al: *University of Virginia Health System Nutrition Support Traineeship Syllabus*, Charlottesville, Va, 2010, University of Virginia Health System.

In general, patients should be assessed for nutrient deficiencies before supplementation is initiated. In all newly diagnosed patients, the clinician should consider checking levels of ferritin, folate, vitamin B₁₂, and 25-OH vitamin D. If patients present with more severe symptoms, such as diarrhea, weight loss, malabsorption, or signs of nutrient deficiencies (e.g., night-blindness, neuropathy, or prolonged

prothrombin time), other vitamins such as fat-soluble vitamins (A, E, K) and minerals (zinc) should be checked.

The healing of the intestinal mucosa that occurs after initiation of a GF diet improves nutrient absorption, and many patients who eat well-balanced GF diets do not need nutritional supplementation. However, most specialty GF products are not fortified with iron, folate,

and other B vitamins like other grain products, so the diet may not be as complete without at least partial supplementation. Anemia should be treated with iron, folate, or vitamin B₁₂, depending on the nature of the anemia. Patients with malabsorption may benefit from a bone-density scan to assess for osteopenia or osteoporosis. Calcium and vitamin D supplementation are likely to be beneficial in these patients. Electrolyte and fluid replacement is essential for those dehydrated from severe diarrhea.

Those who continue to have malabsorption should take a general vitamin-mineral supplement to at least meet DRI recommendations. Lactose and fructose intolerance sometimes occur secondary to CD. A low-lactose or low-fructose diet may be useful in controlling symptoms, at least initially. Once the GI tract returns to more normal function, lactase activity also may return, and the person can incorporate lactose and dairy products back into the diet.

In general, many fruits, vegetables, non-gluten containing grains, meats, and dairy products are safe to eat on a GF diet. Oats were once thought to be questionable for persons with CD; however, extensive studies have shown that they are safe in the GF diet as long as they are pure, uncontaminated oats (Pinto-Sanchez et al, 2017). However, a very small population of patients with CD may not tolerate even GF oats. In general, patients do not need to be advised against including GF oats in their diet unless they have demonstrated intolerance to GF oats.

Flours made from corn, potatoes, rice, soybean, tapioca, arrowroot, sorghum, garbanzo beans, nuts (such as almond flour), amaranth, quinoa, millet, teff, and buckwheat can be substituted in recipes. Patients can expect differences in textures and flavors of common foods using the substitute flours, and new recipes can be palatable once the adjustment is made. Blends of more than one type of GF flour often results in the best recipe outcome. In GF baked goods, gums such as xanthan, guar, and cellulose (from nongluten grains) can be used to provide the elasticity needed to trap leavening gases in baked goods.

A truly GF diet requires careful scrutiny of the labels of all bakery products and packaged foods. Gluten-containing grains are not only used as primary ingredients in many products but also may be added during processing or preparation of foods. For example, hydrolyzed vegetable protein can be made from wheat, soy, corn, or mixtures of these grains.

In the United States there is now a GF labeling law that went into effect in September 2014 (Food and Drug Administration and Health and Human Services, 2013). This law states that all food carrying a GF claim also must contain less than 20 ppm gluten (i.e., below 20 mg gluten per kg of food), including from cross-contact. Thompson discusses the law in detail (Thompson, 2015). Recent studies on the gluten content of labeled GF food in the United States showed that 95% to 99% of the products tested contained less than 20 ppm gluten (Sharma et al, 2015).

The diet for the person with CD requires a major lifestyle change because of the change from traditional grains in the diet. A tremendous number of foods made with wheat (in particular breads, cereals, pastas, and baked goods) are a common part of a Western diet. However, there is increasing awareness among food companies and restaurants of the expanding demand for GF foods, and food businesses are responding. The individual and family members should be taught about label reading, safe food additives, food preparation, sources of cross-contamination (such as toasters, condiment jars, bulk bins, and buffets), and hidden sources of gluten (such as medications and communion wafers) to be compliant with the diet. Box 27.8 provides sources of hidden gluten and cross-contamination. Eating in cafeterias, restaurants, buffets, pot lucks, street markets, at friends' homes, and at social events can be challenging, especially initially.

To avoid misinterpretation of information, newly diagnosed patients should be started with an in-depth instruction from a registered

BOX 27.8 Hidden Gluten Exposure and Cross-Contamination

Hidden Gluten Exposure

Unfortunately, gluten is not always obvious. Review the list below for some “unsuspected” products that may contain gluten.

- Over-the-counter and prescription medications
The labeling requirements of the Food Allergen and Consumer Protection Act of 2004 (FALCPA) **do not** apply to medications (see Box 25.7 in Chapter 25). Check with your pharmacist or call the manufacturer to determine whether there is any gluten in your medications.

Note: Dietary supplements are covered under FALCPA regulations, so wheat must be clearly listed if it is an ingredient in a vitamin, mineral, or herbal supplement.

- Communion wafers: GF alternatives are available
- Toothpaste, mouthwash, and cosmetics, especially shampoo and lipstick
- Children's modeling dough

Cross-Contamination

Below are some of the most common sources of gluten contamination. A few crumbs that may not even be seen can cause damage to the intestine, so it is best to avoid these situations:

- Toasters used for gluten-containing foods
Keep two toasters at home and designate one as GF. Alternatively, there are now bags available that are designed to hold a piece of bread in the toaster.
- Bulk bins. Prepackaged food is a safer bet.
- Condiment jars (peanut butter, jam, mayonnaise, etc.)
It is best to keep a separate GF jar for commonly used items and be sure to label it clearly. At the very least, make sure everyone in the house knows not to “double-dip.”
- Buffet lines
Other customers may use one serving utensil for multiple items. Food from one area may be spilled into another food container. It may be safer to order from the menu.
- Deep-fried foods
Oil is typically used over and over to fry foods. It is highly likely that French fries (or other GF foods) are fried in the same oil as battered and breaded foods such as fried chicken.
- Strainers/colanders
Colanders used to drain gluten-containing pasta may hold onto residual gluten proteins, as they are very difficult to thoroughly clean.

GF, Gluten free.

dietitian nutritionist (RDN) on the GF diet, along with reliable resources for further guidance and support. Persons with CD usually require several educational or counseling sessions and often benefit from a support group (American Gastroenterological Association [AGA], 2015) (see Box 27.9 for CD resources).

Tropical Sprue

Tropical sprue is an acquired diarrheal syndrome with malabsorption that occurs in many tropical areas. In addition to diarrhea and malabsorption, anorexia, abdominal distention, and nutritional deficiency as evidenced by night blindness, glossitis, stomatitis, cheilosis, pallor, and edema can occur. Anemia may result from iron, folic acid, and vitamin B₁₂ deficiencies.

Pathophysiology

The diarrhea of tropical sprue appears to be an infectious type, although the precise cause and the sequence of pathogenic events remain unknown. The syndrome may include bacterial overgrowth, changes in GI motility, and cellular changes in the GI tract. Identified intestinal organisms may differ from one region of the tropics to the next. As in CD, the intestinal villi may be abnormal, but the surface cell alterations are much less severe. The gastric mucosa is atrophied and inflamed, with diminished secretion of hydrochloric acid and intrinsic factor (Langenberg et al, 2014).

Medical Treatment

Treatment of tropical sprue typically includes use of broad-spectrum antibiotics, folate, vitamin B₁₂, fluid, and electrolytes.

Medical Nutrition Therapy

Nutrition management includes restoration and maintenance of fluids, electrolytes, macronutrients, and micronutrients, and introduction of a diet that is appropriate for the extent of malabsorption (see Diarrhea earlier in this chapter). Along with other nutrients, B₁₂ and folate supplementation may be needed if deficiency is identified. Nutritional deficiency increases susceptibility to infectious agents, further aggravating the condition.

INTESTINAL BRUSH-BORDER ENZYME DEFICIENCIES

Intestinal enzyme deficiency states involve deficiencies of the brush-border disaccharidases that hydrolyze disaccharides at the mucosal cell membrane. Disaccharidase deficiencies may occur as (1) rare congenital defects such as the sucrase, isomaltase, or lactase deficiencies seen

in the newborn; (2) generalized forms secondary to diseases that damage the intestinal epithelium (e.g., Crohn's disease or CD); or, most commonly, (3) a genetically acquired form (e.g., lactase deficiency) that usually appears after childhood but can appear as early as 2 years of age. For this chapter, only lactose malabsorption is described in detail (see Chapter 42 for a discussion of inborn metabolic disorders).

Lactose Intolerance

Lactose intolerance is the syndrome of diarrhea, abdominal pain, flatulence, or bloating occurring after lactose consumption. Secondary lactose intolerance can develop as a consequence of infection of the small intestine, gastrointestinal surgeries, inflammatory disorders, HIV, or malnutrition. In children it is typically secondary to viral or bacterial infections. Lactose malabsorption is commonly associated with other GI disorders, such as IBS.

Etiology

High concentrations of the brush-border enzyme, lactase, is present in the small bowel of all newborn mammals. After weaning, about 75% of the world's population dramatically decreases the synthesis of this enzyme despite continued exposure to lactose (Levitt et al, 2013). These people are termed to be lactase nonpersistent. The majority of adults of Asian, African, Latino, and Native American descent are lactase nonpersistent, whereas the majority of Caucasians are lactase persistent. Lactose malabsorption or intolerance has been reported to be low in children younger than age 6 but increases throughout childhood, peaking at age 10 to 16 years.

While evidence indicates that lactose intolerance increases slightly with increasing adult age or varies by race or gender, the difference may be more closely aligned with a dose specific effect, body size, and genetic differences versus lactose intolerance (Lapides and Savaiano, 2018). However, even in adults who retain a high level of lactase levels with age (75% to 85% of white adults of Western European heritage), the quantity of lactase is about half that of other saccharidases such as sucrase, alpha-dextrinase, or glucoamylase. The decline of lactase is known as **hypolactasia** (see *Focus On: Lactose Intolerance: NOT an Uncommon Anomaly*).

Pathophysiology

When large amounts of lactose are consumed, especially by persons who have little remaining lactase enzyme or with concurrent GI problems, loose stools or diarrhea can occur. As is the case with any malabsorbed sugar, lactose may act osmotically and increase fecal water, as well as provide a substrate for rapid fermentation by intestinal bacteria, which may result in bloating, flatulence, and cramps. Malabsorption of lactose is due to a deficiency of lactase, the enzyme that digests the sugar in milk. Lactose that is not hydrolyzed into galactose and glucose in the upper small intestine passes into the colon, where bacteria ferment it to SCFAs, carbon dioxide, and hydrogen gas.

Medical Treatment

Lactose malabsorption is diagnosed by (1) an abnormal hydrogen breath test or (2) an abnormal lactose tolerance test. During a hydrogen breath test, the patient is given a standard dose of lactose after fasting, and breath hydrogen is measured. If lactose is not digested in the small intestine, it passes into the colon, where it is fermented by the gut microbiota to SCFAs, CO₂, and hydrogen. Hydrogen is absorbed into the bloodstream and is exhaled through the lungs. The breath hydrogen test shows increased levels 60 to 90 minutes after lactose ingestion.

During a lactose tolerance test, a dose of lactose is given, and if the individual has sufficient lactase enzyme, blood sugar rises, reflecting the digestion of lactose to galactose and glucose. If the individual is lactose intolerant (lactase deficient), blood sugar will not rise because

FOCUS ON

Lactose Intolerance: NOT an Uncommon Anomaly

When lactose intolerance was first described in 1963, it appeared to be an infrequent occurrence, arising only occasionally in the white population. Because the capacity to digest lactose was measured in people from a wide variety of ethnic and racial backgrounds, it soon became apparent that disappearance of the lactase enzyme shortly after weaning, or at least during early childhood, was actually the predominant (normal) condition in most of the world's population. With a few exceptions, the intestinal tracts of adult mammals produce little, if any, lactase after weaning (the milks of pinnipeds—seals, walruses, and sea lions—do not contain lactose).

The exception of lactose tolerance has attracted the interest of geographers and others concerned with the evolution of the world's population. A genetic mutation favoring lactose tolerance appears to have arisen approximately 10,000 years ago, when dairy farming was first introduced. Presumably, it would have occurred in places where milk consumption was encouraged because of some degree of dietary deprivation and in groups in which milk was not fermented before consumption (fermentation breaks down much of the lactose into monosaccharides). The mutation would have selectively endured, because it would promote greater health, survival, and reproduction of those who carried the gene.

It is proposed that the mutation occurred in more than one location and then accompanied migrations of populations throughout the world. It continues primarily among whites from northern Europe and in ethnic groups in India, Africa, and Mongolia. The highest frequency (97%) of lactose tolerance occurs in Sweden and Denmark, suggesting an increased selective advantage in those able to tolerate lactose related to the limited exposure to ultraviolet light typical of northern latitudes. Lactose favors calcium absorption, which is limited in the absence of vitamin D produced by skin exposure to sunlight.

Dairy farming was unknown in North America until the arrival of Europeans, but the native peoples of North America did have a source of dairy in their diets. Thus Native Americans and those of non-European descent are among the 65% of the world's population who tolerate milk poorly, if at all (Silberman and Jin, 2019). This has practical implications with respect to group feeding programs such as school breakfasts and lunches. However, many lactose-intolerant people are able to digest milk in small to moderate amounts (Shaukat et al, 2010).

the lactose is not absorbed; it passes into the colon and GI symptoms may appear. The lactose tolerance test was based originally on an oral dose of lactose equivalent to the amount in 1 quart of milk (50 g). Recently doses lower than 50 g of lactose have been used to approximate more closely the usual consumption of lactose from milk products.

Demonstrated lactose malabsorption does not always indicate a person will be symptomatic. Many factors play a role, including the amount of lactose ingested, the residual lactase activity, the ingestion of food in addition to lactose, the ability of the gut microbiota to ferment lactose, and the sensitivity of the individual to the lactose fermentation products (Misselwitz et al, 2013). Consumption of small amounts should be of little consequence because the SCFAs are readily absorbed and the gases can be absorbed or passed. Larger amounts, usually greater than 12 g/day, consumed in a single food (the amount typically found in a cup or 240 mL of milk) may result in more substrate entering the colon than can be disposed of by normal processes. Because serving sizes of milk drinks are increasing and more than one source of lactose may be consumed in the same meal, the amounts of lactose consumed may be more important than in years past (Misselwitz et al, 2013).

Medical Nutrition Therapy

Management of lactose intolerance requires dietary change. The symptoms are alleviated by reduced consumption of lactose-containing foods (see Table 27.3 for common foods containing lactose). Those

TABLE 27.3 Lactose Content of Common Foods

Product	Serving Size	Approximate Lactose Content (grams)
Milk (nonfat, 1%, 2%, whole), chocolate milk, acidophilus milk, buttermilk	1 cup	10-12
Butter, margarine	1 tsp	trace
Cheese	1 ounce	0-2
Cheddar, sharp	1 ounce	0
American, Swiss, Parmesan	1 ounce	1
Bleu cheese	1 ounce	2
Cottage cheese	½ cup	2-3
Cream (heavy), whipped cream	½ cup	3-4
Cream cheese	1 ounce	1
Evaporated milk	1 cup	24
Half-and-half	½ cup	5
Ice cream	½ cup	6
Ice milk	½ cup	9
Nonfat dry milk powder (unreconstituted)	1 cup	62
Sherbet, orange	½ cup	2
Sour cream	½ cup	4
Sweetened condensed milk, undiluted	1 cup	40
Yogurt, cultured, low-fat*	1 cup	5-10

*Note: Although most yogurt does contain lactose, yogurt with live cultures is generally well tolerated by those with lactose intolerance.

who avoid dairy products may need calcium and vitamin D supplementation unless they are diligent about including nondairy sources of these nutrients. A completely lactose-free diet is not necessary in lactase-deficient persons. Most lactose maldigesters can consume some lactose (up to 12 g/day) without major symptoms, especially when taken with meals or in the form of cheeses or fermented dairy products (Misselwitz et al, 2013).

Many adults with intolerance to moderate amounts of milk eventually adapt to and tolerate 12 g or more of lactose in milk (equivalent to one cup of full-lactose milk) when introduced gradually, in increments, over several weeks. Incremental or continuous exposure to increasing quantities of fermentable sugar can lead to improved tolerance, not as a consequence of increased lactase enzyme production but by altered gut microbiota composition. This has been shown with lactulose, a nonabsorbed carbohydrate that is biochemically similar to lactose (Lomer, 2015). Individual differences in tolerance may relate to the state of colonic adaptation. Regular consumption of milk by lactase-deficient individuals may increase the threshold at which diarrhea occurs.

Lactase enzyme in tablets or liquid or in milk products treated with lactase enzyme (e.g., Lactaid) are available for lactose maldigesters who have discomfort with milk ingestion. Commercial lactase preparations may differ in their effectiveness. Fermented milk products, such as aged cheeses and yogurts, are well tolerated because their lactose content is low. Tolerance of yogurt may be the result of a microbial galactosidase in the bacterial culture that facilitates lactose digestion in the intestine. The presence of galactosidase depends on the brand and processing method. Because this microbial enzyme is sensitive to freezing, frozen yogurt may

not be as well tolerated. Although the addition of probiotics may change this, evidence is lacking (Morelli, 2014). Lactose-free or reduced lactose enteral nutrition formulas are widely available for hospitalized and long-term feeding tube patients (see Chapter 12 and Appendix 16).

Fructose Malabsorption

Dietary fructose exists in three forms: (1) the monosaccharide, (2) sucrose, a disaccharide of fructose and glucose, and (3) in chains as fructans. Consumption of fructose in the United States, especially from fruit juices, fruit drinks, and high-fructose corn syrup (HFCS) in soft drinks and confections, has increased significantly in recent years. The human small intestine has a limited ability to absorb fructose, compared with the ability to absorb glucose rapidly and completely.

Etiology

Although **fructose malabsorption** is common in healthy people, its appearance depends on the amount of fructose ingested. Absorption of fructose is improved when it is ingested with glucose (such as in sucrose) because glucose absorption stimulates pathways for fructose absorption. Although some degree of fructose malabsorption may be normal, those with coexisting GI disorders may be more likely to experience GI symptoms after fructose ingestion. Patients with IBS and visceral hypersensitivity may be more sensitive to gas, distension, or pain from fructose malabsorption, whereas those with small bowel bacterial overgrowth (SIBO) may experience symptoms from normal amounts of fructose.

Pathophysiology

Breath hydrogen testing has revealed that up to 75% of healthy people will incompletely absorb a large quantity of fructose (50 g) taken alone (Putkonen et al, 2013).

Fructose coexists in food with other poorly absorbed carbohydrates, which have been given the umbrella term FODMAPs. In one recent study, restricting FODMAPs in the diet demonstrated global symptom relief in those with fructose or lactose intolerance, with the benefit indicating possible relationship to changes in intestinal host or microbiome metabolism (Wilder-Smith et al, 2017).

Medical Nutrition Therapy

People with fructose malabsorption and those patients with GI conditions that experience symptoms of fructose malabsorption may not have problems with foods containing balanced amounts of glucose and fructose but may need to limit or avoid foods containing large amounts of free fructose. Pear, apple, mango, and Asian pear are notable in that they have substantially more “free fructose” (more fructose than glucose). In addition, most dried fruits and fruit juices may pose a problem in larger amounts because of the amount of fructose provided per serving. Foods sweetened with HFCS (as opposed to sucrose) are also more likely to cause symptoms. The degree of fructose intolerance and tolerance to the symptoms of fructose malabsorption are so variable that intake of these foods must generally be individualized with each patient (see Table 27.7 for a list of foods high in fructose content).

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is a chronic and relapsing disorder of the gastrointestinal tract. It is characterized by chronic intestinal inflammation and is categorized into two major forms as either **Crohn’s disease** or **ulcerative colitis (UC)**. Crohn’s disease and UC are relatively rare disorders, but they result in frequent use of health care resources. The prevalence and incidence is increasing as IBD emerges

as a global disease, though it remains most prominent in industrialized nations (Lewis et al, 2017). It is also becoming more prevalent in older adults (Ye et al, 2015).

Contrary to older data used in estimates from 1999, in 2015 the CDC found that 3.1 million (1.3%) of adults in the United States had ever been given a diagnosis of IBD. Of these, there were a higher percentage of individuals at ages 45 to 64 (1.5%) and ≥ 65 (1.7%) compared with younger age groups. Hispanics and non-Hispanic whites had a higher prevalence than non-Hispanic blacks. Level of education, employment, and socioeconomic status were also correlated with those who had received an IBD diagnosis (Dahlhamer et al, 2016).

While the onset of IBD occurs most often in patients 15 to 30 years of age, for some it occurs later in adulthood. IBD occurs more commonly in developed areas of the world, but in the United States it is more prevalent in those living in poverty (incomes $<100\%$ vs. $\geq 400\%$ of the federal poverty level). The disease has a higher prevalence for those living outside the central city of a metropolitan statistical area. Factors having no impact on prevalence included region of residence, sex, current marital status, or health insurance coverage type (Dahlhamer et al, 2016). Reasons for the varied prevalence of IBD are not entirely clear but emerging research is investigating many aspects of the increased inflammatory and proliferative state, including etiology, epidemiology, and nutritional factors.

Crohn’s disease and UC share some clinical characteristics, including diarrhea, fever, weight loss, anemia, food intolerances, malnutrition, growth failure, and extraintestinal manifestations (arthritic, dermatologic, and hepatic). In both forms of IBD, the risk of malignancy increases with the duration of the disease. Although malnutrition can occur in both forms of IBD, it is more of a lifelong concern in patients with Crohn’s disease than with UC. The features that distinguish the forms of the disease in terms of genetic characteristics, clinical presentation, and treatment are discussed in Table 27.4.

Etiology

The cause of IBD is not completely understood and there is no known cure, but the most widely accepted pathogenesis involves complex interaction of the GI immunologic system of the host, and genetic and environmental factors. Emerging research is also investigating the role of the microbiota and its potential role in the disease (Nishida et al, 2018). Genetic susceptibility is now recognized to be diverse, with a number of possible gene mutations that affect risk and characteristics of the disease. The diversity in the genetic alterations among individuals may help explain differences in the onset, aggressiveness, complications, location, and responsiveness to different therapies as seen in the clinical setting. The major environmental factors include resident and transient microorganisms in the GI tract and dietary components.

The genes affected (e.g., C677T mutation related to methylenetetrahydrofolate reductase) normally play a role in the reactivity of the host GI immune system to luminal antigens such as those provided by intestinal flora and the diet. In animal models, inflammatory disease does not occur in the absence of gut microbiota. Normally, when an antigenic challenge or trauma occurs, the immune response is initiated; it is then turned off and continues to be held in check after the challenge resolves. In IBD however, increased antigen exposure, decreased host defense mechanisms, and/or decreased tolerance to some components of the gut microbiota occurs. Inappropriate inflammatory response and an inability to suppress it play primary roles in the disease. For example, two genes, NOD2/CARD15 and the autophagy gene ATG16L1 have been linked to one functional pathway of bacterial sensing, invasion, and elimination. Failure of these genes to come together can lead to impaired autophagy and persistence of bacteria, resulting in abnormal immune responses (Bossuyt and Vermeire, 2016).

The Western diet may also be a contributing factor for development of IBD (Lewis et al, 2017). In epidemiologic studies, factors

TABLE 27.4 Ulcerative Colitis versus Crohn's Disease

	Ulcerative Colitis	Crohn's Disease
Presentation	Bloody diarrhea	Perianal disease, abdominal pain (65%), mass in abdomen
Gross pathology	Rectum always involved	Rectum may not be involved
	Moves continuously, proximally from rectum	Can occur anywhere along gastrointestinal tract Not continuous: "skip lesions"
	Thin wall	Thick wall
	Few strictures	Strictures common
	Diffuse ulceration	Cobblestone appearance
Histopathology	No granulomas	Granulomas
	Low inflammation	More inflammation
	Deeper ulcers (hence named ulcerative)	Shallow ulcers
	Pseudopolyps	Fibrosis
	Abscesses in crypts	
Extraintestinal manifestations	Sclerosing cholangitis	Erythema nodosum
	Pyoderma gangrenosum	Migratory polyarthritis Gallstones
Complications	Toxic megacolon	Malabsorption
	Cancer	Cancer
	Strictures and fistulas are very rare	Strictures or fistulas
		Perianal disease

associated with of the development of IBD include increased sucrose intake, lack of fruits and vegetables, a low intake of dietary fiber, increased consumption of red meat and alcohol, altered omega-6/omega-3 fatty acid ratios and insufficient vitamin D intake (Hlavaty et al, 2015). Dietary interventions to modify these factors during IBD flares are still under investigation (Owczarek et al, 2016).

Pathophysiology

Crohn's disease. Crohn's disease may involve any part of the GI tract, but approximately 50% to 60% of cases involve the distal ileum and the colon. Only the small intestine or only the colon is involved in 15% to 25% of cases. Some unique features of Crohn's disease include segments of inflamed bowel that may be separated by healthy segments, and transmural mucosal involvement that affects all layers of the mucosa. Crohn's disease is also characterized by abscesses, fistulas, fibrosis, submucosal thickening, localized strictures, narrowed segments of bowel, and partial or complete obstruction of the intestinal lumen.

Ulcerative colitis. Ulcerative colitis disease activity is limited to only the large intestine and rectum. The disease process is continuous and is normally limited to the mucosa. Bleeding is more common in UC as well. See Fig. 27.5 (A–C) and Table 27.4 to compare and contrast further.

The inflammatory response (e.g., increased cytokines and acute-phase proteins, increased GI permeability, increased proteases, and increased oxygen radicals and leukotrienes) results in GI tissue damage. In IBD either the regulatory mechanisms are defective or the factors perpetuating the immune and acute-phase responses are enhanced, leading to tissue fibrosis and destruction. The clinical course of the disease may be mild and episodic or severe and unremitting (see *Pathophysiology and Care Management Algorithm: Inflammatory Bowel Disease*).

C, From McGowan CE, Lagares-Garcia JA, Bhattacharya B: Retained capsule endoscope leading to the identification of small bowel adenocarcinoma in a patient with undiagnosed Crohn's disease, *Ann Diagn Pathol* 13[6]:390-393, 2009.)

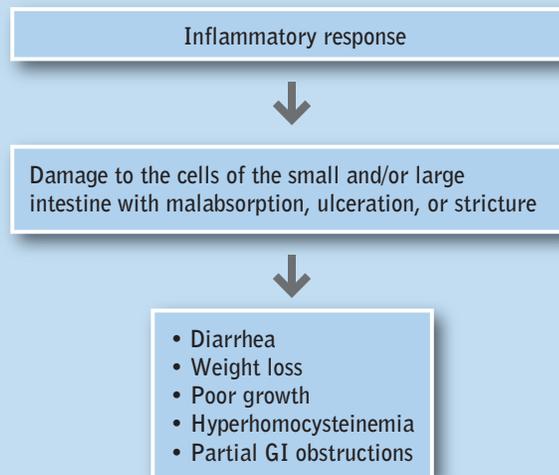

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Inflammatory Bowel Disease

ETIOLOGY

PATHOPHYSIOLOGY

MANAGEMENT

Medical Management

- Corticosteroids
- Antiinflammatory agents
- Immunosuppressants
- Antibiotics
- Anticytokine medications

Surgical Management

- Bowel resection that can result in short bowel syndrome (SBS)

Nutrition Management

- Oral enteral formula (tube feed if necessary)
- Use of foods that are well tolerated
- Parenteral nutrition in patients with severe disease or obstruction
- Supplement with folate, B₆, B₁₂, Vitamin D, iron (if needed), and ω-3 fatty acids
- Consider use of prebiotics and probiotics (especially VSL#3)
- Modify fiber intake according to symptoms
- Test for food intolerances

Diet is an environmental factor that may trigger relapses of IBD. Foods, microbes, individual nutrients, and incidental contaminants provide a huge number of potential antigens, especially considering the complexity and diversity of the modern diet. Malnutrition can affect the function and effectiveness of the mucosal, cellular, and immune barriers; diet also can affect the type and relative composition of the resident microflora. Several nutrients, such as dietary fats or vitamin D, can affect the intensity of the inflammatory response (Hlavaty et al, 2015; Sadeghian et al, 2016).

Food allergies and other immunologic reactions to specific foods have been considered in the pathogenesis of IBD and its symptoms, though the incidence of documented food allergies, compared with food intolerances, is relatively small. Some theorize that intestinal wall permeability to food molecules and cell fragments is likely increased in inflammatory states, which would allow the potential for increased interaction of antigens with host immune systems (Michielan et al, 2015). While damage to epithelial barrier function is a characteristic feature of IBD, further research is needed to determine whether this plays a primary role in disease development or as a secondary response to inflammation in IBD (Antoni et al, 2014).

Food intolerances occur more often in persons with IBD than in the population at large, but the patterns are not consistent among individuals or even between exposures from one time to the next. Reasons for specific and nonspecific food intolerances are abundant and are related to the severity, location, and complications associated with the disease process. Partial GI obstructions, malabsorption, diarrhea, altered GI transit, increased secretions, food aversions, and associations are but a few of the problems experienced by persons with IBD. However, neither food allergies nor intolerances fully explain the onset or manifestations in all patients (see Chapter 25).

Medical Management

The goals of treatment in IBD are to induce and maintain remission and to improve nutrition status. Treatment of the primary GI manifestations appears to correct most of the extraintestinal features of the disease as well. The most effective medical agents include corticosteroids, anti-inflammatory agents (aminosalicylates), immunosuppressive agents (cyclosporine, azathioprine, mercaptopurine), antibiotics (ciprofloxacin and metronidazole), and monoclonal tumor necrosis factor antagonists (anti-TNF), and infliximab, adalimumab, certolizumab, and natalizumab, agents that inactivate one of the primary inflammatory cytokines. Anti-TNF has historically been used in severe cases of Crohn's disease and fistulas, but more recently it has shown promise in UC as well (Mao et al, 2017).

Investigations of various treatment modalities for the acute and chronic stages of IBD are ongoing and include new forms of existing drugs as well as new agents targeted to regulate production and activity of cytokines, eicosanoids, or other mediators of the inflammatory and acute-phase response (Monteleone et al, 2014).

Surgical Management

In Crohn's disease, surgery may be necessary to repair strictures (narrowing of the GI lumen) or remove portions of the bowel when medical management fails. Approximately 50% to 70% of persons with Crohn's disease undergo surgery related to the disease. Surgery does not cure Crohn's disease, and recurrence often occurs within 1 to 3 years of surgery. The chance of needing subsequent surgery in the patient's life is about 30% to 70%, depending on the type of surgery and the age at the first operation. Major resections of the intestine may result in varying degrees of malabsorption of fluid and nutrients. In extreme cases patients may have extensive or multiple resections, resulting in short-bowel syndrome (SBS) and dependence on PN to maintain adequate nutrient intake and hydration (see Chapter 12).

With increased efficacy of pharmaceutical therapies for UC, the percentage of patients who undergo a colectomy to remove the colon and resolve the disease has decreased over time (Barnes et al, 2019). If surgery remains indicated, inflammation does not occur in the remaining GI tract. Whether a colectomy is necessary depends on the severity of the disease and indicators of increased cancer risk. After a colectomy for UC, surgeons may create an ileostomy with an external collection pouch and an internal abdominal reservoir fashioned with a segment of ileum or an ileoanal pouch, which spares the rectum, to serve as a reservoir for stool. The internal Koch pouch also may be used (see later in this chapter for more detailed description).

Medical Nutrition Therapy

Persons with IBD are at increased risk of nutrition problems for a host of reasons related to the disease and its treatment. Thus the primary goal is to restore and maintain the nutrition status of the individual. Foods, dietary and micronutrient supplements, and enteral and parenteral nutrition may be used to accomplish that mission. Oral diet and the other means of nutrition support may change during remissions and exacerbations of the disease. Diet and specific nutrients play a supportive role in maintaining nutrition status and limiting symptom exacerbations, as well as supporting growth in pediatric patients.

In daily life persons with IBD may have intermittent "flares" of the disease characterized by partial obstructions, nausea, abdominal pain, bloating, or diarrhea. Foods that are responsible for some GI symptoms in a normal, healthy population (gas, bloating, diarrhea) are likely to be triggers for the same symptoms in patients with mild stages of IBD or those in remission. Many report specific, individualized food intolerances (Hou et al, 2014) and are sometimes advised to eliminate foods they suspect are responsible for the intolerance. Often, the patient becomes increasingly frustrated as the diet becomes progressively limited and symptoms still do not resolve. Since malnutrition is a significant risk in patients with IBD, an overly restrictive diet only increases the likelihood of malnutrition and weight loss.

There is a great deficit of quality controlled dietary clinical trials for IBD. Because of this, no single dietary regimen for reducing symptoms or decreasing flares has been found to be conclusively effective. Though limited, current dietary research is exploring the specific carbohydrate diet, antiinflammatory diet, low FODMAPs diet, and others, and any potential they may have to help patients with IBD (Kakodkar et al, 2015; Olendzki et al, 2014; Prince et al, 2016; Braly et al, 2017; Suskind, 2016). An important aspect of dietary research is the impact of how the diet acts as an environmental factor that can affect the microbiome (Lee et al, 2015; Nishida et al, 2018). Far more dietary research and clinical trials are needed to make any specific dietary recommendations for IBD, but there is an exciting trend of interest brewing in the scientific community (Lee et al, 2016).

The ability of nutrition support as either PN or enteral nutrition (EN) to induce remission of IBD has been debated for several years. Evaluation is confounded by the natural course of IBD with exacerbations and remissions and by the genetic diversity of the patients. EN is not as effective as corticosteroid therapy to induce remission in adults with Crohn's disease. For children, however, EN is far more effective than the placebo and should be considered as a primary therapy. EN can also be used to reverse malnutrition that can occur with Crohn's, and to encourage growth in the pediatric population (Palmer et al, 2017). Children can also benefit from EN, either as sole source of nutrition or supplemental to an oral diet, to reduce dependence on steroids that may affect growth and bone disease. Complete bowel rest using PN is not necessarily required but may be used in those with inadequate functioning bowel, or for 1 to 2 weeks before surgery in malnourished patients (Palmer et al, 2017). EN has the potential to feed the intestinal epithelium and alter GI flora and is the preferred

route of nutrition support in patients with adequate bowel length. EN may temper some elements of the inflammatory process, serve as a valuable source of nutrients needed for restoration of GI defects, and be steroid sparing (Richman and Rhodes, 2013). Available evidence does not support the use of EN as a first-line therapy in those with UC, but tolerance has been demonstrated during acute flares (Palmer et al, 2017).

Overall, patients and caretakers must be very committed when using EN formulas or tube feeding because it takes 4 to 8 weeks before one sees the clinical effects. Timely nutritional support is a vital component of therapy to restore and maintain nutritional health. Malnutrition compromises digestive and absorptive function by increasing the permeability of the GI tract to potential inflammatory agents. EN is always the preferred route over PN when nutrition support is medically indicated in IBD. PN is not as nutritionally complete, has increased risk of infectious complications, and is more expensive than EN. However, PN may be required in patients with persistent bowel obstruction, fistulas, and major GI resections that result in SBS where EN is not possible.

Energy needs of patients with IBD are not increased (unless weight gain is desired). Generally, when disease activity increases basal metabolic rate, physical activity is greatly curtailed, and overall energy needs, are not substantially changed. Protein requirements may be increased, depending on the severity and stage of the disease and the restoration requirements. Inflammation and treatment with corticosteroids induce a negative nitrogen balance and cause a loss of lean muscle mass. Protein losses also occur in areas of inflamed and ulcerated intestinal mucosa via defects in epithelial tight junctions (see Chapter 37). To maintain positive nitrogen balance, 1.3 to 1.5 g/kg/day of protein is recommended.

Supplemental vitamins, especially folate, B₆, and B₁₂, may be needed, as well as minerals such as iron and trace elements to replace stores or for maintenance because of maldigestion, malabsorption, drug-nutrient interactions, or inadequate intake (Owczarek et al, 2016). Diarrhea can aggravate losses of zinc, potassium, and selenium. Patients who receive intermittent corticosteroids may need supplemental calcium and vitamin D. Patients with IBD are at increased risk of osteopenia and osteoporosis; 25-OH vitamin D levels and bone density should be monitored routinely and vitamin D supplemented appropriately (Hlavaty et al, 2015). Omega-3 fatty acid supplements in Crohn's disease significantly reduce disease activity. Use of omega-3 fatty acids or fish oil supplements in UC appears to result in a significant medication-sparing effect, with reductions in disease activity and increased time in remission reported (Farrukh and Mayberry, 2014). Use of foods and supplements containing prebiotics and probiotic supplements continues to be investigated for their potential to alter the gut microbiota; and further research is indicated (Sinagra et al, 2013; Nishida et al, 2018).

During acute and severe exacerbations of the disease, the diet is tailored to the individual but usually includes reduced fiber intake and decaffeinated, low-sugar beverages for adequate hydration (Academy of Nutrition and Dietetics [AND], 2019). In people with rapid intestinal transit, extensive bowel resections, or extensive small bowel disease, absorption may be compromised. Here, excessive intake of lactose, fructose, or sorbitol may contribute to abdominal cramping, gas, and diarrhea; and high fat intake may result in steatorrhea. However, the incidence of lactose intolerance is no greater in patients with IBD than in the general population. Patients with IBD who tolerate lactose should not necessarily restrict lactose-containing foods because they can be a valuable source of high-quality protein, calcium, and vitamin D.

Patients with strictures or partial bowel obstruction benefit from a reduction in dietary fiber or limited food particle size. Small, frequent

feedings may be tolerated better than large meals. Small amounts of isotonic (having the same solute concentration as bodily fluids), liquid oral supplements, may be valuable in restoring intake without provoking symptoms. In cases in which fat malabsorption is likely, supplementation with foods made with **medium-chain triglycerides (MCTs)** may be useful in adding calories and serving as a vehicle for fat-soluble nutrients but must be introduced slowly to avoid GI distress. However, these products are expensive and may be less effective than more basic treatments.

The information on IBD available to the general public is sometimes inaccurate or exaggerated, or it may pertain only to one individual's situation and not to another's. A critical component of patient education for IBD pertains to helping with the evaluation of nutrition information. Patients' participation in the management of their disease may help to reduce not only the symptoms of the disease but also the associated anxiety level.

Microbiota. Probiotic foods and supplements have been investigated as potential therapeutic agents for IBD because of their ability to modify the gut microbiota and potentially modulate gut inflammatory response. Multistrain probiotic supplements (e.g., VSL#3) have been shown to be beneficial in maintaining disease remission in patients with UC who had **pouchitis**, inflammation in the ileal pouch surgically formed after colectomy (Shen et al, 2014). Specific probiotic supplements appear to be useful for induction and extension of remissions in pediatric and adult UC (Ghouri et al, 2014; Shen et al, 2014).

Although probiotics appear useful in UC, probiotic studies have not demonstrated significant improvement in Crohn's disease activity in adults or pediatric patients, nor do probiotic supplements appear to prolong remission in Crohn's disease (Ghouri et al, 2014). Due to many confounding factors to research including, but not limited to, medication use (antibiotics, proton-pump inhibitors, antidiarrheals), variability in probiotic quality, and differences in dietary intake among participants, it has yet to be established whether probiotics could be of benefit as part of the routine treatment in IBD (Abraham and Quigley, 2017).

Regular intake of prebiotic foods such as oligosaccharides, fermentable fibers, and resistant starches can beneficially affect the gut microbiota, feeding *Lactobacillus* and *Bifidobacteria*, thus providing competition to and theoretically suppression of pathogenic or opportunistic microbiota. In addition, fermentation of prebiotics leads to increased production of SCFAs, theoretically creating a more acidic and less favorable environment for opportunistic bacteria.

Use of probiotics and prebiotics may prevent SIBO in predisposed individuals and may be used to treat diarrhea. Additional study is needed to identify the dose, the most effective prebiotic and probiotic foods, the form in which they can be used for therapeutic and maintenance purposes, and their relative value compared with other therapies (Ghouri et al, 2014).

Microscopic Colitis

Injury of the colon caused by UC, Crohn's disease, infections, radiation injury, and ischemic insult to the colon presents with abnormalities such as edema, redness, bleeding, or ulcerations that are visible on colonoscopy examination. Unlike the colitis of IBD, **microscopic colitis** is characterized by inflammation that is not visible by inspection of the colon during colonoscopy and is apparent only when the colon's lining is biopsied and then examined under a microscope. Patients with microscopic colitis can have diarrhea for months or years before the diagnosis is made. The cause of microscopic colitis is unknown.

Pathophysiology

There are two types of microscopic colitis. In **lymphocytic colitis**, there is an accumulation of lymphocytes within the lining of the colon.

In **collagenous colitis**, there is also a layer of collagen (like scar tissue) just below the lining. Some experts believe that lymphocytic colitis and collagenous colitis represent different stages of the same disease. Symptoms include chronic, watery diarrhea, mild abdominal cramps, and pain. More than 30% of patients report weight loss. Microscopic colitis appears more frequently in patients aged 60 to 70 years, and collagenous colitis occurs more frequently in females (Ohlsson, 2015).

Medical Nutrition Therapy

Research is underway to determine possible effective treatments for microscopic colitis, including corticosteroids and immunosuppressive agents. Medical nutrition therapy is supportive with efforts to maintain weight and nutrition status, avoid symptom exacerbation, and maintain hydration, similar to that for IBD.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder defined by the American College of Gastroenterology (ACG) IBS Task Force as “abdominal discomfort associated with altered bowel habits” (Ford et al, 2014). The **Rome IV criteria** for IBS and its subtypes are used to define the diagnosis based on the presence of GI symptoms (Box 27.10). IBS is a condition characterized by unexplained abdominal discomfort or pain that is associated with changes in bowel habits (Schoenfeld, 2016). Other common symptoms include gas, bloating, diarrhea and constipation, and increased GI distress associated with psychosocial distress. These symptoms may be vague and transient, making IBS a diagnosis of exclusion. It is classified as a functional disorder because tests show no histologic abnormalities and, therefore, diagnosis depends on symptoms. The diagnostic criteria also include a refining of subtypes of IBS based on predominant stool patterns (Table 27.5).

Research is underway to better define IBS, which may be reflected in a new name for this challenging disease process.

An estimated 10% to 20% of the United States population has IBS, with twice as many women as men being affected, although this may be a factor of reporting (Koff and Mullin, 2012). There are between 2.4 and 3.5 million annual physician visits for IBS in the United States alone. IBS is the most common disorder diagnosed by gastroenterologists and accounts for 20% to 40% of visits (International Foundation for Functional Gastrointestinal Disorders [IFFGD], 2014). Patients with IBS often miss school and work days, resulting in decreased productivity, increased health care costs, and decreased quality of life as a result of their symptoms.

Etiology

No specific marker or test is diagnostic for IBS. Lactulose breath testing has been used to measure breath hydrogen and methane levels resulting from an overgrowth of bacteria in the small intestine, and this has been correlated with some cases of IBS (Rezaie et al, 2017). When assessing a patient for IBS, the clinician must carefully review medication records because numerous over-the-counter and prescribed medications can cause abdominal symptoms such as pain and changes in bowel habits. In addition, the symptoms of IBS overlap with or are similar to other GI diseases such as CD, IBD, functional dyspepsia, and functional constipation. IBS may be present with CD and IBD. Rectal bleeding, iron deficiency anemia, unintentional weight loss, and family history should also be considered when assessing symptoms as they are not common for patients with IBS (Ireton-Jones, 2017; Chey et al, 2015).

Pathophysiology

The pathophysiology of IBS is not completely understood. Several factors are presumed to play a role in the etiology of IBS, including

BOX 27.10 Rome IV Criteria for Diagnosing Irritable Bowel Syndrome (IBS)

Rome IV Criteria for Diagnosing IBS*:

Recurrent abdominal pain, on average, at least 1 day/week in the last 3 months, associated with two or more of the following criteria:

- Related to defecation
- Associated with a change in frequency of stool
- Associated with a change in form (appearance) of stool

*Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Data from: Lacy BE, et al. Bowel Disorders. *Gastroenterology*. 2016;150:1393-1407; Rome III Diagnostic Criteria for Functional Gastrointestinal Disorders. http://www.romecriteria.org/assets/pdf/19_Romelll_apA_885-898.pdf; <https://irritablebowelsyndrome.net/clinical/new-rome-iv-diagnostic-criteria/>.

TABLE 27.5 Subtypes of Irritable Bowel Syndrome (IBS) Based on Stool Patterns

Type	Symptoms
IBS with predominant constipation (IBS-C)	Stool type 1 and 2 more than 25% Stool type 6 and 7 less than 25%
IBS with predominant diarrhea (IBS-D)	Stool type 1 and 2 less than 25% Stool type 6 and 7 more than 25%
IBS with mixed bowel habits (IBS-M)	Stool type 1 and 2 more than 25% Stool type 6 and 7 more than 25%
Unsubtyped IBS	Meet criteria for IBS but bowel habits cannot be categorized into IBS-C, D, or M

Data from Lacy BE, et al. Bowel Disorders, *Gastroenterology* 150:1393-1407, 2016.

nervous system alterations (abnormal GI motility and visceral hypersensitivity), gut flora alterations, genetics, and psychosocial stress (Chey et al, 2015). Research traditionally has focused on intestinal motility; however, studies of small-bowel and colonic motility show inconsistent results with changes in the intestinal microbiome playing a large role in the development of IBS (Dupont, 2014).

Sensation in the GI tract results from stimulation of various receptors and sensory nerves in the gut wall, which transmit signals to the spinal cord and brain. Alterations in areas of the brain involved in pain modulation, autonomic nervous system dysregulation, and impaired brain-gut communication result in hyperalgesia (increased sensation to pain in the gut), visceral hypersensitivity, and altered motility (Chey et al, 2015; Anastasi et al, 2013). Dysregulation of serotonin concentrations in the GI tract has been correlated with the type of IBS a patient experiences; low serotonin concentrations are associated with constipation or a sluggish gut and higher serotonin concentrations are associated with diarrhea or increased peristalsis in the intestine (Kanazawa et al, 2011; Stasi et al, 2014).

Often SIBO is seen with IBS; however, additional studies are needed to understand whether SIBO is directly connected to IBS or is a separate entity. Although treatment of SIBO usually includes antibiotic and or herbal therapy, the low FODMAP diet is also recommended concomitantly.

Psychological conditions, such as depression and anxiety, often are observed in patients with IBS. Although it is unclear whether stress is a cause of IBS, it is known to trigger and exacerbate symptoms (Staudacher, 2017). It is not unusual for patients with

IBS to link their symptoms with lifetime or daily stress (Fadgyas-Stanculete et al, 2014).

Medical Management

The first step in the management of IBS and other functional GI disorders includes validating the reality of the patient's complaints and establishing an effective clinician-patient relationship. Care should be tailored to help the patient manage the symptoms and the factors that may trigger them. Nutrition therapy using the FODMAP elimination diet should be a primary consideration for IBS. Gibson noted that the high quality of evidence for the FODMAP elimination diet supports its use as first-line therapy (Gibson, 2017b). Drug therapy is aimed at management of symptoms associated with GI motility, visceral hypersensitivity, or psychological issues. Combination herbal remedies may be employed as well and have been found to be as effective as antibiotic treatment (Mullin et al, 2014). The treatment option is usually determined by the predominant bowel pattern and the symptoms that most disrupt the patient's quality of life (Table 27.6).

Medical Nutrition Therapy

The goals of nutrition therapy for IBS are to ensure adequate nutrient intake and explain the potential roles of foods in the management of symptoms. First-line therapy to treat IBS is the implementation of the

FODMAP elimination diet or low FODMAP diet, which is defined later in this chapter. Because the symptoms may have been ongoing for a period of time, a thorough nutrition assessment should be completed initially. This should include (1) assessment of nutritional status-body weight status, loss or gain, and food intake; (2) review of current medications for IBS and other medications; (3) review of GI symptoms (duration, severity, frequency); (4) review of supplement intake (vitamins, minerals, fats, pre- and probiotics, herbals); and (5) review of use of mind-body therapies and the results achieved (Ireton-Jones, 2017; Mullin et al, 2014). Presence of CD should be ruled out as well as any disease associated with symptoms such as delayed gastric emptying or bleeding, which are not key signs of IBS.

The FODMAPs Elimination Diet

A diet low in fermentable oligo-, di-, & monosaccharides and polyols (FODMAP) has been shown to be an effective therapy in the management of GI symptoms in patients with IBS. FODMAPs are made up of the fermentable carbohydrate portion of plant based foods. When metabolized by gut bacteria, FODMAPs increase gas production and and cause intestinal dysmotility (Ireton-Jones, 2017; Chey et al, 2015; Mullin, 2014; Shepherd and Gibson, 2006). In addition, these foods increase luminal water content and fluid status in the GI tract. When these are limited or eliminated, symptoms are also reduced or eliminated in up to 70% of people with IBS (Gibson, 2017a). This has been demonstrated in children as well (Chumpitazi et al, 2015).

The low FODMAPs diet limits foods that contain lactose, fructose, fructo-oligosaccharides (fructans), galacto-oligosaccharides (galactans), and polyols or sugar alcohols (sorbitol, xylitol, mannitol, isomaltase, and maltitol). These short-chain carbohydrates are poorly absorbed in the small intestine, are highly osmotic, and are rapidly fermented by bacteria in the small and large intestine, resulting in gas, pain, and diarrhea in sensitive individuals. FODMAPs have a cumulative impact on GI symptoms. A threshold level for acceptable amounts of FODMAPs has not been well defined and is likely patient specific. Patients may tolerate small amounts, but symptoms can develop if they consume quantities that surpass their threshold. Lactulose breath testing, ordered by a physician, can be useful to demonstrate the presence of SIBO by measuring increases in breath hydrogen and methane (Rezaie et al, 2017). These gases are increased when gut bacteria metabolize FODMAPs, especially in the small intestine.

Nutrition intervention begins with elimination of all high FODMAPs foods from the diet for a trial period of approximately 6 weeks although symptoms may improve within 2 weeks (Ireton-Jones, 2017; Barrett, 2017; Catsos, 2017; Gibson, 2011). The challenge or reintroduction phase begins after the elimination phase with a slow, methodical, or controlled reintroduction of one FODMAPs category at a time to observe for symptoms and identify the most challenging foods (Vakil, 2018). The goal is to eventually reduce or eliminate GI symptoms by creating a diet that includes FODMAPs at the most tolerable intake level, and with use of alternative foods. It does not present a cure but a dietary approach to improve symptoms and quality of life.

The key to the successful FODMAP elimination diet is to work with an RDN who is very knowledgeable of the diet principles. There are many "lists" of low FODMAP foods available, and they can be confusing and challenging for the patient who is trying to follow the low FODMAP diet on their own. For this reason, no specific list of low FODMAP foods is provided in this chapter. Monash University is a reliable source for FODMAP content of foods (Gibson, 2017b). The Monash FODMAPs app, available on both iPhone and Android, is constantly being updated and an excellent resource for clinicians and clients. Monash University has other resources on the low FODMAP diet as well.

TABLE 27.6 Medical and Herbal Treatment Options for Irritable Bowel Syndrome (IBS) Symptoms

Symptom	Treatment
Abdominal pain and discomfort	Antispasmodic agents Tricyclic antidepressants Serotonin-directed agents (selective serotonin reuptake inhibitors, serotonin-3 receptor antagonists, or serotonin-4 receptor agonists) Digestive enzymes Peppermint oil Melatonin
Constipation	Fiber supplements: psyllium husk, soluble, nonfermentable Stool softeners Laxatives (osmotic, i.e., Mg; stimulant, i.e., senna)
Diarrhea	Antidiarrheal agents (loperamide, diphenoxylate with atropine) Soluble fiber supplements
Small intestinal bacterial overgrowth (SIBO)	Antibiotics Herbal treatments including berberine and oregano Elemental diet (2-week therapy) Digestive enzymes
Global symptoms and/or overall well-being	Psychotherapy (cognitive behavioral therapy, relaxation therapy, gut-directed hypnotherapy) Complementary and integrative medicine (acupuncture, meditation, stress reduction) Probiotics Prebiotics (use with caution if bloating is present)

Data from Chey W, Kurlander J, Eswaran S: Irritable bowel syndrome: a clinical review, *JAMA* 313(9):949–958, 2015; Mullin G, Shepherd SJ, Roland CB, et al: Irritable bowel syndrome: contemporary nutrition management strategies, *JPEN J Parenter Enteral Nutr* 38(7):781–799, 2014.

Nutritional deficiencies that can arise with the low FODMAPs diet include folate, thiamin, vitamin B₆, and fiber (from limiting cereals and breads), as well as calcium and vitamin D (if avoiding all dairy products in addition to lactose). An RDN can provide appropriate food substitutions to ensure an adequate diet. Patients may wish to stay on a low FODMAP diet to manage their symptoms; however, it is important to add other foods in the reintroduction phase, as these may have fibers and other key nutrients which will enhance overall health.

Several qualified dietitians have written cookbooks and have websites dedicated to assisting clients with the low FODMAP diet. Two of these are Patsy Catsos, MS, RDN and Kate Scarlata, RDN. A training course has been established at the University of Michigan called FOOD: The Main Course to Digestive Health, and also at Monash University (available online).

Diverticular Disease

Diverticular disease is one of the most common medical conditions among industrialized societies. **Diverticulosis** is characterized by the formation of sac-like outpouchings or pockets (diverticula) within the colon that form when colonic mucosa and submucosa herniate through weakened areas in the muscle. The prevalence of diverticulosis is difficult to determine given that most individuals remain asymptomatic. This condition becomes more common as people age, particularly in people older than age 60 (Feuerstein and Falchuk, 2016). **Diverticulitis** is a complication of diverticulosis that indicates inflammation of one or more diverticulum. It often represents a flare-up of diverticulosis, and after it subsides into a period of remission, it reverts to the state of diverticulosis.

Etiology

The cause of diverticulosis has not been elucidated clearly. Epidemiologic studies have implicated low-fiber diets in the development of diverticular disease, but the evidence is ambiguous regarding high-versus low-fiber diets and diverticular disease with regard to prevention and treatment. Low-fiber diets reduce stool volume, predisposing individuals to constipation and increased intracolonic pressures, which suggests that diverticulosis occurs as a consequence of pressure-induced damage to the colon. However, while dietary fiber intake has been shown as inversely related to the risk of developing the disease, a large recent study failed to show a direct correlation between low-fiber diets and diverticulosis. In that study, higher-fiber diets were associated with a higher prevalence of diverticulosis. The American Gastroenterology Association recommends increasing fiber after a diverticulitis attack but even it states that the recommendation is conditional based on weak evidence (Feuerstein and Falchuk, 2016).

More recent research has started to explore theories including genetic differences, diet, motility, microbiome, and inflammation (Feuerstein and Falchuk, 2016). Other studies have focused on the role of decreased levels of the neurotransmitter serotonin in causing decreased relaxation and increased spasms of the colon muscle. Studies have found links between diverticular disease and diets high in red meat and fat, obesity, vitamin D insufficiency, lack of exercise, smoking, and certain medications, including nonsteroidal antiinflammatory drugs such as aspirin and steroids (Maguire et al, 2015; Feuerstein and Falchuk, 2016).

Pathophysiology

Evolving pathophysiologic mechanisms in diverticulosis and diverticulitis suggest chronic inflammation, alterations in colonic microbiota, disturbed colonic sensorimotor function, and abnormal colon motility have interrelated roles in the development of diverticular disease (Feuerstein and Falchuk, 2016). Complications of diverticular disease

range from painless, mild bleeding and altered bowel habits to diverticulitis. Acute diverticulitis includes a spectrum of inflammation, abscess formation, bleeding, obstruction, fistula, and sepsis from perforation (rupture).

Medical and Surgical Treatment

Treatment typically includes antibiotics and adjustment of oral intake as tolerated. Patients with severe cases of diverticulitis with acute pain and complications often require a hospital stay and treatment with intravenous (IV) antibiotics and a few days of bowel rest (clear liquids only, no solid foods). Surgery is reserved for patients with recurrent episodes of diverticulitis and complications when there is little or no response to medication. Surgical treatment for diverticulitis removes the diseased part of the colon: most commonly, the left or sigmoid colon.

Medical Nutrition Therapy

Historically, it has been common in clinical practice to recommend avoidance of nuts, seeds, hulls, corn, and popcorn to prevent symptoms or complications of diverticular disease. However, newer studies have found no association between nut, corn, or popcorn consumption and diverticular bleeding (Feuerstein and Falchuk, 2016). In fact, an inverse relationship between nut and popcorn consumption and the risk of diverticulitis was demonstrated, suggesting a protective effect.

During an acute episode of diverticulitis or diverticular bleeding, oral intake is usually reduced until symptoms subside. Complicated cases may necessitate bowel rest and require PN. Once oral intake is resumed it is prudent to begin a low-fiber diet (10 to 15 g/day) as the diet is being advanced, followed by a gradual return to a high-fiber diet.

Although there is conflicting evidence regarding fiber intake and diverticular disease, in symptomatic uncomplicated diverticular disease (SUUD), increasing fiber did demonstrate a reduction in abdominal symptoms and prevention of acute diverticulitis (Carabotti et al, 2017). A high-fiber diet in combination with adequate hydration promotes soft, bulky stools that pass more swiftly and require less straining with defecation. Recommended intakes of dietary fiber, preferably from foods, are 25 g/day for adult women and 38 g/day for men.

Fiber intake should be increased gradually because it may cause bloating or gas. If a patient cannot or will not consume the necessary amount of fiber, methylcellulose or psyllium fiber supplements have been used with good results. A high-fiber diet, sometimes with fiber supplementation, is advocated in asymptomatic diverticulosis to reduce the likelihood of disease progression, prevent the recurrence of symptom episodes, and prevent acute diverticulitis. Adequate fluid intake should accompany the high fiber intake. A recent systematic review involving 11 (mostly uncontrolled) studies of probiotic use for the treatment of diverticular disease concluded that the evidence did not show a clear benefit (Lahner et al, 2016; Feuerstein and Falchuk, 2016).

Intestinal Polyps and Colorectal Cancer

In the United States, colorectal cancer (CRC) is the fourth most common cancer in adults and the second leading cause of cancer death. It is estimated that there were 140,250 new cases of CRC in 2018, and the incidence is more common in men than women and among those of African American descent (National Cancer Institute, 2018).

Etiology

About 85% of CRCs are considered to be sporadic, whereas about 15% are familial. Familial adenomatous polyposis (FAP) accounts for less than 1% of CRCs. It is a hereditary syndrome characterized by the

development of hundreds to thousands of polyps in the colon and rectum during the second decade of life. Almost all patients with FAP will develop CRC if they are not identified and treated at an early stage.

An evaluation of the association of major known risk factors for CRC with colorectal polyp risk by histology type, quantified the impact of lifestyle modifications on the prevention of polyps (Fu et al, 2012). Several lifestyle factors, including cigarette smoking, obesity, high intake of red meat, low intake of fiber, low intake of calcium, and low vitamin D levels were found to be independently associated with the risk of polyps. Additionally, use of nonsteroidal antiinflammatory drugs has shown to be protective. The risk of polyps increased progressively with an increasing number of these adverse lifestyle factors (Bostick, 2015; Fu et al, 2012).

Pathophysiology

Polyps are established precursors of CRCs and defined as a mass that arises from the surface of the intestinal epithelium and projects into the intestinal lumen. Factors that increase the risk of CRC include family history, chronic IBD, FAP, adenomatous polyps, and several dietary components. Patterns of dietary practices rather than specific nutrients may be more predictive of the risk of developing CRC.

Medical Management

The treatment of a colorectal polyp is removal, usually by colonoscopy. Large polyps often require surgery for complete removal, even if the presence of cancer is not confirmed before resection. Patients diagnosed with CRC may require moderate to significant interventions, including medications, radiation therapy, chemotherapy, surgery, and EN and/or PN support.

Medical Nutrition Therapy

Recommendations from national cancer organizations include sufficient exercise; weight maintenance or reduction; modest and balanced intake of lipids; adequate intake of fiber and optimal micronutrients from fruits, vegetables, legumes, and whole grains; and limited use of alcohol. Supplements are normally encouraged if the diet is not adequate in calories, protein, or micronutrients. The diet for cancer survivors typically follows these prevention guidelines (see Chapter 35).

NUTRITIONAL CONSEQUENCES OF INTESTINAL SURGERY

Small Bowel Resections and Short-Bowel Syndrome

Short-bowel syndrome (SBS) can be defined as inadequate absorptive capacity resulting from reduced length or decreased functional bowel after resection. A loss of 70% to 75% of small bowel usually results in SBS, defined as 100 to 120 cm of small bowel without a colon, or 50 cm of small bowel with the colon remaining. A more practical definition of SBS is the inability to maintain nutrition and hydration needs with normal fluid and food intake, regardless of bowel length, as adaptation to bowel resections can vary widely among those who have had them.

Patients with SBS often have complex fluid, electrolyte, and nutritional management issues. Consequences of SBS include malabsorption of micronutrients and macronutrients, frequent diarrhea, steatorrhea, dehydration, electrolyte imbalances, weight loss, and growth failure in children (Limketkai, 2017). Other complications include gastric hypersecretion, oxalate renal stones, and cholesterol gallstones. Individuals who eventually need long-term PN have increased risk of catheter infection, sepsis, cholestasis, and liver disease, and reduced quality of life associated with chronic intravenous nutrition support (DiBaise, 2014).

Etiology

The most common reasons for major resections of the intestine in adults include Crohn's disease, radiation enteritis, mesenteric infarct, malignant disease, and volvulus. In the pediatric population most cases of SBS result from congenital anomalies of the GI tract, atresia, volvulus, or necrotizing enterocolitis (Shatnawei et al, 2010).

Pathophysiology

Duodenal resection. Resection of the duodenum (approximately 10 to 15 inches) is rare, which is fortunate because it is the preferred site for absorption of key nutrients such as iron, zinc, copper, and folate. The duodenum is a key player in the digestion and absorption of nutrients, because it is the portal of entry for pancreatic enzymes and bile salts (see Chapter 1).

Jejunal resections. The jejunum (6 to 10 feet) is also responsible for a large portion of nutrient absorption. Normally most digestion and absorption of food and nutrients occurs in the first 100 cm of small intestine, which also includes the duodenum. Jejunal enterohormones play key roles in digestion and absorption. Cholecystokinin (CCK) stimulates pancreatic secretion and gallbladder contraction, and secretin stimulates secretion of bicarbonate from the pancreas. Gastric inhibitory peptide slows gastric secretion and gastric motility, whereas vasoactive inhibitory peptide inhibits gastric and bicarbonate secretion (see Chapter 1). What remains to be digested or fermented and absorbed are small amounts of sugars, resistant starch, lipids, dietary fiber, and fluids. After jejunal resections, the ileum typically adapts to perform the functions of the jejunum. The motility of the ileum is comparatively slow, and hormones secreted in the ileum and colon help to slow gastric emptying and secretions. Because jejunal resections result in reduced surface area and faster intestinal transit, the functional reserve for absorption of micronutrients, excess amounts of sugars (especially lactose), and lipids is reduced.

Ileal resections. Significant resections of the ileum, especially the distal ileum, produce major nutritional and medical complications. The distal ileum is the only site for absorption of bile salts and the vitamin B₁₂-intrinsic factor complex. The ileum also absorbs a major portion of the 7 to 10 L of fluid ingested and secreted into the GI tract daily (see Chapter 1). The ileocecal valve, at the junction of the ileum and cecum, maximizes nutrient absorption by controlling the rate of passage of ileal contents into the colon and preventing reflux of colonic bacteria, which may decrease risk for SIBO.

Although malabsorption of bile salts may appear to be benign, it creates a cascade of consequences. If the ileum cannot "recycle" bile salts secreted into the GI tract, hepatic production cannot maintain a sufficient bile salt pool or the secretions to emulsify lipids. The gastric and pancreatic lipases are capable of digesting some triglycerides to fatty acids and monoglycerides, but, without adequate micelle formation facilitated by bile salts, lipids are poorly absorbed. This can lead to malabsorption of fats and fat-soluble vitamins A, D, E, and K. In addition, malabsorption of fatty acids results in their combination with calcium, zinc, and magnesium to form fatty acid–mineral soaps, thus leading to their malabsorption as well. To compound matters, colonic absorption of oxalate is increased, leading to hyperoxaluria and increased frequency of renal oxalate stones. Relative dehydration and concentrated urine, which are common with ileal resections, further increase the risk of stone formation (see Chapter 34).

Colon Resections

The colon (approximately 5 ft long) is responsible for reabsorbing 1 to 1.5 L of electrolyte-rich (particularly sodium and chloride) fluid each day but is capable of adapting to increase this capacity to 5 to 6 L daily. Preservation of colon is key to maintaining hydration status.

However, if the patient has any colon left, malabsorption of bile salts can act as a mucosal irritant, increasing colonic motility with fluid and electrolyte losses. Consumption of high-fat diets with ileal resections and retained colon also may result in the formation of hydroxy fatty acids, which also increase fluid loss. Cholesterol gallstones occur because the ratio of bile acid, phospholipid, and cholesterol in biliary secretions is altered. Dependence on PN increases the risk of biliary “sludge,” secondary to decreased stimulus for evacuation of the biliary tract (see Chapters 12 and 28).

Medical and Surgical Management of Resections

The first step in management is assessment of the remaining bowel length from patient surgical and health records or interview. Assessment should quantify dietary intake, as well as stool and urine output, over 24 hours. Medications and hydration status should be assessed. Medications may be prescribed to slow GI motility, decrease secretions, increase absorption with the remaining bowel, or treat bacterial overgrowth. The primary “gut slowing” medications include loperamide and occasionally narcotic medications, such as tincture of opium and liquid codeine. Somatostatin and somatostatin analogs; growth hormone; and other hormones with antisecretory, antimotility, or trophic actions have been studied for use to slow motility and secretions. Further, glucagon-like peptide analog, Teduglutide, carries the unique ability to enhance absorptive capacity in an attempt to reduce or eliminate the need for PN (Kim and Keam, 2017). Surgical procedures such as creation of reservoirs (“pouches”) to serve as a form of colon, intestinal lengthening, and intestinal transplant have been performed to help patients with major GI resections. Intestinal transplant is very complex and is reserved for gut failure, or when patients develop significant complications from PN.

Medical Nutrition Therapy

Most patients who have significant bowel resections require PN initially to restore and maintain nutrition status. The duration of PN and subsequent nutrition therapy will be based on the extent of the bowel resection, the health of the patient, and the condition of the remaining GI tract. In general, older patients with major ileal resections, patients who have lost the ileocecal valve, and patients with residual disease in the remaining GI tract do not do as well. Enteral feeding provides a trophic stimulus to the GI tract; PN is used to restore and maintain nutrient status.

The more extreme and severe the problem, the slower the progression to a normal diet. Small, frequent mini meals (six to ten per day) are likely to be better tolerated than larger feedings. Tube feeding may be useful to maximize intake when a patient would not typically eat, such as during the night (see Chapter 12). Because of malnutrition and disuse of the GI tract, the digestive and absorptive functions of the remaining GI tract may be compromised, and malnutrition will delay postsurgical adaptation. The transition to more normal foods may take weeks to months, and some patients may never tolerate normal concentrations or volumes of foods and always require supplemental PN to maintain adequate fluid and nutritional status.

Maximum adaptation of the GI tract may take 1 to 2 years after surgery. Adaptation improves function, but it does not restore the intestine to normal length or capacity. Complex, intact nutrients (vs. elemental/ pre-digested formulas) are the most important stimuli of the GI tract. Other nutritional measures also have been studied as a means of hastening the adaptive process and decreasing malabsorption, but their evidence for use is limited. For example, the amino acid **glutamine** is the preferred fuel for small intestinal enterocytes and thus may be valuable in enhancing adaptation. Nucleotides (in the form of purines, pyrimidine, ribonucleic acid) also may enhance mucosal

adaptation, but unfortunately they are often lacking in parenteral and enteral nutritional products. SCFAs (e.g., butyrate, propionate, acetate), carbohydrate fermentation byproducts of commensal gut microbiota, are major fuels for the colonic epithelium.

Patients with jejunal resections and an intact ileum and colon will have a good chance of adapting quickly to a normal diet with a balance of protein, fat, and carbohydrate that is satisfactory. Six small feedings with avoidance of lactose, large amounts of concentrated sweets, and caffeine may help to reduce the risk of bloating, abdominal pain, and diarrhea. Because the typical American diet may be nutritionally lacking, and the intake of some micronutrients may be marginal, patients should be advised that the quality of the diet is of utmost importance. A multivitamin and mineral supplement may be required to meet nutritional needs.

Patients with ileal resections require increased time and patience in the advancement from PN to EN. Because of losses, fat-soluble vitamins, calcium, magnesium, and zinc may have to be supplemented. Dietary fat may have to be limited, especially in those with little remaining colon. Small amounts at each feeding are more likely to be tolerated and absorbed.

MCT products add to the caloric intake and serve as a vehicle for lipid-soluble nutrients. Because boluses of MCT oil (e.g., taken as a medication in tablespoon amounts) may add to the patient’s diarrhea, it is best to divide the doses equally in feedings throughout the day. Fluid and electrolytes, especially sodium, should be provided in small amounts and frequently.

In patients with SBS an oral diet or EN plus the use of gut-slowing medications should be maximized to prevent dependence on PN. Frequent meals, removal of osmotic medications and foods, use of oral hydration therapies, and other interventions should be pursued. In some cases, overfeeding in an attempt to compensate for malabsorption results in further malabsorption, not only of ingested foods and liquids but also of the significant amounts of GI fluids secreted in response to food ingestion. Patients with an extremely short bowel may depend on parenteral solutions for at least part of their nutrient and fluid supply. Small, frequent snacks provide some oral gratification for these patients, but typically they can supply only a portion of their fluid and nutrient needs (see Chapter 12 for discussion of home PN).

Small Intestine Bacterial Overgrowth

Small intestinal bacterial overgrowth (SIBO) is a syndrome characterized by overproliferation of bacteria normally found in the large intestine within the small intestine. In a normally functioning bowel, a number of physiologic processes limit the number of bacteria in the small intestine. Among these, gastric acid, bile, and pancreatic enzymes have bacteriostatic and bactericidal action within the small bowel. Normal intestinal peristalsis leads to bowel motility that effectively “sweeps” bacteria into the distal bowel. The ileocecal valve prevents retrograde migration of the large numbers of colonic bacteria into the small intestine. SIBO also has been referred to as “blind loop syndrome” because one cause of bacterial overgrowth can result from stasis of the intestinal tract as a result of obstructive disease, strictures, adhesions (scar tissue), radiation enteritis, or surgical procedures that leave a portion of bowel without normal flow (a blind loop or Roux limb).

Etiology

Frequently, more than one of the normal homeostatic defenses listed previously must be impaired before small intestine bacteria overproliferate to the point that symptoms develop. Chronic use of antibiotics or medications that suppress gastric acid allow more ingested bacteria to survive and pass into the small bowel. Liver diseases or chronic pancreatitis can decrease the production or flow into the bowel of bile and

pancreatic enzymes that control bacterial growth. Gastroparesis, narcotic medications, or bowel dysmotility disorders decrease peristalsis and can impair the ability to propel bacteria to the distal bowel. Surgical resection of the distal ileum and ileocecal valve can result in retrograde proliferation of colonic bacteria. Research also demonstrates that SIBO is a common problem for patients with IBS-D (diarrhea predominant) (Palmer et al, 2017).

Pathophysiology

Although symptoms vary depending on the amount and type of bacteria present in the small intestine, the most common symptoms of SIBO include gas, bloating, nausea, constipation, diarrhea, abdominal pain and discomfort (especially after eating), and weight loss. Bacteria within the small bowel also deconjugate bile salts, resulting in impaired formation of micelles and thus impaired fat digestion and steatorrhea. Carbohydrate malabsorption occurs because of injury to the brush border secondary to the toxic effects of bacterial products and consequent enzyme loss (Palmer et al, 2017). The expanding numbers of bacteria use the available vitamin B₁₂ and other nutrients for their own growth, and the host becomes deficient. Bacteria within the small bowel produce folate as a byproduct of their metabolism, and vitamin B₁₂ deficiency with normal or elevated serum folate is common. Bloating and distention also are reported frequently in SIBO, resulting from the action of bacteria on carbohydrates with production of hydrogen and methane within the small bowel.

D-lactic acidosis or D-lactate encephalopathy is a rare complication of SIBO in SBS patients with the colon in continuity and ileocecal valve removed. In these individuals, malabsorption of a large carbohydrate load can lead to excess carbohydrates being delivered to the bacteria in the colon. A lower colonic pH, induced by a large production of lactate and SCFAs, promotes growth of acid-resistant bacteria that go on to produce D-lactate. Because of the lack of D-lactate dehydrogenase, humans cannot metabolize D-lactate and symptoms of D-lactic acidosis develop. These can range from lethargy to altered mental status, ataxia, and slurred speech to aggression and coma (Htyte et al, 2011; White, 2015).

Medical Treatment

The most common pathway for medical diagnosis of SIBO is a lactulose breath test which measures levels of breath hydrogen and methane. Higher levels correlate with bacterial overgrowth in the small intestine (Rezaie et al, 2017; Palmer et al, 2017). A more invasive, small bowel aspirate and culture is the traditional gold standard. Testing for SIBO in patients with SBS may present more challenges. Some clinicians treat based on symptomatology reports in combination with preexisting risk factors. Treatment is directed toward control of the bacterial growth by administration of antibiotics or herbs or the use of an elemental diet. Historically, the most favored antibiotics have included rifaximin, metronidazole, ciprofloxacin, amoxicillin/clavulanate, or doxycycline. Treatment may involve cycling of several antibiotics until improvement of symptoms is observed (Rezaie et al, 2016). Unfortunately, recurrences can occur, warranting further treatment (Palmer et al, 2017). Typically, a 7- to 10-day course of antibiotics is successful, but some patients may require 1 to 2 months of treatment (Bohm et al, 2013). The antibiotic should be rotated to prevent bacterial resistance. There is some evidence that specific herbal preparations may be as beneficial as antibiotic therapies in the treatment of SIBO (Mullin, 2014). Research is ongoing with regard to pairing probiotics and antibiotic therapies.

Medical Nutrition Therapy

Dietary modification should target alleviation of symptoms and correction of nutrient deficiencies. With bacterial overgrowth in the small intestine, carbohydrates reaching the site where microbes are harbored

serve as fuel for their proliferation, with subsequent increased production of gases and organic acids. A low FODMAP diet (previously discussed in IBS section) has the most evidence for reducing GI symptoms in SIBO. If the patient exhibits more severe carbohydrate sensitivity, a more restrictive specific carbohydrate diet (SCD) or a combination of both could be tried. In extreme cases, medically supervised elemental diets may be recommended along with the antibiotics until remission is achieved. Close support and monitoring of a trained nutrition professional is always recommended as an adjunct to medical treatments as noted above. More information can be found at Monash University at <https://www.monash.edu>, <https://www.katescarlata.com>, and SIBO Center for Digestive Health at <https://sibocenter.com/category/sibo-diets/>.

An assessment of the medical problem and the patient's dietary intake is necessary, as vitamin B₁₂ may be lost in fermentation; the diet may lack key dietary nutrients; or the absence or removal of greater than 60 cm of the terminal ileum has occurred, putting the patient at risk for deficiencies. A routine intramuscular vitamin B₁₂ may be required. If bile salts are being degraded, as in the case of blind loop syndrome, MCTs may be helpful if they provide a source of lipid and energy. Deficiencies of fat-soluble vitamins A, D, and E are of concern if fat malabsorption is present, and a water miscible version of these critical fat-soluble nutrients should be considered.

Fistula

A **fistula** is an abnormal passage of an organ to another organ, skin, or wound. An **enterocutaneous fistula (ECF)** is an abnormal passage from a portion of the intestinal tract to the skin or to a wound (e.g., colocolic fistula between the large intestine and the skin).

Etiology

Fistulas may occur in any part of the GI tract but are most common in the small and large intestine. ECF can be classified several ways: by volume of output per day, cause (surgical vs. spontaneous), site of origin, and number of fistula tracts. Surgery accounts for the majority of ECF development and usually manifests 7 to 10 days postoperatively. Fistulas of the intestinal tract can be serious threats to nutrition status because large amounts of fluids and electrolytes are lost, and malabsorption and sepsis can occur. Box 27.11 lists conditions associated with fistula development.

Medical Treatment

Wound care, resuscitation, source control, and the use of nutrition support during the healing phase are the primary approaches for

BOX 27.11 Conditions Associated With Fistula Development

- Bowel resection for cancer
- Bowel resection for inflammatory bowel disease
- Surgery for pancreatitis
- Surgery on radiated bowel
- Emergent surgery
- Surgical wound dehiscence
- Inflammatory bowel disease (Crohn's disease or ulcerative colitis)
- Radiation enteritis
- Bowel ischemia
- Diverticular disease

Data from Frantz D et al: Gastrointestinal disease. In Mueller CM et al, editors: *The ASPEN Adult Nutrition Support Core Curriculum*, ed 2, Silver Spring, Md, 2012, American Society for Parenteral and Enteral Nutrition.

medical treatment (Bhutiani et al, 2017). A fistulogram is considered the gold standard for identifying the location and route of the fistulous tract. Fluid and electrolyte balance must be restored, infection must be brought under control, and aggressive nutrition support may be necessary to permit spontaneous closure or to maintain optimal nutritional status before surgical closure.

Medical Nutrition Therapy

Nutrition management of patients with ECF can be very challenging. Initial management may include keeping the patient *nil per os* (NPO) as fistula output is quantified and administering nutritional support during the initial workup phase. PN, EN, oral diet, or a combination is used in patients with ECF. The decision regarding which route to feed patients with ECF depends on several factors, including the origin of the fistula, the presence of obstructions or abscesses, the length of functional bowel, the likelihood of fistula closure, the ability to manage fistula output, and the patient's overall medical condition (see Chapter 12).

Intestinal Ostomies

The word **ostomy**, derived from the Latin word *ostium*, refers to mouth or opening. An **intestinal ostomy** is a surgically created opening between the intestinal tract and the skin and is specifically named according to the site of origin along the intestinal tract. About 100,000 people in the United States undergo operations that result in a colostomy or ileostomy each year (Sheetz et al, 2014). The high incidence of ostomy is due in part to the increasing prevalence of CRC and diverticular surgeries in the United States. Ostomies are created for many reasons; Table 27.7 lists indications for the creation of ostomies.

Colostomies and ileostomies can be categorized as either loop or end ostomies. A **loop ostomy** is formed when a loop of bowel is brought up to the skin, and an incision is made on one side. The distal end is sutured to the skin, whereas the proximal side of the loop is everted back on itself (Martin and Vogel, 2012). The result is a stoma with two openings: the proximal (functional) limb from which the effluent or stool is discharged, and the distal limb, which may connect to the anus and secrete mucus. A loop ostomy is used most often when a

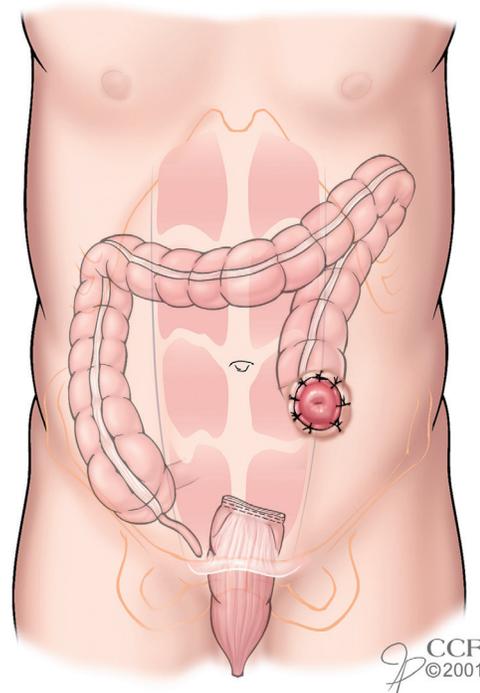

Fig. 27.6 Colostomy. (Cleveland Clinic, Cleveland, Ohio, USA.)

temporary ostomy is formed. An **end ostomy** is created when the bowel is cut and the end is brought through the skin to create the stoma. End and loop ostomies are potentially reversible. The output from an ileostomy is termed effluent, whereas output from a colostomy is stool.

Colostomy

A **colostomy** is a surgically created opening from the colon to the skin when a portion of the large intestine is removed or bypassed (Fig. 27.6). It can originate from any part of the colon: ascending, transverse, descending, or sigmoid. It typically starts functioning 2 to 5 days after surgery and the amount and type of output varies slightly, depending on the amount of remaining colon. Stool from a colostomy on the left side of the colon is firmer than that from a colostomy on the right side, with stool output ranging from 200 to 600 mL/day. Patients with sigmoid colostomies have elimination patterns similar to their preoperative states, usually one to two soft stools daily.

Ileostomy

An **ileostomy** is a surgically created opening from the distal small bowel (most often the terminal ileum) to the skin when the entire colon, rectum, and anus are removed or bypassed (Fig. 27.7). Typically, a new ileostomy will start functioning within 24 hours after surgery, and the effluent is initially bilious in color and watery (Willcutts and Touger-Decker, 2013). Stoma output increases initially to about 1200 mL per 24 hours for the first 1 to 2 weeks. As the bowel adapts over the next 2 to 3 months, the effluent thickens (semiliquid to porridge-like consistency) and output drops to less than a liter per day.

Medical Management

Management of a new ostomy patient involves maintenance of nutritional and hydration status, meticulous skin care, and adequate

TABLE 27.7 Potential Indications for Creation of Intestinal Ostomy

Ileostomy	Colostomy
Crohn's disease	Colon cancer
Ulcerative colitis	Rectal cancer
FAP	Diverticulitis
Colon cancer	Rectal trauma
Rectal cancer	Radiation proctitis
Bowel perforation	Distal obstruction
Bowel ischemia	Fecal incontinence
Rectal trauma	Complex fistula

containment of the fecal stream using a pouching system in the hospital and as the patient transitions to home (McDonough, 2013). It is very helpful when a patient is evaluated by an enterostomal therapist (a nurse who specializes in the care of stomas) before surgery to mark the most appropriate site for an ostomy. This minimizes potential skin and pouch system problems. A poorly constructed ostomy can cause skin excoriation and difficulty with pouch application and may significantly affect patient quality of life (QoL). A well-functioning ostomy is associated with a superior QoL. In those patients who express concerns regarding suboptimal QoL, social restrictions, psychosexual issues, and fear of the ostomy appliance leaking seem to be the major limiting factors (Charua-Guindic et al, 2011).

Medical Nutrition Therapy

Traditional recommendations for postoperative feeding of patients with either a colostomy or ileostomy was to hold feeding until the bowel started to “function” or put out stool or effluent. However, there is evidence that an oral diet or tube feeding can start early after surgery for any type of fecal diversion stoma that was created during an elective surgery. The AND and the United Ostomy Associations of America recommend a low-fiber diet for approximately 6 to 8 weeks after surgery (AND, 2014; United Ostomy Associations of America, 2011). This advice is based on the premise that the bowel is edematous and therefore at risk for being damaged and or becoming obstructed after surgery. Most patients transition to a normal diet with a gradual increase in dietary fiber intake after 6 weeks.

Vitamin B₁₂ and bile salts or fat malabsorption are normally not a concern with a distal ileostomy. Greater than 100 cm of ileum must be resected before steatorrhea or fat-soluble vitamin deficiency occurs, and greater than 60 cm must be resected before vitamin B₁₂ absorption is compromised (Parrish and DiBaise, 2014).

Controlling flatus and odor is a common concern for the colostomy patient rather than for a patient with an ileostomy. Many patients

elect to limit foods that have the potential to increase flatus or cause increased odor of stool output. A patient must experiment with how different foods affect output. Deodorants are available, and ostomy appliances are made with odor-barrier material and can include charcoal filters that vent and deodorize gas.

Another concern for an ileostomy is the potential for intestinal blockage or obstruction at the stoma site resulting from narrowing of the intestinal lumen at the point where the ileum is brought through the abdominal wall. Patients are instructed to chew their food very well to reduce the chance of blockage. Ileostomy patients with higher volumes of watery effluent are encouraged to incorporate thickening foods to help thicken stoma output. The patient may have to experiment because thickened output may be desirable at times but can cause discomfort if output is thickened too much. Refer to Table 27.8 for the effects of various foods on ostomy output.

TABLE 27.8 Foods That Affect Ostomy Output

Gas-Forming Foods	Odor-Producing Foods	Foods That May Control Odor
Broccoli	Asparagus	Buttermilk
Brussels sprouts	Beans	Cranberry juice
Cabbage	Broccoli	Orange juice
Cauliflower	Brussels sprouts	Yogurt
Garlic	Cabbage	Parsley
Onions	Cauliflower	Spinach
Fish	Garlic	Tomato juice
Eggs	Onions	
Carbonated beverages	Fish	
Alcoholic beverages	Eggs	
Dairy products	Some vitamins	
Legumes (dried beans)	Strong cheese	
Chewing gum		
Foods That May Thicken Stool	Foods That May Cause Obstruction	Foods That May Cause Diarrhea
Pasta	Apple peel	Alcoholic beverages
White bread	Orange	Caffeinated fluids
White rice	Pineapple	Chocolate
Potatoes	Grapes	Whole grains
Cheese	Dried fruits	Bran cereals
Pretzels	Raw cabbage	Fresh fruits
Creamy peanut butter	Raw celery	Grape juice
Applesauce	Chinese vegetables	Prune juice
Banana	Corn	Raw vegetables
Marshmallow	Mushrooms	Spicy foods
Tapioca	Coconut	Fried foods
	Popcorn	High-fat foods
	Nuts	Foods high in refined sugar or sorbitol

McDonough MR: A dietitian's guide to colostomies and ileostomies, *Support Line* 35(3):3, 2013; United Ostomy Associations of America: Diet and Nutrition Guide (website): http://www.ostomy.org/ostomy_info/pubs/OstomyNutritionGuide.pdf, 2011; Willcutts K et al: Ostomies and fistulas: a collaborative approach, *Pract Gastroenterol* 29:63, 2005.

Maintenance of adequate fluid and electrolyte status is an important nutrition-related issue in managing a patient with colostomy or ileostomy. Patients with an ileostomy must recognize the symptoms of dehydration and understand the importance of maintaining adequate fluid intake throughout the day. In addition, patients may have to increase their salt, potassium, and magnesium intake resulting from losses in ileostomy output.

Ostomy output may become acutely or chronically elevated, and this is much more common with an ileostomy. The generally accepted definition of a **high-output stoma (HOS)** is output that exceeds 2000 mL/day over 3 consecutive days, at which point water, sodium, and magnesium depletion are expected (Baker et al, 2011). There are multiple potential causes of HOS, including IBD, *Clostridium difficile*, intraabdominal sepsis, partial or intermittent obstruction, medication-related causes, drinking too much fluid (especially hypertonic/hyposmotic fluids), or surgery that results in less than 200 cm of residual small bowel and no colon (Parrish and DiBaise, 2014).

Management of HOS includes assessment and correction of depleted electrolytes and minerals; initiation of an ORS sipped throughout the day; avoidance of hypertonic, simple sugar-containing liquids and foods; restriction of foods high in insoluble fiber; separation of solids and liquids at meals; and consumption of smaller meals, more often (up to six to eight per day) (McDonough, 2013; Parrish and DiBaise, 2014). Malnutrition can occur in cases of persistent HOS, and many patients must increase their intake to maintain their nutritional status. Meeting the increased nutritional demand may not be possible via oral means for some patients, and nutrition support via enteral tube feeding may become necessary. Antidiarrheal and antisecretory medications are the two major classes of medications recommended to reduce output in HOS.

Restorative Proctocolectomy with Ileal Pouch Anal Anastomosis

Restorative **proctocolectomy** with **ileal pouch anal anastomosis (IPAA)** has evolved as the surgical treatment of choice for patients with medically refractory UC and FAP. For UC patients requiring a colectomy, the majority elect to have an IPAA. This procedure involves removal of the entire colon and rectum (proctocolectomy) while preserving the anal sphincter, followed by creation of a reservoir using a portion of the distal ileum (ileal pouch). This pouch is then reconnected (pouch-anal anastomosis) to the preserved anal canal in which the diseased mucosa has been removed, thus maintaining continence and voluntary function. This offers a cure for the disease processes and avoids a permanent ileostomy.

Construction usually requires use of the distalmost 30 to 40 cm of ileum, with pouch configuration determined by the number of bowel limbs used. The most common pouch is the **ileal J-pouch**, which uses two limbs of bowel (Fig. 27.8) to create a “J”-shaped reservoir out of the patient’s own small intestine. It is the preferred ileal pouch because of the efficiency of construction and optimal functional results by allowing a more normal route of defecation. Alternatives to the J-pouch configuration include three- and four-limbed pouches, such as an **S-pouch** or **W-pouch**. These alternative configurations are rarely performed because of the complexity of construction. The final decision as to which type is used remains at the discretion of the surgeon.

With any pouch surgery the recovery is longer than in those who have a conventional ileostomy because of the two-stage procedure. There will be a period of adaptation of the new reservoir after the ileostomy is closed. Initially, there could be up to 15 bowel movements a

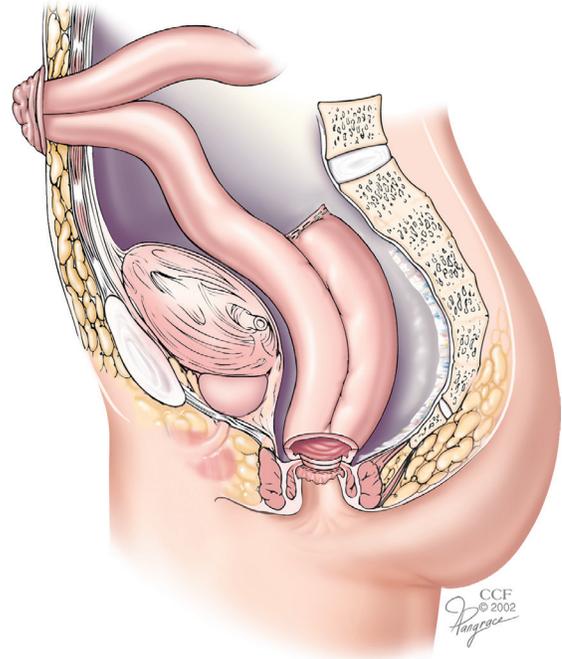

Fig. 27.8 J-pouch. (Cleveland Clinic, Cleveland, Ohio, USA.)

day with some problems of control and the need to get up several times at night. Eventually, most patients experience four to six bowel movements daily, have good control, and are not troubled by nighttime incontinence. This improves over time as the pouch capacity gradually increases.

A **Koch pouch** is a type of appliance-less ileostomy that uses an internal reservoir with a one-way valve, constructed from a loop of intestine that is attached to the abdominal wall with a skin-level stoma. Patients must insert a tube or catheter into the stoma to open the valve and allow drainage of the ileostomy contents. The technical difficulties of surgical construction and the potential for complications has led to decreased use of the Koch pouch in favor of the ileal J-pouch.

Medical Management

Acute and chronic complications can necessitate removal of the ileal pouch and eventual construction of a permanent ileostomy. **Pouchitis** is a nonspecific inflammation of the mucosal tissue forming the ileal pouch and is the most frequent long-term complication of IPAA in patients with UC. The cause of pouchitis is not entirely clear, but it may be related to bacterial overgrowth, unrecognized Crohn’s disease, immunologic changes, bile salt malabsorption, or insufficient SCFA production. The usual presenting symptoms include increased stool frequency, urgency, incontinence, nocturnal seepage, abdominal cramps, and pelvic discomfort. Pouchitis may be classified based on the cause, disease duration and activity, and response to medical therapy. In the majority of patients the etiology of pouchitis is not clear and thus termed as idiopathic pouchitis (Zezos and Saibil, 2015).

Pouch endoscopy is the main modality in the diagnosis and differential diagnosis in patients with pouch dysfunction. Antibiotic therapy is the mainstay of treatment for active pouchitis. Some patients may develop dependency on antibiotics, requiring long-term maintenance therapy. The evidence for the use of probiotics in maintenance treatment of pouchitis is controversial. There may be roles for

postoperative probiotic supplementation to prevent pouchitis and in maintaining remission in antibiotic-dependent pouchitis (Shen et al, 2014). Clinical expert-generated guidelines concur that the probiotic called VSL#3 can be effective for preventing recurrence of pouchitis (Ciorba, 2012; Shen et al, 2014).

Medical Nutrition Therapy

Patients who have undergone an IPAA procedure usually require supplemental vitamin B₁₂ injections. The cause of vitamin B₁₂ deficiency may be multifactorial: (1) reduced absorptive capacity due to distal ileal resection (main site of vitamin B₁₂ absorption); (2) bacterial overgrowth is a well-known phenomenon in patients with an ileal pouch, and anaerobic bacteria can bind vitamin B₁₂ in its free and intrinsic forms, leading to a decreased concentration available for absorption; and (3) insufficient B₁₂ intake. The anemia experienced by patients after IPAA can also be due to iron deficiency because of impaired

absorption, decreased oral intake, increased requirements, and blood loss.

Patients with a pouch often describe specific food sensitivities that may require diet alteration, even more so than do patients with permanent ileostomy (United Ostomy Associations of America, 2011). Problems often reported include obstructive symptoms and increased stool output, frequency, and gas. The incidence of obstruction may be avoided by limiting insoluble fibers, chewing thoroughly, and consuming small meals frequently throughout the day. Patients may try to experiment with timing of meals by eating larger meals earlier in the day and limiting the amount of food and fluid intake toward the end of the day to minimize sleep interruptions. The same dietary measures that are used to reduce excessive stool output (reduced caffeine, lactose avoidance if lactase-deficient, and limitation of foods high in simple sugars, fructose, and sorbitol) will likely reduce stool volume and frequency in patients with IPAA.

CLINICAL CASE STUDY

Jimmy is a 76-year-old male with a recent emergent small bowel resection due to a ruptured mesh hernia causing traumatic injury to his small intestine. He had a difficult postoperative course complicated by *Clostridium difficile* infection, clinically involuntary weight loss, diarrhea, and dehydration. At his readmission for *C. difficile* infection, a nutrition consult was received for management of diarrhea and hydration status, and to assess for any nutrient malabsorption.

Nutrition Assessment

- Anatomy: During surgery, 100 cm of the small intestine was removed, including the ileocecal valve (ICV). The majority of the colon remains intact.
- Oral intake history: Decline in appetite and oral intake since surgery due to very poor appetite and diarrhea. Before admission Jimmy was eating ¼ of his usual meals with ½ of the usual snacks and taking one oral nutrition supplement per day. Fluids: drinks coffee, iced tea, and water, and estimates he is taking in 3 to 4 cups per day.
- Current intake: In the hospital, Jimmy is eating 50% of meals provided, tolerating snacks, and sipping up to 500 mL of commercial electrolyte beverage per day. He reports never feeling hungry, is apathetic about eating, and reports not wanting to “overdo it” for fear of more bathroom trips.
- Weight and body mass index (BMI): Height: 177.8 cm (70 inches), Weight: 75 kg (165 lb), BMI: 23.7 kg/m²
- Usual body weight (UBW): 100 kg (220 lb): 25% weight loss × 3 months (clinically significant loss)
- Physical examination: pale skin; dark eye sockets; slight depression at temples; scapula pronounced; noted losses at quadriceps, gastrocnemius, and triceps; no edema noted
- Functional capacity: low energy level over past 3 months, unable to garden or cook meals, which he previously enjoyed, fatigued and tired all the time, memory slightly decreased
- Medications: started loperamide 2 mg before meals and bedtime, senior multivitamin, potassium chloride (KCl) sustained-release tablet, lisinopril dose reduced due to weight loss, statin discontinued due to cholesterol levels normalized within a few months of surgery
- 24-hour urine and stool output: 650 mL and 2200 mL
- Pertinent labs: high serum sodium (147), low serum potassium (3.0 mEq/L), low normal serum magnesium (1.3), high blood urea nitrogen (BUN): 7.6 mmol/L, stool toxin analysis for *C difficile*: positive
- Current diet: General diet

Nutrition Diagnostic Statements

- Severe protein calorie malnutrition related to poor appetite as evidenced by energy intake 25% to 50% × 3 months, involuntary weight loss at 25% × 3 months,

subcutaneous fat loss, muscle loss, and decline in strength and functional capacity

- Suboptimal protein-energy intake related to altered gastrointestinal (GI) function as evidenced by diarrhea, involuntary weight loss at 25% × 3 months, UBW 220 lbs

Interventions

- Estimated energy needs: 2625 to 3000 calories/day (35 to 40 kcal/kg/day)
- Estimated protein needs: 115 to 150 g protein/day (1.5 to 2.0 g protein/kg/day)
- Nutrition goal(s): Oral intake to meet estimated needs, decrease stool output to the point where patient's hydration is maintained; maintain optimal micronutrient status.
- Replace electrolyte and fluid losses. Monitor fluid balance.
- Continue general diet with moderate insoluble fiber until diarrhea is under control, reduce simple sugars in the diet. Patient to make high-salt, high-starch, low-simple sugar food choices from the menu. Encourage separation of beverages at mealtimes.
- Provide salty/starchy snacks between meals. Encourage “thickening foods,” such as boiled white rice, pasta, noodles, bread, potatoes, banana, oatmeal, applesauce, peanut butter, cheese, and tapioca pudding.
- Sip 2 L of oral rehydration solution (ORS) between meals as an alternative to commercial electrolyte beverage.
- Avoid caffeinated and hypertonic fluids.
- Consider trial of soluble fiber supplement to slow down transit time and thicken stool.
- Continue antiarrheal medications with dosage adjusted by physician depending on volume and consistency of stool.
- Diet education: Discuss with patient and family nutrition management of micronutrient status, including intake of water-miscible versions of fat-soluble vitamins, and vitamin B₁₂ shots monthly, and maintaining adequate weight and hydration status with changed bowel length.
- Recommend outpatient follow up with nutrition professional specializing in GI nutrition.
- Evaluate micronutrient status.

Monitoring and Evaluation

- Monitor oral intake via calorie counts with a goal of meeting 75% to 100% of estimated energy and protein needs.
- Monitor stool and urinary output and weight trends to assess need for home intravenous fluids (HIVF) or home parenteral nutrition (HPN) if weight and fluid status do not stabilize with increased intake and ORS.

Medical Nutrition Therapy for Hepatobiliary and Pancreatic Disorders

Jeanette M. Hasse, PhD, RDN, LD, CNSC, FADA
Laura E. Matarese, PhD, RDN, LDN, CNSC, FADA, FASPEN, FAND

KEY TERMS

acalculous cholecystitis	fasting hypoglycemia	pancreaticoduodenectomy (Whipple procedure)
alcoholic liver disease	fatty liver	pancreatic islet autotransplantation
aromatic amino acids (AAAs)	fulminant liver disease	pancreatitis
ascites	hemochromatosis	paracentesis
bile	hepatic encephalopathy	portal hypertension
branched-chain amino acids (BCAAs)	hepatic failure	portal systemic encephalopathy
calculi	hepatic osteodystrophy	postcholecystectomy syndrome
cholangitis	hepatic steatosis	primary biliary cirrhosis (PBC)
cholecystectomy	hepatitis	primary sclerosing cholangitis (PSC)
cholecystitis	hepatorenal syndrome	secondary biliary cirrhosis
choledocholithiasis	icteric	steatorrhea
cholelithiasis	jaundice	transamination
cholestasis	Kayser-Fleischer ring	varices
cirrhosis	Kupffer cells	Wernicke encephalopathy
detoxification	nonalcoholic fatty liver disease	Wilson's disease
dry weight	(NAFLD)	
encephalopathy	nonalcoholic steatohepatitis (NASH)	
end stage liver disease (ESLD)	oxidative deamination	

The liver is of primary importance; one cannot survive without a liver. The liver and pancreas are essential to digestion and metabolism. Although it is important, the gallbladder can be removed, and the body will adapt comfortably to its absence. Knowledge of the structure and functions of these organs is vital. When they are diseased, the necessary medical nutrition therapy (MNT) is complex.

PHYSIOLOGY AND FUNCTIONS OF THE LIVER

Structure

The liver is the largest gland in the body, weighing approximately 1500 g. The liver has two main lobes: the right and left. The right lobe is further divided into the anterior and posterior segments; the right segmental fissure, which cannot be seen externally, separates the segments. The externally visible falciform ligament divides the left lobe into the medial and lateral segments. The liver is supplied with blood from two sources: the hepatic artery, which supplies approximately one third of the blood from the aorta; and the portal vein, which supplies the other two thirds and collects blood drained from the digestive tract.

Approximately 1500 mL of blood per minute circulates through the liver and exits via the right and left hepatic veins into the inferior vena cava. The liver has a system of blood vessels and a series of bile ducts.

Bile, which is formed in the liver cells, exits the liver through a series of bile ducts that increase in size as they approach the common bile duct. Bile is a thick, viscous fluid secreted from the liver, stored in the gallbladder, and released into the duodenum when fatty foods enter the duodenum. It emulsifies fats in the intestine and forms compounds with fatty acids to facilitate their absorption.

Functions

The liver has the ability to regenerate itself. Only 10% to 20% of functioning liver is required to sustain life, although removal of the liver results in death, usually within 24 hours. The liver is integral to most metabolic functions of the body and performs more than 500 tasks. The main functions of the liver include (1) metabolism of carbohydrate, protein, and fat; (2) storage and activation of vitamins and minerals; (3) formation and excretion of bile; (4) conversion of ammonia to urea; (5) metabolism of steroid hormones; (6) detoxification of substances such as drugs, alcohol, and organic compounds; and (7) acting as a filter and flood chamber.

The liver plays a major role in carbohydrate metabolism. Galactose and fructose, products of carbohydrate digestion, are converted into glucose in the hepatocyte (liver cell). The liver stores glucose as glycogen (glycogenesis) and then returns it to the blood when glucose levels

become low (glycogenolysis). The liver also produces “new” glucose (gluconeogenesis) from precursors such as lactic acid, glycogenic amino acids, and intermediates of the tricarboxylic acid (TCA) cycle.

Important protein metabolic pathways occur in the liver. **Transamination** (transfer of an amino group from one compound to another) and **oxidative deamination** (removal of an amino group from an amino acid or other compound) are two such pathways that convert amino acids to substrates that are used in energy and glucose production as well as in the synthesis of nonessential amino acids. Blood-clotting factors such as fibrinogen and prothrombin, as well as serum proteins including albumin, alpha-globulin, beta-globulin, transferrin, ceruloplasmin, and lipoproteins, are formed by the liver.

Fatty acids from the diet and adipose tissue are converted in the liver to acetyl-coenzyme A by the process of beta-oxidation to produce energy. Ketones also are produced. The liver synthesizes and hydrolyzes triglycerides, phospholipids, cholesterol, and lipoproteins as well.

The liver is involved in the storage, activation, and transport of many vitamins and minerals. It stores all the fat-soluble vitamins in addition to vitamin B₁₂ and the minerals zinc, iron, copper, and manganese. Hepatically synthesized proteins transport vitamin A (retinol binding protein), iron (transferrin), zinc (metallothionein), and copper (ceruloplasmin) in the bloodstream. Carotene is converted to vitamin A, folate to 5-methyl tetrahydrofolic acid, and vitamin D to an active form (25-hydroxycholecalciferol, calcitriol) by the liver.

In addition to functions of nutrient metabolism and storage, the liver forms and excretes bile. Bile salts are metabolized and used for the digestion and absorption of fats and fat-soluble vitamins. Bilirubin is a metabolic end product from red blood cell destruction; it is conjugated and excreted in the bile.

Hepatocytes detoxify ammonia by converting it to urea, 75% of which is excreted by the kidneys. The remaining urea finds its way back to the gastrointestinal tract (GIT). The liver also metabolizes steroid hormones. It inactivates and excretes aldosterone, glucocorticoids, estrogen, progesterone, and testosterone. It is responsible for the **detoxification** of substances, including drugs and alcohol, as well as toxins such as pollutants, chemicals, pesticides and herbicides, bioactive compounds, and biological poisons such as those from toxic mushrooms. Finally, the liver acts as a filter and flood chamber by removing bacteria and debris from blood through the phagocytic action of specialized macrophages called **Kupffer cells** located in the sinusoids and by storing blood backed up from the vena cava as in right heart failure.

Assessment of Liver Function

Biochemical markers are used to evaluate and monitor patients having or suspected of having liver disease. Enzyme assays measure the release of liver enzymes, and other tests measure liver function. Screening tests for hepatobiliary disease include serum levels of bilirubin, alkaline phosphatase (Alk Phos), aspartate amino transferase (AST), and alanine aminotransferase (ALT). [Table 28.1](#) elaborates common laboratory tests for liver disorders (see also Appendix 12).

TABLE 28.1 Common Laboratory Tests Used to Test Liver Function

Laboratory Test	Comment
Hepatic Excretion	
Total serum bilirubin	When increased, may indicate bilirubin overproduction or impaired hepatic uptake, conjugation, or excretion
Indirect serum bilirubin	Unconjugated bilirubin; increased with excessive bilirubin production (hemolysis), immaturity of enzyme systems, inherited defects, drug effects
Direct serum bilirubin	Conjugated bilirubin; increased with depressed bilirubin excretion, hepatobiliary disease, intrahepatic or benign postoperative jaundice and sepsis, and congenital conjugated hyperbilirubinemia
Cholestasis	
Serum alkaline phosphatase	Enzyme widely distributed in liver, bone, placenta, intestine, kidney, leukocytes; mainly bound to canalicular membranes in liver; increased levels suggest cholestasis but can be increased with bone disorders, pregnancy, normal growth, and some malignancies
γ-Glutamyl transpeptidase (GGT)	Enzyme found in high concentrations in epithelial cells lining bile ductules in the liver; also present in kidney, pancreas, heart, brain; increased with liver disease, but also after myocardial infarction, in neuromuscular disease, pancreatic disease, pulmonary disease, diabetes mellitus, and during alcohol ingestion
Hepatic Serum Enzymes	
Alanine aminotransferase (ALT, formerly SGPT, serum glutamic pyruvic transaminase)	Located in cytosol of hepatocyte; found in several other body tissues but highest in liver; increased with liver cell damage
Aspartate aminotransferase (AST, formerly SGOT, serum glutamic oxaloacetic transaminase)	Located in cytosol and mitochondria of hepatocyte; also in cardiac and skeletal muscle, heart, brain, pancreas, kidney; increased with liver cell damage
Serum lactic dehydrogenase	Located in liver, red blood cells, cardiac muscle, kidney; increased with liver disease but lacks sensitivity and specificity because it is found in most other body tissues
Serum Proteins	
Prothrombin time (PT)	Most blood coagulation factors are synthesized in the liver; vitamin K deficiency and decreased synthesis of clotting factors increase prothrombin time and risk of bleeding
International Normalized Ratio (INR)	A standardized way to report PT levels so that levels from different laboratories can be compared

TABLE 28.1 Common Laboratory Tests Used to Test Liver Function—cont'd

Laboratory Test	Comment
Serum albumin	Main export protein synthesized in the liver and most important factor in maintaining plasma oncotic pressure; hypoalbuminemia can result from expanded plasma volume or reduced synthesis as well as increased losses as occurs with protein-losing enteropathy, nephrotic syndrome, burns, gastrointestinal bleeding, exfoliative dermatitis
Serum globulin	Alpha ₁ and alpha ₂ -globulins are synthesized in the liver; levels increase with chronic liver disease; limited diagnostic use in hepatobiliary disease, although the pattern may suggest underlying cause of liver disease (e.g., elevated immunoglobulin [Ig]G suggests autoimmune hepatitis, elevated IgM suggests primary biliary cirrhosis, elevated IgA suggests alcoholic liver disease)
Markers of Specific Liver Diseases	
Serum ferritin	Major iron storage protein; increased level sensitive indicator of genetic hemochromatosis
Ceruloplasmin	Major copper-binding protein synthesized by liver; decreased in Wilson's disease
Alpha-fetoprotein	Major circulating plasma protein; increased with hepatocellular carcinoma
Alpha ₁ -antitrypsin	Main function is to inhibit serum trypsin activity; decreased levels indicate alpha ₁ -antitrypsin deficiency, which can cause liver and lung damage
Markers for Viral Hepatitis	
Anti-HAV IgM (antibody to hepatitis A virus)	Marker for hepatitis A; indicates current or recent infection or convalescence
HBsAg (hepatitis B surface antigen)	Marker for hepatitis B; positive in most cases of acute or chronic infection
Anti-HBc (antibody to hepatitis B core antigen)	Antibody to hepatitis B core antigen; marker for hepatitis B; denotes recent or past hepatitis infection
Anti-HBs (antibody to hepatitis B surface antigen)	Antibody to HBsAg; marker for hepatitis B; denotes prior hepatitis B infection or hepatitis B vaccine; protective
HBeAg (hepatitis Be antigen)	Marker for hepatitis B; transiently positive during active virus replication; reflects concentration and infectivity of virus
Anti-HBe (antibody to hepatitis Be antigen)	Marker for hepatitis B; positive in all acute and chronic cases; positive in carriers; not protective
HBV-DNA (hepatitis B deoxyribonucleic acid)	Measures hepatitis B viral load
Anti-HCV (antibody to hepatitis C virus)	Marker for hepatitis C; positive 5-6 weeks after onset of hepatitis C virus; not protective; reflects infectious state and is detectable during and after treatment
HCV-RNA (hepatitis C virus ribonucleic acid)	Measures hepatitis C viral load
Anti-HDV	Marker for hepatitis D; indicates infection; not protective
Miscellaneous	
Ammonia	Liver converts ammonia to urea; may increase with hepatic failure and portal-systemic shunts

Data from Wedemeyer H, Pawlotsky JM: Acute viral hepatitis. In Goldman L et al, editors: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Elsevier Saunders. Pawlotsky JM, Mchuthinson J: Chronic viral and autoimmune hepatitis. In Goldman L et al, editors: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Elsevier Saunders. Woreta TA, Alqahtani SA: Evaluation of abnormal liver tests, *Med Clin North Am* 98:1, 2014. Martin P, Friedman LS: Assessment of liver function and diagnostic studies. In Gines P et al, editors: *Clinical gastroenterology: chronic liver failure*, New York, 2011, Springer.

Physical examination as well as diagnostic procedures (e.g., endoscopy) or abdominal imaging tests (e.g., abdominal ultrasound, magnetic resonance imaging, or computed tomography scan) can be used to diagnose or evaluate patients for liver disease. A liver biopsy is considered the gold standard to assess the severity of hepatic inflammation and fibrosis (scar tissue).

DISEASES OF THE LIVER

Diseases of the liver can be acute or chronic, inherited or acquired. The following section provides a brief overview of viral hepatitis, nonalcoholic fatty liver disease (NAFLD), alcoholic liver disease, cholestatic liver diseases, inherited disorders, and other liver diseases.

Viral Hepatitis

Viral hepatitis is a widespread inflammation of the liver and is caused by various hepatitis viruses, including A, B, C, D, and E (Fig. 28.1 and Table 28.2). Hepatitis A and E are the infectious forms, mainly spread by fecal-oral route. Hepatitis B, C, and D exist in the serum and are spread by blood and body fluids (Pawlotsky, 2016). Infectious agents such as Epstein-Barr virus, cytomegalovirus, and herpes simplex virus also can cause an acute hepatitis.

The clinical manifestations of acute viral hepatitis are divided into four phases. The first phase, the incubation phase, often is characterized by nonspecific symptoms such as malaise, loss of appetite, nausea, and right upper quadrant pain (Pawlotsky, 2016). This is followed by the preicteric phase, in which the nonspecific symptoms continue. In addition, about

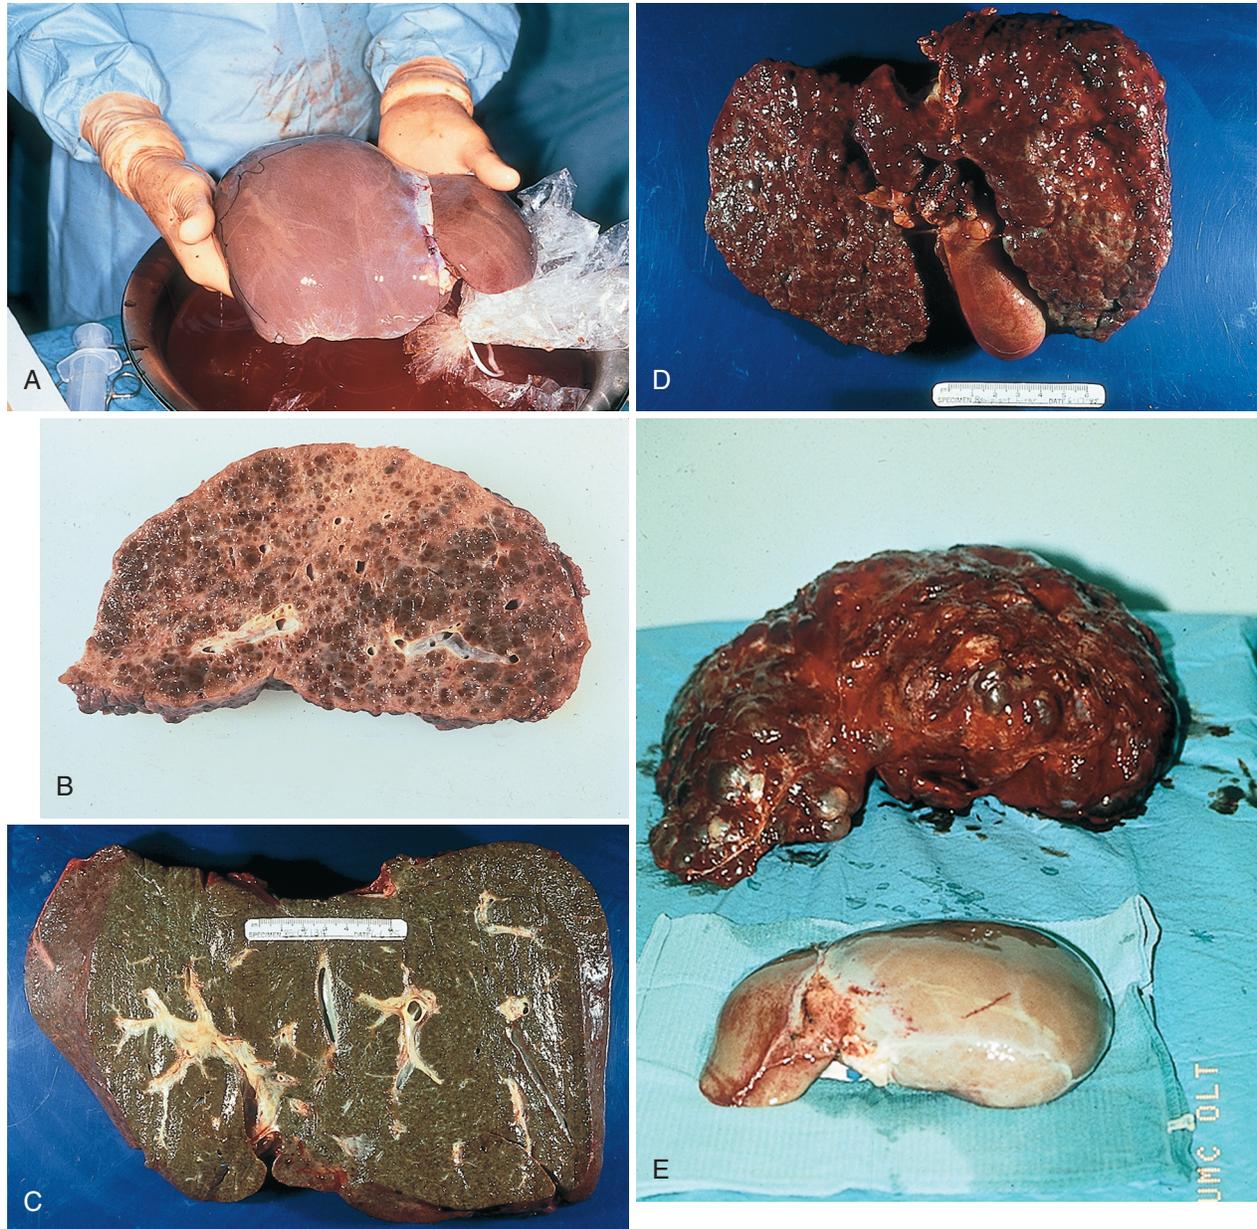

Fig. 28.1 **A**, Normal liver. **B**, Liver with damage from chronic active hepatitis. **C**, Liver with damage from sclerosing cholangitis. **D**, Liver with damage from primary biliary cirrhosis. **E**, Liver with damage from polycystic liver disease (*background*) and normal liver (*foreground*). (Courtesy Baylor Simmons Transplant Institute, Baylor University Medical Center, Dallas, TX.)

10% to 20% of patients can have immune-mediated symptoms such as fever, arthralgia, arthritis, rash, and angioedema in the preicteric phase. The third phase is the **icteric** phase, in which **jaundice** (a yellowing of the skin, mucous membranes, and the eyes) appears and the nonspecific symptoms worsen and weight loss, dysgeusia (distortion of taste), and pruritus (itchy skin) may develop. Finally, during the convalescent or recovery phase, jaundice and other symptoms begin to subside.

Complete spontaneous recovery is expected in all of hepatitis A cases, in nearly 99% of acute hepatitis B cases acquired as an adult, but in only 20% to 50% of acute hepatitis C cases. Chronic hepatitis usually does not develop with hepatitis E (Pawlotsky, 2016). Vaccines exist only for hepatitis A and B; however, recent advances have resulted in effective antiviral drugs to treat chronic hepatitis B and C.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is a spectrum of liver disease ranging from steatosis to steatohepatitis and cirrhosis. It involves the accumulation of fat droplets in the hepatocytes and can lead to inflammation, fibrosis, cirrhosis, and even hepatocellular carcinoma. Causes of NAFLD can include drugs, inborn errors of metabolism, and acquired metabolic disorders (type 2 diabetes mellitus, lipodystrophy, jejunal ileal bypass, obesity, and malnutrition). However, NAFLD is associated most commonly with obesity, type 2 diabetes mellitus, dyslipidemia, and metabolic syndrome (Chalasani, 2016). Insulin resistance with hyperinsulinism and elevated nonesterified fatty acid levels in hepatocytes characterize metabolic defects associated with NAFLD.

TABLE 28.2 Types of Viral Hepatitis

Virus	Transmission	Comments
Hepatitis A	Fecal-oral route; is contracted through contaminated drinking water, food, and sewage.	Anorexia is the most frequent symptom, and it can be severe. Other common symptoms include nausea, vomiting, right upper quadrant abdominal pain, dark urine, and jaundice (icterus). Recovery is usually complete, and long-term consequences are rare. Serious complications may occur in high-risk patients; subsequently, great attention must be given to adequate nutritional intake.
Hepatitis B and C	HBV and HCV are transmitted via blood, blood products, semen, and saliva. For example, they can be spread from contaminated needles, blood transfusions, open cuts or wounds, splashes of blood into the mouth or eyes, or sexual contact.	HBV and HCV can lead to chronic and carrier states. Chronic active hepatitis also can develop, leading to cirrhosis and liver failure.
Hepatitis D	HDV is rare in the United States and depends on HBV for survival and propagation in humans.	HDV may be a coinfection (occurring at the same time as HBV) or a superinfection (superimposing itself on the HBV carrier state). This form of hepatitis usually becomes chronic.
Hepatitis E	HEV is transmitted via the oral-fecal route.	HEV is rare in the United States (typically only occurs when imported), but it is reported more frequently in many countries of southern, eastern, and central Asia; northern, eastern, and western Africa; and Mexico. Contaminated water appears to be the source of infection, which usually afflicts people living in crowded and unsanitary conditions. HEV is generally acute rather than chronic.
Hepatitis G/GB	HGV and a virus labeled GBV-C appear to be variants of the same virus.	Although HGV infection is present in a significant proportion of blood donors and is transmitted through blood transfusions, it does not appear to cause liver disease.

HBV, Hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HGV, hepatitis G virus.

The initial stage of NAFLD is steatosis, which is characterized by the simple accumulation of fat within the liver. Some patients will progress to **nonalcoholic steatohepatitis (NASH)**, which is an inflammatory condition associated with hepatocyte injury with or without fibrous tissue in the liver. NASH can develop into chronic liver disease and NASH cirrhosis up to 20% of the time. The progression to cirrhosis (permanent damage and scarring) is variable depending on age and the presence of obesity and type 2 diabetes mellitus, which contribute to a worsening prognosis (Chalasanani, 2016).

The treatment suggestions for NAFLD from the American Association for the Study of Liver Diseases (AASLD) include lifestyle change (diet and exercise), weight loss, insulin-sensitizing drugs such as thiazolidinediones, and vitamin E (Chalasanani, 2016). Based on the AASLD panel, a 3% to 5% weight loss can improve steatosis, but up to 10% weight loss may be needed to improve NASH and fibrosis. The AASLD recommendations state that pioglitazone (an oral antihyperglycemia medication used to treat diabetes mellitus) may be considered for NASH treatment, but not NAFLD. Vitamin E (800 IU/day of alpha-tocopherol) is considered first-line treatment for biopsy-proven NASH in patients without diabetes mellitus (Chalasanani, 2016). Because disease progression and hepatocellular injury appears to be linked to oxidative stress, Vitamin E, as an antioxidant, is thought to be beneficial (Chalasanani et al, 2018). Omega-3 fatty acids could be considered to treat hypertriglyceridemia in individuals with NAFLD (Chalasanani et al, 2018). Emerging data suggest drinking moderate amounts of unsweetened coffee is protective against chronic liver disease, NAFLD, and hepatocellular carcinoma (Morisco et al, 2014; Chen et al, 2014; Setiawan et al, 2015).

Alcoholic Liver Disease

Alcoholic liver disease is one of the most common liver diseases in the United States, with 1% of North Americans having alcoholic liver disease. Forty percent of deaths from cirrhosis are attributed to alcohol (Chalasanani, 2016). Acetaldehyde is a toxic byproduct of alcohol

metabolism that causes damage to mitochondrial membrane structure and function. Acetaldehyde is produced by multiple metabolic pathways, one of which involves alcohol dehydrogenase (see *Focus On: Metabolic Consequences of Alcohol Consumption*).

FOCUS ON

Metabolic Consequences of Alcohol Consumption

Ethanol is metabolized primarily in the liver by alcohol dehydrogenase. This results in acetaldehyde production with the transfer of hydrogen to nicotinamide adenine dinucleotide (NAD), reducing it to NADH. The acetaldehyde then loses hydrogen and is converted to acetate, most of which is released into the blood.

Many metabolic disturbances occur because of the excess of NADH, which overrides the ability of the cell to maintain a normal redox state. These include hyperlactacidemia, acidosis, hyperuricemia, ketonemia, and hyperlipemia. The tricarboxylic acid (TCA) cycle is depressed because it requires NAD. The mitochondria, in turn, use hydrogen from ethanol rather than from the oxidation of fatty acids to produce energy via the TCA cycle, which leads to a decreased fatty acid oxidation and accumulation of triglycerides. In addition, NADH may actually promote fatty acid synthesis. Hypoglycemia also can occur in early alcoholic liver disease secondary to the suppression of the TCA cycle, coupled with decreased gluconeogenesis resulting from ethanol.

Several variables predispose some people to alcoholic liver disease. These include amount and duration of alcohol intake, genetic polymorphisms of alcohol-metabolizing enzymes, gender (females more than males), simultaneous exposure to other drugs, infections with hepatotropic viruses, immunologic factors, obesity, and poor nutrition status. The pathogenesis of alcoholic liver disease progresses in three stages (Fig. 28.2): hepatic steatosis (Fig. 28.3), alcoholic hepatitis, and finally cirrhosis.

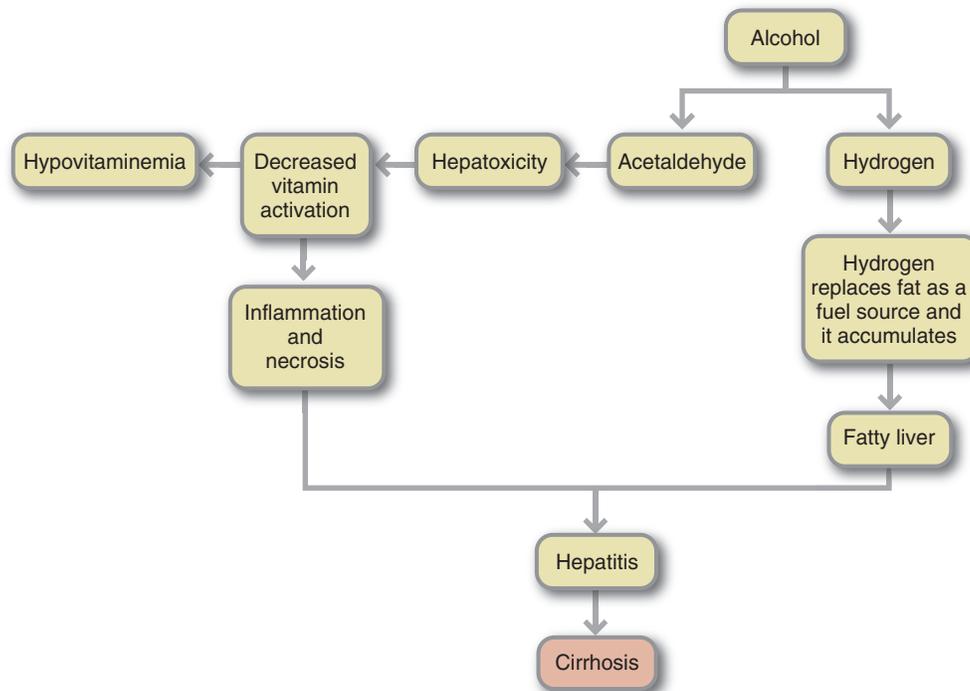

Fig. 28.2 Complications of excessive alcohol consumption stem largely from excess hydrogen and from acetaldehyde. Hydrogen produces fatty liver and hyperlipemia, high blood lactic acid, and low blood sugar. The accumulation of fat, the effect of acetaldehyde on liver cells, and other factors as yet unknown lead to alcoholic hepatitis. The next step is cirrhosis. The consequent impairment of liver function disturbs blood chemistry, notably causing a high ammonia level that can lead to coma and death. Cirrhosis also distorts liver structure, inhibiting blood flow. High pressure in vessels supplying the liver may cause ruptured varices and accumulation of fluid in the abdominal cavity. Response to alcohol differs among individuals; in particular, not all heavy drinkers develop hepatitis and cirrhosis.

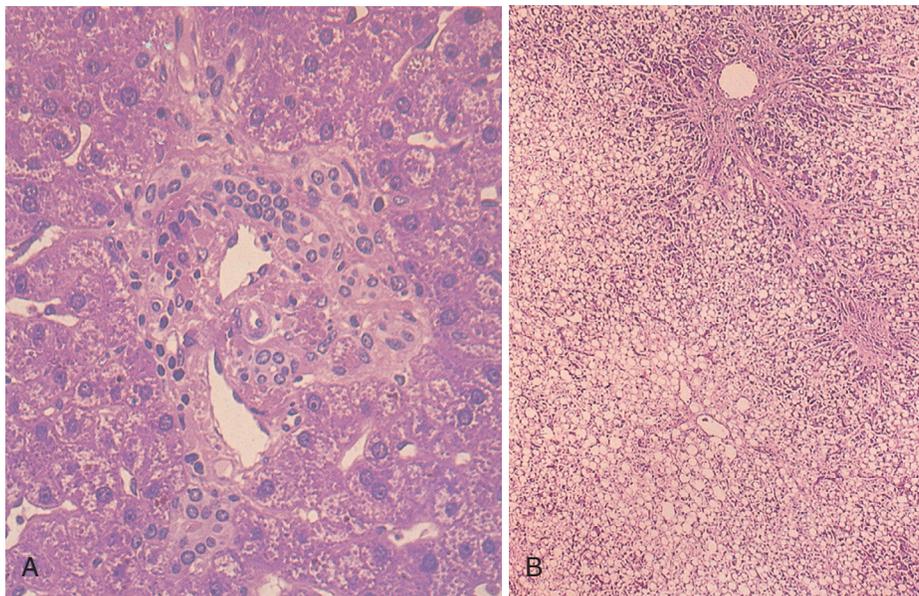

Fig. 28.3 A, Microscopic appearance of a normal liver. A normal portal tract consists of the portal vein, hepatic arteriole, one to two interlobular bile ducts, and occasional peripherally located ductules. **B,** Acute fatty liver. This photomicrograph on low power exhibits fatty change involving virtually all the hepatocytes, with slight sparing of the liver cells immediately adjacent to the portal tract (*top*). (From Kanel G, Korula J, editors: *Atlas of liver pathology*, Philadelphia, 1992, Saunders.)

Fatty infiltration, known as **hepatic steatosis** or **fatty liver**, is caused by a culmination of these metabolic disturbances: (1) an increase in the mobilization of fatty acids from adipose tissue; (2) an increase in hepatic synthesis of fatty acids; (3) a decrease in fatty acid oxidation; (4) an increase in triglyceride production; and (5) a trapping of triglycerides in the liver. Hepatic steatosis is reversible with abstinence from alcohol. Conversely, if alcohol abuse continues, cirrhosis can develop. Patients with alcoholic fatty liver disease usually are asymptomatic but can have symptoms such as fatigue, poor appetite, right upper quadrant discomfort, or hepatomegaly.

Alcoholic hepatitis generally is characterized by an enlarged liver (hepatomegaly), modest elevation of serum transaminase levels (ALT and AST), increased serum bilirubin concentrations, normal or depressed serum albumin concentrations, or anemia. Patients also may have abdominal pain, anorexia, nausea, vomiting, weakness, diarrhea, weight loss, or fever. Some patients can develop jaundice, coagulopathy, **ascites** (abdominal fluid retention), or mental impairment

(**encephalopathy**). If patients discontinue alcohol intake, hepatitis may resolve; however, the condition often progresses to the third stage.

Clinical features of alcoholic cirrhosis, the third stage, vary. Symptoms can mimic those of alcoholic hepatitis; or patients can develop complications of cirrhosis such as gastrointestinal bleeding, hepatic encephalopathy, or **portal hypertension** (elevated blood pressure in the portal venous system caused by the obstruction of blood flow through the liver). Patients with alcoholic cirrhosis often develop ascites, the accumulation of fluid, serum protein, and electrolytes within the peritoneal cavity caused by increased pressure from portal hypertension and decreased production of albumin (which maintains serum colloidal osmotic pressure). A liver biopsy usually reveals micronodular cirrhosis, but it can be macronodular or mixed. Prognosis depends on abstinence from alcohol and the degree of complications already developed. Ethanol ingestion creates specific and severe nutritional abnormalities (see *Clinical Insight: Malnutrition Related to Alcoholic Liver Disease*).

CLINICAL INSIGHT

Malnutrition Related to Alcoholic Liver Disease

Several factors contribute to the malnutrition common in individuals with chronic alcoholic liver disease:

1. Alcohol can replace food in the diet of moderate and heavy drinkers, displacing the intake of adequate calories and nutrients. In light drinkers, it is usually an additional energy source, or empty calories. Although alcohol yields 7.1 kcal/g, when it is consumed in large amounts it is not used efficiently as a fuel source. When individuals consume alcohol on a regular basis but do not fulfill criteria for alcohol abuse, they are often overweight because of the increased calories (alcohol addiction). This is different from the heavy drinker who replaces energy-rich nutrients with alcohol (alcohol substitution).
2. In the person with alcoholism, impaired digestion and absorption are related to pancreatic insufficiency, as well as morphologic and functional alterations of the intestinal mucosa. Acute and chronic alcohol intake impairs hepatic amino acid uptake and synthesis into proteins, reduces protein synthesis and secretion from the liver, and increases tissue catabolism in the gut.
3. Use of lipids and carbohydrates is compromised. An excess of reduction equivalents (e.g., nicotinamide adenine dinucleotide phosphate [NADH]) and

impaired oxidation of triglycerides result in fat deposition in the hepatocytes and an increase in circulating triglycerides. Insulin resistance is also common.

4. Vitamin and mineral deficiencies occur in alcoholic liver disease as a result of reduced intake and alterations in absorption, storage, and ability to convert the nutrients to their active forms. Steatorrhea resulting from bile acid deficiency is also common in alcoholic liver disease and affects fat-soluble vitamin absorption. Vitamin A deficiency can lead to night blindness. Thiamin deficiency is the most common vitamin deficiency in people with alcoholism and is responsible for Wernicke encephalopathy. Folate deficiency can occur as a result of poor intake, impaired absorption, accelerated excretion, and altered storage and metabolism. Inadequate dietary intake and interactions between pyridoxal-5-phosphate (active coenzyme of vitamin B₆) and alcohol reduce vitamin B₆ status. Deficiency of all B vitamins and vitamins C, D, E, and K is also common. Hypocalcemia, hypomagnesemia, and hypophosphatemia are not uncommon among people with alcoholism; furthermore, zinc deficiency and alterations in other micronutrients can accompany chronic alcohol intake.

Cholestatic Liver Diseases

Cholestatic liver diseases refer to conditions affecting the bile ducts.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic cholestatic disease caused by progressive destruction of small and intermediate-size intrahepatic bile ducts. The extrahepatic biliary tree and larger intrahepatic ducts are normal. Ninety-five percent of patients with PBC are women. The disease progresses slowly, eventually resulting in cirrhosis, portal hypertension, the need for liver transplantation, or death (Fogel and Sherman, 2016).

PBC is an autoimmune disorder that typically presents with an elevation of serum levels of Alk Phos and gamma glutamyl transferase (GGT) with physical symptoms of pruritus and fatigue. Several nutritional complications from **cholestasis** (a blockage of bile flow) can occur with PBC, including osteopenia, hypercholesterolemia, and fat-soluble vitamin deficiencies.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is characterized by fibrosing inflammation of segments of intra- and extrahepatic bile ducts. This

progressive disease can be characterized by three syndromes. The first is cholestasis with biliary cirrhosis, followed by recurrent **cholangitis** (inflammation of the bile ducts) with large bile duct strictures, and finally cholangiocarcinoma (gall bladder cancer) (Fogel and Sherman, 2016). Like PBC, PSC is considered an autoimmune disorder. In patients with PSC, about two thirds also have inflammatory bowel disease (especially ulcerative colitis), and men are more likely than women (2:1) to have PSC (Fogel and Sherman, 2016). Patients with PSC are also at increased risk of fat-soluble vitamin deficiencies resulting from steatorrhea associated with this disease. **Hepatic osteodystrophy** may occur from vitamin D and calcium malabsorption, resulting in secondary hyperparathyroidism, osteomalacia, or rickets. Known fat-soluble vitamin deficiencies should be treated, and calcium supplementation could be considered. Treatment of PSC is moderately successful with administration of cholestyramine, ursodeoxycholic acid, rifampin, or phenobarbital (Fogel and Sherman, 2016).

Inherited Disorders

Inherited disorders of the liver include hemochromatosis, Wilson's disease, alpha₁-antitrypsin deficiency, and cystic fibrosis. Porphyria,

glycogen storage disease, and amyloidosis are metabolic diseases with a genetic component.

Hemochromatosis

Although iron overload can be associated with other conditions, hereditary **hemochromatosis** is an inherited disease of iron overload usually associated with the gene HFE (Martin, 2015; Bacon, 2015). Patients with hereditary hemochromatosis absorb and store excessive iron from the gut in the liver, heart, pancreas, joints, and endocrine organs (Bacon, 2015; see Chapter 30). Increased transferrin saturation (at least 45%) and ferritin (more than two times normal) suggest hemochromatosis. Hepatomegaly, esophageal bleeding, ascites, impaired hepatic synthetic function, abnormal skin pigmentation, glucose intolerance, cardiac involvement, hypogonadism, arthropathy, and hepatocellular carcinoma may develop. Early diagnosis includes clinical, laboratory, and pathologic testing, including elevated serum transferrin levels. Life expectancy is normal if phlebotomy (or regular blood donation) is initiated before the development of cirrhosis or diabetes mellitus. Patients with hemochromatosis should avoid dietary supplements that contain iron, avoid cooking in cast iron pans, and should limit foods high in iron such as liver and red meats (see Appendix 42).

Wilson's Disease

Wilson's disease is an autosomal-recessive disorder associated with impaired biliary copper excretion (Kaler and Schilsky, 2015). Copper accumulates in various tissues, including the liver, brain, cornea, and kidneys. **Kayser-Fleischer rings** are greenish-yellow pigmented rings encircling the cornea just within the corneal margin, formed by copper deposits. Patients can present with acute, fulminant (occurring suddenly with great severity), or chronic active hepatitis and neuropsychiatric symptoms. Low serum ceruloplasmin levels, elevated copper concentration in a liver biopsy, and high urinary copper excretion confirm the diagnosis.

Copper-chelating agents (such as D-penicillamine, trientine, or tetrathiomolybdate) (Kaler and Schilsky, 2015) and zinc supplementation (150 mg elemental zinc daily given in three divided doses to inhibit intestinal copper absorption and binding in the liver) are used to treat Wilson's disease once it is diagnosed (Schilsky, 2017). Vitamin B₆ supplementation should be considered when penicillamine is given to prevent vitamin B₆ deficiency (Kaler and Schilsky, 2015). Ongoing intravenous copper chelation is required to prevent relapses and liver failure; liver transplantation corrects the metabolic defect. A low-copper diet is no longer required but may be helpful in the initial phase of treatment. High-copper foods include organ meats, shellfish, chocolate, nuts, and mushrooms. For a comprehensive list of copper content of food, refer to the U.S. Department of Agriculture National Nutrient Database. If this disease is not diagnosed until onset of fulminant failure, survival is not possible without liver transplantation.

Alpha₁-Antitrypsin Deficiency

Alpha₁-antitrypsin deficiency is an inherited disorder that can cause liver and lung disease. Alpha₁-antitrypsin is a glycoprotein found in serum and body fluids; it inhibits serine proteinases. Cholestasis or cirrhosis is caused by this deficiency, and there is no treatment except liver transplantation.

Other Liver Diseases

Liver disease can be caused by several conditions other than those already discussed. Liver tumors can be primary or metastatic,

benign or malignant. Hepatocellular carcinoma (HCC) usually develops in cirrhotic livers with highest risk in individuals with hepatitis B virus (HBV), hepatitis C virus (HCV), or NAFLD (Kelly and Venook, 2015). The liver also can be affected by rheumatic diseases such as rheumatoid arthritis, systemic lupus erythematosus, polymyalgia, temporal arteritis, polyarteritis nodosa, systemic sclerosis, and Sjögren syndrome (see Chapter 38). When hepatic blood flow is altered—as in acute ischemic and chronic congestive hepatopathy, Budd-Chiari syndrome, and hepatic venoocclusive disease—dysfunction occurs. Individuals with hepatic or portal vein thromboses should be evaluated for a myeloproliferative disorder. Parasitic, bacterial, fungal, and granulomatous liver diseases also occur. Finally, cryptogenic cirrhosis is any cirrhosis for which the cause is unknown.

Classifying Liver Disease According to Duration

Liver disease can be classified according to the time of onset and duration of the disease. Liver disease can be fulminant, acute, and chronic.

Fulminant hepatitis is a syndrome in which severe liver dysfunction is accompanied by **hepatic encephalopathy**, a clinical syndrome characterized by impaired mentation, neuromuscular disturbances, and altered consciousness. **Fulminant liver disease** is defined by the absence of preexisting liver disease and the rapid development of hepatic encephalopathy within 2 to 8 weeks of the onset of illness. The main cause of fulminant hepatitis is viral hepatitis; however, chemical toxicity (e.g., acetaminophen, drug reactions, poisonous mushrooms, industrial poisons), and other causes (e.g., Wilson's disease, fatty liver of pregnancy, Reye syndrome, hepatic ischemia, hepatic vein obstruction, and disseminated malignancies) are examples of other causes. Extrahepatic complications of fulminant hepatitis are cerebral edema, coagulopathy and bleeding, cardiovascular abnormalities, renal failure, pulmonary complications, acid-base disturbances, electrolyte imbalances, sepsis, and **pancreatitis** (inflammation of the pancreas).

Acute liver disease is identified typically as liver dysfunction that has been present for less than 6 months. Recovery is expected in a majority of patients who develop acute liver disease.

To be diagnosed with chronic hepatitis, a patient must have at least a 6-month course of hepatitis or biochemical and clinical evidence of liver disease with confirmatory biopsy findings of unresolving hepatic inflammation. Chronic hepatitis can be caused by autoimmune disease, viral infections, metabolic disorders, alcohol, drugs, or toxins. The most common causes of chronic hepatitis are hepatitis B, hepatitis C, and autoimmune hepatitis. Other causes are drug-induced liver disease, metabolic diseases, and NASH.

Clinical symptoms of chronic hepatitis are usually nonspecific, occur intermittently, and are mild. Common symptoms include fatigue, sleep disorders, difficulty concentrating, and mild right upper quadrant pain. Severe advanced disease can lead to jaundice, muscle wasting, tea-colored urine, ascites (fluid accumulation in the abdomen), edema (fluid accumulation in the tissues), hepatic encephalopathy, gastrointestinal **varices** (abnormal enlarged veins often caused by portal hypertension) with resultant gastrointestinal bleeding, splenomegaly, palmar erythema (red palms), and spider angiomas (broken blood vessels).

In some instances, chronic hepatitis leads to cirrhosis and liver failure, also known as end-stage liver disease (ESLD). **Cirrhosis**, a build up of scar tissue and fibrosis of the liver, has many clinical manifestations, as illustrated in Fig. 28.4. There are several major complications of cirrhosis and ESLD.

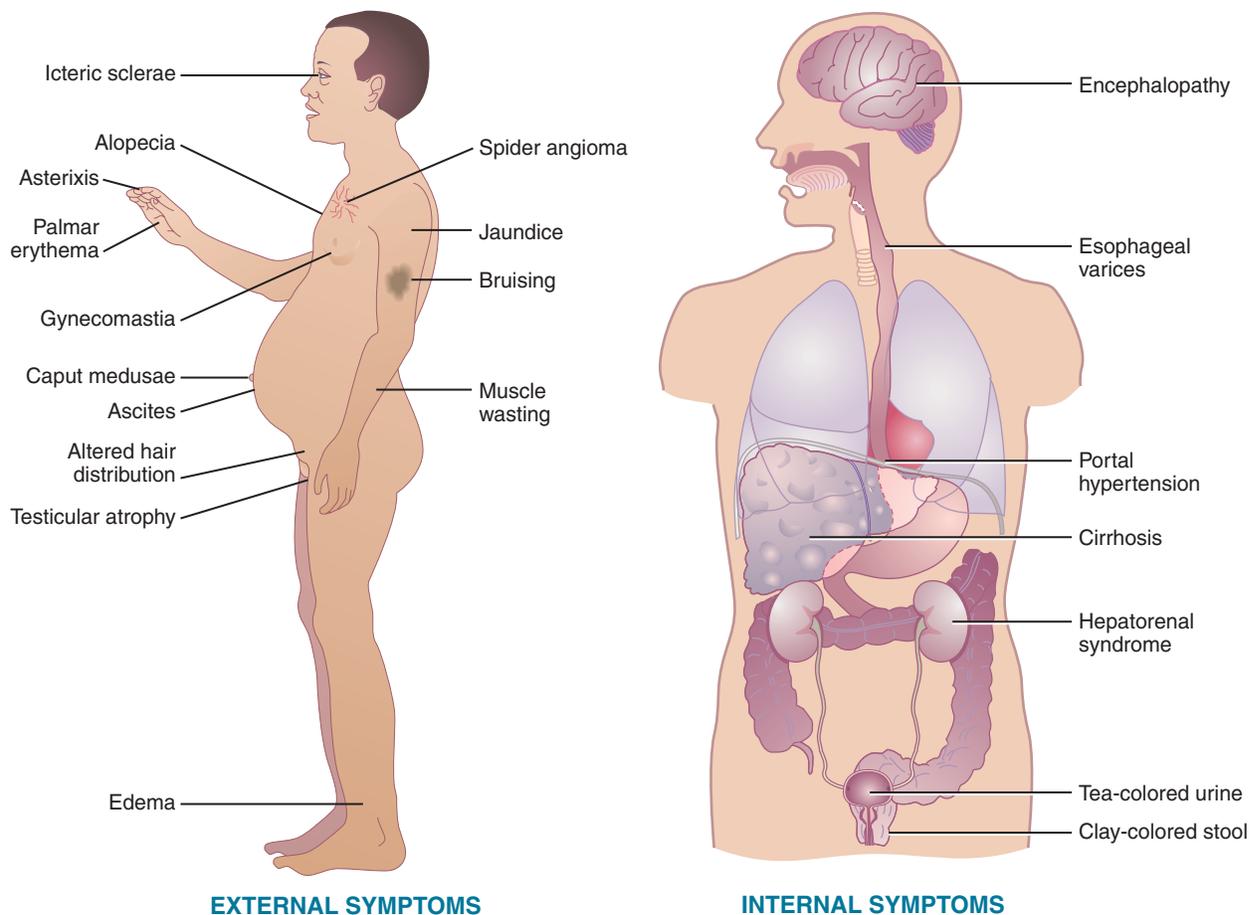

Fig. 28.4 Clinical manifestations of cirrhosis.

COMPLICATIONS OF ESLD: CAUSE AND NUTRITION TREATMENT

Decompensated ESLD can have several physical manifestations, including portal hypertension, ascites and edema, hyponatremia, and hepatic encephalopathy. It is important to understand the underlying cause of these complications as well as the medical and nutrition treatment options.

Portal Hypertension

Pathophysiology and Medical Treatment

Portal hypertension increases collateral blood flow and can result in swollen veins (varices) in the gastrointestinal tract (GIT). These varices often bleed, causing a medical emergency. Treatment includes administration of alpha-adrenergic blockers to decrease heart rate, endoscopic variceal banding, and radiologic placement of shunts. A transjugular intrahepatic portosystemic shunt (TIPS) involves a radiologically placed stent between the portal vein and the hepatic vein. During an acute bleeding episode, somatostatin or its analog may be administered to decrease bleeding, or a nasogastric tube equipped with an inflatable balloon is placed to alleviate bleeding from vessels.

Medical Nutrition Therapy

During acute bleeding episodes, nutrition cannot be administered enterally (using the gut); parenteral nutrition (PN) is indicated if a patient will be taking nothing enterally for at least 5 to 7 days (see Chapter 12). Repeated endoscopic therapies may cause esophageal

strictures or impair a patient's swallowing. Finally, placement of shunts may increase the incidence of encephalopathy and reduce nutrient metabolism because blood is shunted past the liver cells.

Ascites

Pathophysiology and Medical Treatment

Fluid retention is common, and **ascites** (accumulation of fluid in the abdominal cavity) is a serious consequence of liver disease. Portal hypertension, hypoalbuminemia, lymphatic obstruction, and renal retention of sodium and fluid contribute to fluid retention. Increased release of catecholamines, renin, angiotensin, aldosterone, and antidiuretic hormone secondary to peripheral arterial vasodilation causes renal retention of sodium and water.

Large-volume **paracentesis** (a procedure to drain the fluid) may be used to relieve ascites. Diuretic therapy often is used and frequently includes the medications spironolactone and furosemide. These drugs often are used in combination for best effect. Major side effects of loop diuretics such as furosemide include hyponatremia, hypokalemia, hypomagnesemia, hypocalcemia, and hypochloremic acidosis. Because spironolactone is potassium sparing, serum potassium levels must be monitored carefully and supplemented or restricted if necessary because deficiency or excess can contribute to metabolic abnormalities, including cardiac arrhythmias. Weight, abdominal girth (due to fluid accumulation), urinary sodium concentration, and serum levels of urea nitrogen, creatinine, albumin, uric acid, and electrolytes should be monitored during diuretic therapy.

Medical Nutrition Therapy

Dietary treatment for ascites includes restricting dietary sodium to 2 g/day (see Appendix 46). More severe limitations may be imposed; however, caution is warranted because of limited palatability and the risk of overrestricting sodium, which can lead to insufficient intake of sodium, or limited intake of calories and protein. Adequate protein intake is also important to replace losses from frequent paracentesis.

Hyponatremia

Pathophysiology

Hyponatremia (low sodium level in the blood) often occurs because of decreased ability to excrete water resulting from the persistent release of antidiuretic hormone, sodium losses via paracentesis, excessive diuretic use, or overly aggressive sodium restriction.

Medical Nutrition Therapy

Fluid intake is often restricted to 1 to 1.5 L/day, depending on the severity of the edema and ascites, although fluid restriction is utilized primarily if the sodium level is less than 125 mg/dL. Restricting sodium to about 2 g/day should be continued because excessive sodium intake results in worsened fluid retention and the further dilution of serum sodium levels (hyponatremia).

Hepatic Encephalopathy

Pathophysiology and Medical Treatment

Hepatic encephalopathy is a syndrome characterized by impaired mentation, neuromuscular disturbances, and altered consciousness. Gastrointestinal bleeding, fluid and electrolyte abnormalities, uremia, infection, use of sedatives, hyperglycemia or hypoglycemia, alcohol withdrawal, constipation, azotemia, dehydration, portosystemic shunts, and acidosis can precipitate hepatic encephalopathy. Subclinical or minimal hepatic encephalopathy also affects patients with chronic **hepatic failure**. Hepatic or **portal systemic encephalopathy** results in neuromuscular and behavioral alterations. **Box 28.1** describes the four stages of hepatic encephalopathy.

Different theories exist regarding the mechanism by which hepatic encephalopathy occurs. However, one of the most common theories involves ammonia accumulation because it is considered to be an important causal factor in the development of encephalopathy. When the liver fails, it is unable to detoxify ammonia to urea. Ammonia levels are elevated in the brain and bloodstream, leading to impaired neural function through a complex system. The main source of ammonia is its endogenous production by the GIT from the metabolism of protein and from the degradation of bacteria and blood from gastrointestinal bleeding. Exogenous protein is also a source of ammonia. Some clinicians suggest that

dietary protein causes an increase in ammonia levels and subsequently hepatic encephalopathy, but this has not been proven in studies.

Drugs such as lactulose and rifaximin are given to treat hepatic encephalopathy. Lactulose is a nonabsorbable disaccharide. It acidifies the colonic contents, retaining ammonia as the ammonium ion. It also acts as an osmotic laxative to remove the ammonia. Rifaximin is a nonabsorbable antibiotic that helps decrease colonic ammonia production.

One nutrition-related hypothesis is the “altered neurotransmitter theory,” which involves amino acid imbalance. A plasma amino acid imbalance exists in ESLD in which the **branched-chain amino acids (BCAAs)** valine, leucine, and isoleucine are decreased. The BCAAs furnish as much as 30% of energy requirements for skeletal muscle, heart, and brain when gluconeogenesis and ketogenesis are depressed, causing serum BCAA levels to fall. **Aromatic amino acids (AAAs)** tryptophan, phenylalanine, and tyrosine, plus methionine, glutamine, asparagine, and histidine are increased. Plasma AAAs and methionine are released into circulation by muscle proteolysis, but the synthesis into protein and liver clearance of AAAs is depressed. This changes the plasma molar ratio of BCAAs to AAAs and has been theorized to contribute to the development of hepatic encephalopathy. Conversely, high levels of AAAs have been theorized to limit the cerebral uptake of BCAAs because they compete for carrier-mediated transport at the blood-brain barrier. Convincing evidence to support this theory is lacking.

Medical Nutrition Therapy

The outdated practice of protein restriction in patients with low-grade hepatic encephalopathy is based on the premise that protein intolerance causes hepatic encephalopathy, but it has never been proven in a study. True dietary protein intolerance is rare except in fulminant hepatic failure, or in a rare patient with chronic endogenous hepatic encephalopathy. Unnecessary protein restriction may worsen body protein losses and must be avoided. In fact, patients with encephalopathy often do not receive adequate protein. Most patients with cirrhosis can tolerate mixed-protein diets up to 1.5 g/kg of body weight.

Studies evaluating the benefit of supplements enriched with BCAAs and restricted in AAAs have varied in study design, sample size, composition of formulas, level of encephalopathy, type of liver disease, duration of therapy, and control groups. When high-methodological quality studies are evaluated, no significant improvements or survival benefits are associated with giving extra BCAAs to patients.

Other theories postulate that vegetable proteins and casein may improve mental status compared with meat protein. Casein-based diets are lower in AAAs and higher in BCAAs than meat-based diets. Vegetable protein is low in methionine and ammoniagenic amino acids but BCAA rich. The high-fiber content of a vegetable-protein diet also may play a role in the excretion of nitrogenous compounds.

Finally, it has been proposed that probiotics and synbiotics (sources of gut-friendly bacteria and fermentable fibers) can be used to treat hepatic encephalopathy. Probiotics may improve hepatic encephalopathy by reducing ammonia and endotoxin levels. In a meta-analysis, probiotics were shown to reduce serum ammonia levels as effectively as lactulose (Cai et al, 2018) and improve minimal hepatic encephalopathy (Cao et al, 2018; Dalal et al, 2017). They decrease inflammation and oxidative stress in the hepatocyte (thus increasing hepatic clearance of toxins including ammonia), and minimize uptake of other toxins.

BOX 28.1 Four Stages of Hepatic Encephalopathy

Stage	Symptoms
I	Mild confusion, agitation, irritability, sleep disturbance, decreased attention
II	Lethargy, disorientation, inappropriate behavior, drowsiness
III	Somnolent but arousable, incomprehensible speech, confused, aggressive behavior when awake
IV	Coma

Glucose Alterations

Pathophysiology

Glucose intolerance occurs in almost two thirds of patients with cirrhosis, and as many as one third of patients develop diabetes mellitus. Glucose intolerance in patients with liver disease occurs because of insulin resistance in peripheral tissues. Hyperinsulinism also occurs in patients with cirrhosis, possibly because insulin production is increased, hepatic clearance is decreased, portal systemic shunting occurs, there is a defect in the insulin-binding action at the receptor site, or there is a postreceptor defect.

Fasting hypoglycemia, or low blood glucose, can occur because of the decreased availability of glucose from glycogen in addition to the failing gluconeogenic capacity of the liver when the patient has ESLD. Hypoglycemia occurs more often in acute or fulminant liver failure than in chronic liver disease. Hypoglycemia also may occur after alcohol consumption in patients whose glycogen stores are depleted by starvation because of the block of hepatic gluconeogenesis by ethanol.

Medical Nutrition Therapy

Patients with diabetes mellitus should receive standard medical and nutrition therapy to achieve normoglycemia (see Chapter 29). Patients with hypoglycemia need to eat frequently to prevent this condition (see *Clinical Insight: Fasting Hypoglycemia*). Evening snacks that contain low glycemic carbohydrates balanced with protein may help prevent morning hypoglycemia.

CLINICAL INSIGHT

Fasting Hypoglycemia

Two thirds of the glucose requirement in an adult is used by the central nervous system. During fasting, plasma glucose concentrations are maintained for use by the nervous system and the brain because liver glycogen is broken down, or new glucose is made from nonglucose amino acid precursors such as alanine. Fasting hypoglycemia occurs in liver and biliary disease when there is reduced synthesis of new glucose or reduced liver glycogen breakdown.

Causes of fasting hypoglycemia include cirrhosis, consumption of alcohol, extensive intrahepatic cancer, deficiency of cortisol and growth hormone, or non- β -cell tumors of the pancreas (insulinomas). All patients with liver or pancreatic disease should be monitored for fasting hypoglycemia. Nutrition therapy involves balanced meals with small, frequent snacks to avoid periods of fasting. Monitoring of blood glucose and insulin levels is required.

Fat Malabsorption

Pathophysiology

Fat absorption may be impaired in liver disease. Possible causes include decreased bile salt secretion (as in PBC, sclerosing cholangitis, and biliary strictures), administration of medications such as cholestyramine, and pancreatic enzyme insufficiency. Stools may be greasy, floating, or light- or clay-colored, signifying malabsorption, which can be verified by a 72-hour fecal fat study (see Chapter 27).

Medical Nutrition Therapy

If significant **steatorrhea** (the presence of fat in the stool) is present, replacement of some of the long-chain triglycerides or dietary fat with medium-chain triglycerides (MCTs) can be useful. Because MCTs do not require bile salts and micelle formation for absorption, they are readily taken up via the portal route. Some nutrition supplements

contain MCTs, which can be used in addition to liquid MCT oil (see Chapter 12).

Significant stool fat losses may warrant a trial of a low-fat diet or evaluation of pancreatic insufficiency. If diarrhea does not resolve, fat restriction should be discontinued because it decreases the palatability of the diet and makes it difficult to take in adequate calories. Because of the degree of malabsorption and steatorrhea, it is important to consider that the patient may have deficiencies of multiple micronutrients, especially fat-soluble vitamins.

Renal Insufficiency and Hepatorenal Syndrome

Pathophysiology, Medical, and Nutrition Therapies

Hepatorenal syndrome is renal failure associated with severe liver disease without intrinsic kidney abnormalities. Hepatorenal syndrome is diagnosed when the urine sodium level is less than 10 mEq/L and oliguria persists in the absence of intravascular volume depletion. If conservative therapies, including discontinuation of nephrotoxic drugs, optimization of intravascular volume status, treatment of underlying infection, and monitoring of fluid intake and output fail, dialysis may be required. In any case, renal insufficiency and failure may necessitate alteration in fluid, sodium, potassium, and phosphorus intake (see Chapter 34).

Osteopenia

Pathophysiology

Osteopenia often exists in patients with PBC, sclerosing cholangitis, and alcoholic liver disease. Depressed osteoblastic function and osteoporosis also can occur in patients with hemochromatosis, and osteoporosis is prevalent in patients who have had long-term treatment with corticosteroids. Corticosteroids increase bone resorption; suppress osteoblastic function; and affect sex hormone secretion, intestinal absorption of dietary calcium, renal excretion of calcium and phosphorus, and vitamin D.

Medical Nutrition Therapy

Prevention or treatment options for osteopenia include prevention of excessive weight loss, ingestion of a well-balanced diet, adequate protein to maintain muscle mass, a minimum of the dietary reference intake (DRI) for calcium per day (1000 to 1300 mg depending on age), adequate vitamin D from the diet or supplements, avoidance of alcohol, and monitoring for steatorrhea, with diet adjustments as needed to minimize nutrient losses.

NUTRITION ISSUES RELATED TO END-STAGE LIVER DISEASE

Nutrition Assessment

Nutrition assessment must be performed to determine the extent and cause of malnutrition in patients with liver disease. However, many traditional markers of nutrition status are affected by liver disease, making traditional assessment difficult. [Table 28.3](#) summarizes the factors that affect interpretation of nutrition assessment parameters in patients with liver dysfunction.

Objective nutrition assessment parameters that are helpful when monitored serially include anthropometric measurements and dietary intake evaluation (see Chapters 4 and 5). Caution should be taken when assessing biochemical markers in the advanced liver disease patient because the typical nutrition criteria will be affected due to the liver

TABLE 28.3 Factors That Affect Interpretation of Objective Nutrition Assessment Parameter in Patients With End-Stage Liver Disease

Parameter	Factors Affecting Interpretation
Body weight	Affected by edema, ascites, and diuretic use
Anthropometric measurements	Questionable sensitivity, specificity, and reliability
	Multiple sources of error
	Unknown if skinfold measurements reflect total body fat
	References do not account for variation in hydration status and skin compressibility
Nitrogen balance studies	Nitrogen is retained in the body in the form of ammonia
	Hepatorenal syndrome can affect the excretion of nitrogen
Single-frequency bioelectrical impedance	Invalid with ascites and edema

Modified from Hasse J: Nutritional aspects of adult liver transplantation. In Busuttill RW, Klintmalm GB, editors: *Transplantation of the liver*, ed 3, Philadelphia, 2015, Elsevier Saunders.

disease itself. The best way to perform a nutrition assessment may be to combine these parameters with the subjective global assessment (SGA) approach, which has demonstrated an acceptable level of reliability and validity. The SGA gives a broad perspective, but it is not sensitive to changes in nutrition status. Other available parameters should also be reviewed. The SGA approach is summarized in [Box 28.2](#).

BOX 28.2 Subjective Global Assessment Parameters for Nutrition Evaluation of Liver Disease Patients

History

Weight change (consider fluctuations resulting from ascites and edema)
 Appetite
 Taste changes and early satiety
 Dietary intake (calories, protein, sodium)
 Persistent gastrointestinal problems (nausea, vomiting, diarrhea, constipation, difficulty chewing or swallowing)

Physical Findings

Muscle wasting
 Fat stores
 Ascites or edema

Existing Conditions

Disease state and other problems that could influence nutrition status such as hepatic encephalopathy, gastrointestinal bleeding, renal insufficiency, infection

Nutritional Rating Based on Results

Well nourished
 Moderately (or suspected of being) malnourished
 Severely malnourished

From Hasse J: Nutritional aspects of adult liver transplantation. In: Busuttill RW, Klintmalm GB, editors: *Transplantation of the liver*, ed 2, Philadelphia, 2005, Elsevier Saunders.

Malnutrition

Moderate to severe malnutrition is a common finding in patients with advanced liver disease ([Fig. 28.5](#)). This is extremely significant, considering that malnutrition plays a major role in the pathogenesis of liver injury and has a profound negative effect on prognosis. The prevalence of malnutrition depends on nutrition assessment parameters used, type and degree of liver disease, and socioeconomic status.

Numerous coexisting factors are involved in the development of malnutrition in liver disease (see *Pathophysiology and Care Management Algorithm: Malnutrition in Liver Disease*). Inadequate oral intake, a major contributor, is caused by anorexia, dysgeusia, early satiety, nausea, or vomiting associated with liver disease and the drugs used to treat it. Another cause of inadequate intake is dietary restriction.

Maldigestion and malabsorption also play a role. **Steatorrhea** is common in cirrhosis, especially if there is disease involving bile duct injury and obstruction. Medications also may cause specific malabsorptive losses. In addition, altered metabolism secondary to liver dysfunction causes malnutrition in various ways. Micronutrient function is affected by altered storage in the liver, decreased transport by liver-synthesized proteins, and renal losses associated with alcoholism and advanced liver disease. Abnormal macronutrient metabolism and increased energy expenditure also can contribute to malnutrition. Finally, protein losses can occur from large-volume paracentesis when several liters of fluid from the abdomen (ascites) are removed through a needle.

Route of Nutrition

Although oral diet is the preferred route of nutrition for patients with ESLD, anorexia, nausea, dysgeusia, and other gastrointestinal symptoms can make adequate nutrition intake difficult to achieve. Early satiety is also a frequent complaint such that smaller, more frequent meals are better tolerated than three large meals. In addition, frequent feedings

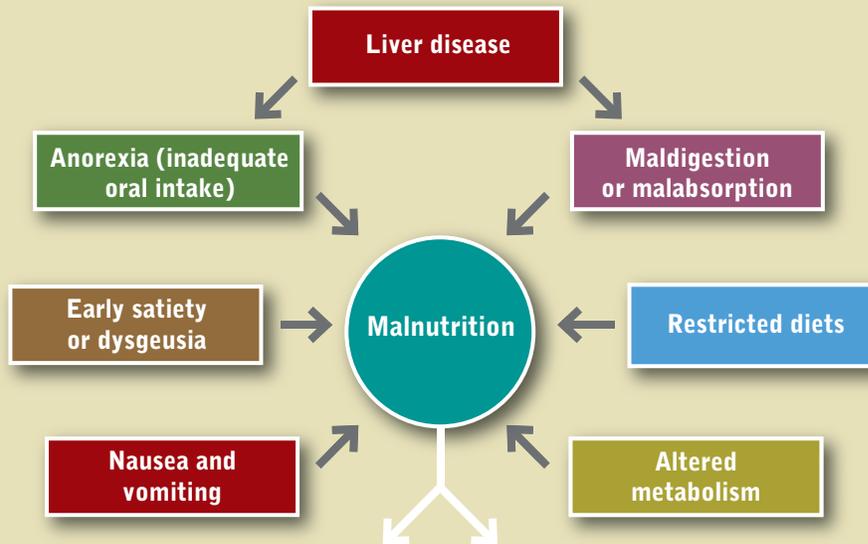

Fig. 28.5 Severe malnutrition and ascites in a man with end-stage liver disease.

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Malnutrition in Liver Disease

ETIOLOGY

PATHOPHYSIOLOGY

Clinical Findings

- Abnormal liver function tests
- Jaundice
- Ascites and edema
- Hepatic encephalopathy
- Portal hypertension and varices
- Vitamin/mineral deficits
- Glucose intolerance or fasting hypoglycemia

Nutrition Assessment

- Serial monitoring of body weight and anthropometry
- Dietary intake
- Subjective global assessment
- Laboratory tests for nutritional deficiencies such as vitamins, magnesium, iron, and others

MANAGEMENT

Medical Management

- Diuretic therapy
- Medication for encephalopathy (e.g., lactulose, rifaximin)
- Management of portal hypertensive bleeding (e.g., pharmacologic therapy, shunts, banding)
- Monitoring of blood glucose

Nutrition Management

- Increased energy intake via small, frequent meals
- 1.0–1.5 g/kg protein
- Sodium restriction for fluid retention
- Fluid restriction for hyponatremia
- Carbohydrate-controlled diets for hyperglycemia
- Vitamin and mineral supplements
- Oral liquid supplements or enteral (tube) feeding

may also improve nitrogen balance and prevent hypoglycemia. Nutrient-dense snacks or supplements in the form of homemade or commercial oral drinks or foods should be encouraged, and, when necessary, use of enteral tube feedings should occur. Adjunctive nutrition support should be given to malnourished patients with liver disease if their intake is suboptimal and if they are at risk for fatal complications from the disease. Enteral nutrition (EN) is preferred over parenteral nutrition (PN) and history of varices are usually not a contraindication for tube feeding via a nasoenteric tube, provided there is no active bleeding (see Portal Hypertension Pathophysiology and Medical Treatment). Generally,

gastrostomy or jejunostomy tubes are not viable options in patients with liver disease given common complications of cirrhosis, including ascites and gastric varices. Instead, a nasoenteric tube (nasogastric, nasointestinal) tube is preferred although those could be contraindicated if the patient has severe epistaxis.

Treatment

EN support may be necessary in malnourished patients or patients with inadequate nutrient intake. The amount and duration of nutrition support depends on the goals of treatment (e.g., providing

support during an acute event vs. improving nutrition to qualify for transplant), severity of the liver disease and malnutrition, and other comorbidities (e.g., infection, renal insufficiency, hepatic encephalopathy, etc.). If improved survival is considered the desired outcome for nutrition support, there is no consensus on how EN affects survival in this population. A multicenter study that evaluated effects of EN in patients with cirrhosis and jaundice did not find that EN was associated with a survival benefit (Dupont et al, 2012). However, a meta-analysis by Ney et al. (2013) suggested that nutrition therapy was associated with reduced mortality in patients with cirrhosis or alcoholic hepatitis disease, but a concern of the study was high risk of bias among the studies analyzed. Additional studies are required to determine how much nutrition support is needed and over what period of time to improve nutrition status or influence chosen outcomes.

NUTRIENT REQUIREMENTS FOR CIRRHOSIS

Energy

Energy requirements vary among patients with cirrhosis. Several studies have measured resting energy expenditure (REE) in patients with liver disease to determine energy requirements. Some studies found that patients with ESLD had normal metabolism and that others had hypometabolism or hypermetabolism. Ascites or shunt placement may increase energy expenditure slightly.

In general, energy requirements for patients with ESLD and without ascites are approximately 120% to 140% of the REE. Requirements increase to 150% to 175% of REE if ascites, infection, and malabsorption are present, or if nutritional repletion is necessary due to malnutrition. This equates to approximately 25 to 35 calories per kilogram body weight, although needs could be as low as 20 calories per kilogram for obese patients and as high as 40 calories per kilogram for underweight patients (Amodio et al, 2013). Estimated **dry body weight** (i.e., weight without fluid retention) or ideal weight should be used in calculations to prevent overfeeding.

Carbohydrate

Determining carbohydrate needs is challenging in liver failure because of the primary role of the liver in carbohydrate metabolism. Liver failure

reduces glucose production and peripheral glucose use. The rate of gluconeogenesis is decreased, with preference for lipids and amino acids for energy. In addition, insulin resistance can be present with liver dysfunction.

Lipid

In cirrhosis, plasma-free fatty acids, glycerol, and ketone bodies are increased in the fasting state. The body prefers lipids as an energy substrate. Lipolysis is increased with active mobilization of lipid deposits, but the net capacity to store exogenous lipid is not impaired. An average of 30% of calories as fat is sufficient, but additional fat can be given as a concentrated source of calories for those who need additional calories. In patients with severe steatorrhea, use of MCT oil could be considered.

Protein

Protein is by far the most controversial nutrient in liver failure, and its management is also the most complex. Cirrhosis has long been thought of as a catabolic disease with increased protein breakdown, inadequate synthesis, depleted status, and muscle wasting. However, protein kinetic studies demonstrate increased nitrogen losses only in patients with fulminant hepatic failure or decompensated disease, but not in stable cirrhosis.

Patients with cirrhosis also have increased protein utilization. Studies suggest that 0.8 g of protein/kg/day is the mean protein requirement to achieve nitrogen balance in stable cirrhosis. Therefore in uncomplicated hepatitis or cirrhosis with or without encephalopathy, protein requirements range from 1 to 1.5 g/kg of ideal weight per day (Amodio et al, 2013).

To promote nitrogen accumulation or positive balance, at least 1.2 to 1.3 g/kg daily is needed. In situations of stress such as alcoholic hepatitis or decompensated disease (sepsis, infection, gastrointestinal bleeding, or severe ascites), at least 1.5 g of protein per kg per day should be provided. Small frequent meals not only provide additional calories but also prevent gluconeogenesis and wasting of muscle (Amodio et al, 2014).

Vitamins and Minerals

Vitamin and mineral supplementation should be considered for all patients with ESLD because of the essential role of the liver in nutrient transport, storage, and metabolism, in addition to the presence of

TABLE 28.4 Vitamin and Mineral Deficits in Severe Hepatic Failure

Vitamin or Mineral	Predisposing Factors	Signs of Deficiency (See Appendix 21)
Vitamin A	Steatorrhea, neomycin, cholestyramine, alcoholism	Night blindness, increased infection risk
Vitamin B ₁ (thiamine)	Alcoholism, high-carbohydrate diet	Neuropathy, ascites, edema, central nervous system (CNS) dysfunction
Vitamin B ₃ (niacin)	Alcoholism	Dermatitis, dementia, diarrhea, inflammation of mucous membranes
Vitamin B ₆ (pyridoxine)	Alcoholism	Mucous membrane lesions, seborrheic dermatitis, glossitis, angular stomatitis, blepharitis, peripheral neuropathy, microcytic anemia, depression
Vitamin B ₁₂ (cyanocobalamin)	Alcoholism, cholestyramine	Megaloblastic anemia, glossitis, CNS dysfunction
Folate	Alcoholism	Megaloblastic anemia, glossitis, irritability
Vitamin D	Steatorrhea, glucocorticoids, cholestyramine	Osteomalacia, rickets (in children), possible link to cancer or autoimmune disorders
Vitamin E	Steatorrhea, cholestyramine	Peripheral neuropathy, ataxia, skeletal myopathy, retinopathy, immune system impairment
Vitamin K	Steatorrhea, antibiotics, cholestyramine	Excessive bleeding, bruising
Iron	Chronic bleeding	Stomatitis, microcytic anemia, malaise
Magnesium	Alcoholism, diuretics	Neuromuscular irritability, hypokalemia, hypocalcemia
Phosphorus	Anabolism, alcoholism	Anorexia, weakness, cardiac failure, glucose intolerance
Zinc	Diarrhea, diuretics, alcoholism	Immunodeficiency, impaired taste acuity, delayed wound healing, impaired protein synthesis

nutrient depletions due to drugs (Table 28.4). Vitamin deficiencies can contribute to complications. For example, folate and vitamin B₁₂ deficiencies can lead to macrocytic anemia. Deficiency of pyridoxine, thiamin, or vitamin B₁₂ can result in neuropathy. Confusion, ataxia, and ocular disturbances can result from a thiamin deficiency.

Deficiencies of fat-soluble vitamins have been found in all types of liver failure, especially in cholestatic diseases in which malabsorption and steatorrhea occur. Impaired dark adaptation can occur from vitamin A deficiency. Hepatic osteodystrophy or osteopenia can develop from vitamin D deficiency. Therefore supplementation is necessary, and may require using water-miscible forms of fat soluble vitamins. Intravenous or intramuscular vitamin K often is given for 3 days to rule out vitamin K deficiency as the cause of a prolonged prothrombin time. Water-soluble vitamin deficiencies associated with liver disease include thiamin (which can lead to **Wernicke encephalopathy**), pyridoxine (B₆), cyanocobalamin (B₁₂), folate, and niacin (B₃). Large doses (100 mg) of thiamin are given daily for a limited time if deficiency is suspected (see Appendices 12 and 13).

Mineral nutriture also is altered in liver disease. Iron stores may be depleted in patients experiencing gastrointestinal bleeding; however, iron supplementation should be avoided by persons with hemochromatosis or hemosiderosis (see Chapter 31). Manganese deposition has been noted to accumulate in brains of patients with cirrhosis, leading to impaired motor function and parkinsonism and increased occurrence of hepatic encephalopathy (Butterworth, 2013; Kobtan et al, 2016; Sureka et al, 2015). Elevated serum copper levels are found in cholestatic liver diseases (i.e., PBC and PSC).

In Wilson's disease, excess copper in various organs causes severe damage. Treatment typically includes administration of oral chelating agents such as D-penicillamine, trientine, or tetrathiomolybdate. Zinc acetate can block absorption of copper from food but typically is used with one of the chelating drugs. Dietary copper restriction can be useful during initial therapy. Copper also can be present in water where copper pipes are used. Running tap water for several seconds before using the water can reduce copper concentrations.

Zinc and magnesium levels are low in liver disease related to alcoholism and diuretic therapy. Calcium, as well as magnesium and zinc, may be malabsorbed with steatorrhea. Therefore the patient should take supplements of these minerals at least at the level of the DRI.

HERBAL AND DIETARY SUPPLEMENTS AND LIVER DISEASE

Hepatotoxicity is one of the greatest concerns associated with herbal and dietary supplementation. While most culinary herbs are safe, there are case reports of some herbal supplements resulting in liver failure (Box 28.3). One review lists more than 150 herbal products that have been reported as a cause of hepatotoxicity (Teschke et al, 2013). This extensive list emphasizes the gravity of the potential for harm to the liver from some herbal products, so practitioners should be vigilant in asking patients about supplement usage.

Other dietary products also have been implicated in hepatotoxicity. Among the most common products are garcinia cambogia, Herbalife products, Hydroxycut, and OxyElite Pro (Crescioli et al, 2018; Centers for Disease Control and Prevention [CDC], 2013; Fong et al, 2010; Jóhannsson et al, 2010; Schoepfer et al, 2007; Sharma et al, 2010). One of the most significant events occurred in 2013 when 56 individuals (43 in Hawaii) taking OxyElite Pro developed acute or fulminant liver failure. Several patients required liver transplantation and at least one patient died (CDC, 2013; Food and Drug Administration [FDA], 2014).

BOX 28.3 Selected Herbal Supplements Associated With Hepatotoxicity

Baikal skullcap (*Scutellaria*)
 Chaparral (*Larrea tridentate*)
 Pyrrolizidine alkaloids (found in herbs of the *Compositae*, *Leguminosae*, *Boraginaceae* family)
 Comfrey (*Symphytum officinale*)
Heliotropium
 Crotonaria
 Germander (*Teucrium chamaedrys*)
 Greater celandine (*Chelidonium majus*)
 Saw palmetto (*Serenoa repens*)
 Noni juice (*Morinda citrifolia*)
 Margosa oil (*Antelaea azadirachta*)
 Aloe vera (aloe latex)
 Black cohosh (*Actea racemosa* or *Actea cimicifuga*)
 LipoKinetix (*usnic acid*)
Atractylis gummifera
 Impila (*Callilepis laureola*)
 Mistletoe (*Viscum album*)
 Valerian (*Valerian officinalis*)
 Senna (*Cassia angustifolia*)
 Pennyroyal (squaw mint oil)
 Kava (*Piper methysticum*)
Liatris callilepis
 Green tea extract (*Camellia sinensis*), although green tea in reasonable amounts appears safe
 Cascara sagrada
 OxyElite Pro
 Jin Bu Huan (*Lycopodium serratum*)
 Ma Huang (*Ephedra sinica*)
 Dai-saiko-to (*Sho-saiko-to*)
 Hydroxycut

LipoKinetix (Syntrax Innovations, Inc, Cape Girardeau, MO), OxyElite Pro (USP Labs, LLC, Dallas, TX), Hydroxycut (Iovate Health Sciences USA, Inc, Blasdel, NY).

Reprinted with permission from: Corey RL, Rakela J: Complementary and alternative medicine: risks and special considerations in pre- and post-transplant patients, *Nutr Clin Pract* 29:322, 2014.

Despite reports of hepatotoxicity with numerous herbal supplements, some supplements have been investigated for benefits on liver disease. S-adenosyl-L-methionine (SAMe) is sometimes suggested for use with liver disease. It is purported to act as a methyl donor for methylation reactions and participates in glutathione synthesis (an antioxidant). A recent systematic review and meta-analysis suggested SAMe may improve liver function but does not improve outcomes for chronic liver disease (Guo et al, 2015). Betaine has been proposed for treatment of NASH, alcoholic liver disease, and other conditions. Betaine functions in the liver as a methyl donor. Although there is theoretical promise, there is a lack of strong evidence for benefit (Day and Kempson, 2016; Abdelmalek et al, 2009; Mukherjee, 2011).

Milk thistle appears to be the most popular and extensively studied herbal supplement for liver disease. The active component in milk thistle is silymarin with silybin (constituting 50% to 70% of silymarin) believed to have the most biologic activity. Milk thistle is proposed to have antiinflammatory, antioxidant, and antifibrotic properties, which would be beneficial in liver disease (Abenavoli et al, 2010). Milk thistle has been evaluated for viral hepatitis, alcoholic liver disease, and toxin-induced liver disease. A recent meta-analysis evaluated

the benefits of silymarin on NAFLD. The study showed that silymarin may reduce transaminases, but there was no evaluation of histologic changes in the liver (Zhong et al, 2017). Despite its popularity and widespread use, a clear consensus is lacking as to a beneficial effect of milk thistle on all forms of liver disease, so individual assessment is needed. However, data are not sufficient to suggest that it is unsafe or toxic for patients with liver disease.

LIVER RESECTION AND TRANSPLANTATION

As with any major surgery, protein and energy needs increase after liver resection. Needs also are increased for liver cell regeneration. EN can be beneficial by providing portal hepatotropic factors necessary for liver cell proliferation. Optimal nutrition is most important for patients with poor nutrition status before hepatectomy (e.g., patients with cholangiocarcinoma).

Liver transplantation has become an established treatment for ESKD. Malnutrition is common in liver transplant candidates. Dietary intake often can be enhanced if patients eat small, frequent, nutrient-dense meals, and oral nutritional supplements also may be well tolerated. EN is indicated when oral intake is inadequate or contraindicated.

Varices are not an absolute contraindication for placement of a feeding tube. Because PN can affect liver function adversely, EN is preferred. PN is reserved for patients without adequate gut function (see Chapter 12).

In the acute posttransplant phase, nutrient needs are increased to promote healing, deter infection, provide energy for recovery, and replenish depleted body stores. Nitrogen requirements are elevated in the acute posttransplant phase and can be met with early postoperative EN. Early postoperative EN has been associated with reduced infections in liver transplant recipients (Hasse et al, 1995; Ikegami et al, 2012; Masuda et al, 2014). Administration of probiotics and fiber with tube feeding may reduce postoperative infection rate better than tube feeding or fiber alone (Rayes et al, 2005).

Multiple medications used after transplant have nutritional side effects such as anorexia, gastrointestinal upset, hypercatabolism, diarrhea, hyperglycemia, hyperlipidemia, sodium retention, hypertension, hyperkalemia, and hypercalciuria. Therefore dietary modification is based on the specific side effects of drug therapy (Table 28.5). During the posttransplant phase, nutrient requirements are adjusted to prevent or treat problems of obesity, hyperlipidemia, hypertension, diabetes mellitus, and osteopenia. Table 28.6 summarizes nutrient needs after liver transplantation.

TABLE 28.5 Drugs Commonly Used After Liver Transplantation

Immunosuppressant Drug	Possible Nutritional Side Effects	Proposed Nutrition Therapy
Azathioprine	Macrocytic anemia Mouth sores Nausea, vomiting, diarrhea, anorexia, sore throat, stomach pain, decreased taste acuity	Give folate supplements. Adjust food and meals as needed; monitor intake.
Antithymocyte globulin (ATG), lymphocyte immune globulin	Nausea, vomiting	Adjust food and meals as needed; monitor intake.
Cyclosporine	Sodium retention	Decrease sodium intake.
	Hyperkalemia	Decrease potassium intake.
	Hyperlipidemia	Limit fat and simple carbohydrate intake.
	Hyperglycemia	Decrease simple carbohydrate intake.
	Decreased serum magnesium level	Increase magnesium intake; give supplements.
	Hypertension	Limit sodium intake.
Glucocorticoids	Nausea, vomiting	Adjust food and meals as needed; monitor intake.
	Sodium retention	Decrease sodium intake.
	Hyperglycemia	Decrease simple carbohydrate intake.
	Hyperlipidemia	Limit fat and simple carbohydrate intake.
	False hunger	Avoid overeating.
Mycophenolate mofetil, mycophenolic acid	Protein wasting with high doses	Increase protein intake.
	Decreased absorption of calcium and phosphorus	Increase calcium and phosphorus intake; give supplements as needed.
	Nausea, vomiting, diarrhea	Adjust food and meals as needed; monitor intake.
Sirolimus	Possible GI symptoms	Adjust food and meals as needed; monitor intake.
	Hyperlipidemia	Limit fat and simple carbohydrate intake.
	Inhibits wound healing	Ensure adequate macro- and micronutrients.
	Depressed appetite.	Consider appetite stimulants.
Tacrolimus	Hyperglycemia	Decrease simple carbohydrate intake.
	Hyperkalemia	Decrease potassium intake.
	Nausea, vomiting	Adjust food and meals as needed; monitor intake.

GI, Gastrointestinal.

TABLE 28.6 General Nutrient Requirements for Liver Transplant Patients

	Pretransplantation	Immediate Posttransplantation (First 2 Posttransplant Months)	Long-Term Posttransplantation
*Protein	Dependent on nutrition status and medical condition but usually 1-1.5 g/kg	Dependent on nutrition status, medical condition, and dialysis requirement but usually 1.2-2 g/kg	Maintenance – about 1 g/kg
*Calories	Dependent on nutrition status and losses; usually 20%-50% above basal	Dependent on nutrition status and metabolic stress but usually 20%-30% above basal	Dependent on activity and weight goals; usually 20% above basal for sedentary activity if at goal weight
Fat	As needed	Approximately 30% of calories	Moderate fat (30% of calories)
Carbohydrate	Reduced carbohydrate if diabetes or obesity present	Reduced carbohydrate if diabetes present	Reduced simple carbohydrate, especially if diabetes or obesity present
Sodium	2 g/day	2 g/day (as indicated)	2 g/day (as indicated)
Fluid	Restrict to 1000-1500 mL/day (if hyponatremic)	As needed	As needed
Calcium	800-1200 mg/day	800-1200 mg/day	1200-1500 mg/day
Vitamins	Multivitamin/mineral supplementation to DRI levels; additional water- and fat-soluble vitamins as indicated	Multivitamin/mineral supplementation to DRI levels; additional water- and fat-soluble vitamins as indicated	Multivitamin/mineral supplementation to DRI levels

*Use estimated dry or ideal weight.

DRI, Dietary reference intake.

PHYSIOLOGY AND FUNCTIONS OF THE GALLBLADDER

The gallbladder lies on the undersurface of the right lobe of the liver (Fig. 28.6). The main function of the gallbladder is to concentrate, store, and excrete bile, which is produced by the liver. During the concentration process, water and electrolytes are resorbed by the gallbladder mucosa. Bile is composed of bile salts and excretory endogenous and exogenous compounds. Other components include fatty acids, cholesterol, phospholipids, bilirubin, protein, and other compounds. Bile salts are made by liver cells from cholesterol and are essential for the digestion and absorption of fats, fat-soluble vitamins, and some minerals (see Chapter 1). Bilirubin, the main bile pigment, is derived

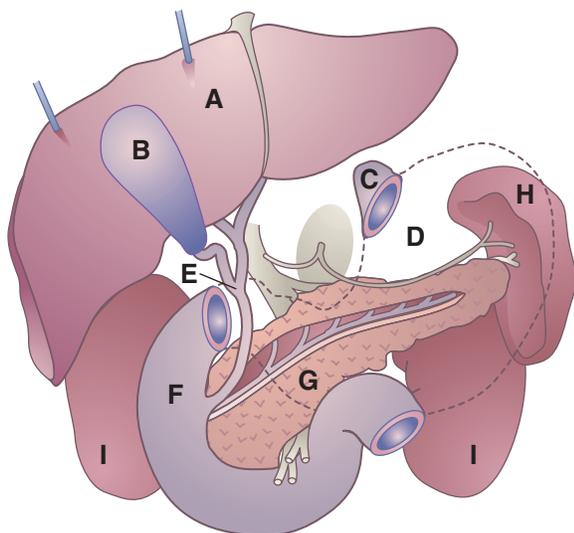

Fig. 28.6 Schematic drawing showing relationship of organs of the upper abdomen. **A**, Liver (retracted upward); **B**, gallbladder; **C**, esophageal opening of stomach; **D**, stomach (shown in dotted outline); **E**, common bile duct; **F**, duodenum; **G**, pancreas and pancreatic duct; **H**, spleen; **I**, kidneys. (Courtesy Cleveland Clinic, Cleveland, Ohio, 2002.)

from the release of hemoglobin from red blood cell destruction. It is transported to the liver, where it is conjugated and excreted via bile.

The primary transporter responsible for bile salt secretion is the bile salt export pump (BSEP). Overall, bile salts play a key role in a wide range of physiologic and pathophysiologic processes (Kubit et al, 2012). Excreted into the small intestine via bile, bile salts are later resorbed into the portal system (enterohepatic circulation). This is the primary excretory pathway for the minerals copper and manganese.

Bile contains immunoglobulins that support the integrity of the intestinal mucosa. Fibroblast growth factor receptor (FGFR4) controls bile acid metabolism and protects the liver from fibrosis; FGFR1 and FGFR2 assist in regeneration of the liver (Böhm et al, 2010). Molecular crosstalk between bile acid-activated nuclear receptors and proinflammatory nuclear mediators provides new understanding of inflammation-induced cholestasis (Kosters and Karpen, 2010; Lam et al, 2010).

Bile is removed by the liver via bile canaliculi that drain into intrahepatic bile ducts. The ducts lead to the left and right hepatic ducts, which leave the liver and join to become the common hepatic duct. The bile is directed to the gallbladder via the cystic duct for concentration and storage. The cystic duct joins the common hepatic duct to form the common bile duct. The bile duct then joins the pancreatic duct, which carries digestive enzymes.

During the course of digestion, food reaches the duodenum, causing the release of intestinal hormones such as cholecystokinin (CCK) and secretin. This stimulates the gallbladder and pancreas and causes the sphincter of Oddi to relax, allowing pancreatic juice and bile to flow into the duodenum at the ampulla of Vater to assist in fat digestion. For this reason diseases of the gallbladder, liver, and pancreas often are interrelated.

DISEASES OF THE GALLBLADDER

Disorders of the biliary tract affect millions of people each year, causing significant suffering and even death by precipitating pancreatitis and sepsis. A diverse spectrum of disease affects the biliary system, often presenting with similar clinical signs and symptoms. Treatment may involve diet, medication, and/or surgery.

Cholestasis

Pathophysiology and Medical Management

Cholestasis is a condition in which little or no bile is secreted or the flow of bile into the digestive tract is obstructed. This can occur in patients without oral or enteral feeding for a prolonged period, such as those requiring PN, and can predispose to **acalculous cholecystitis**, an inflammatory disease of the gall bladder without evidence of gallstones or cystic duct obstruction. BSEP is the major transporter for the secretion of bile acids from the hepatocytes into bile. BSEP deficiency results in several different genetic forms of cholestasis and acquired forms of cholestasis such as drug-induced cholestasis and intrahepatic cholestasis of pregnancy (Lam et al, 2010). Prevention of cholestasis requires stimulation of biliary motility and secretions by at least minimum enteral feedings. If this is not possible, drug therapy is used.

Cholelithiasis

Pathophysiology

The formation of gallstones (**calculi**) is known as **cholelithiasis**. Virtually all gallstones form within the gallbladder. Gallstone disease affects millions of Americans each year and can cause significant health risks. In most cases gallstones are asymptomatic. Gallstones that pass from the gallbladder into the common bile duct may remain there indefinitely without causing symptoms, or they may pass into the duodenum with or without symptoms.

Choledocholithiasis develops when stones slip into the bile ducts, producing obstruction, pain, and cramps. If passage of bile into the duodenum is interrupted, **cholecystitis**, inflammation of the gallbladder, can develop. In the absence of bile in the intestine, lipid absorption is impaired, and without bile pigments, stools become light in color (acholic). If uncorrected, bile backup can result in jaundice and liver damage (**secondary biliary cirrhosis**). Obstruction of the distal common bile duct can lead to pancreatitis if the pancreatic duct is blocked.

Most gallstones are unpigmented cholesterol stones composed primarily of cholesterol, bilirubin, and calcium salts. Bacteria also play a role in gallstone formation. Low-grade chronic infections produce changes in the gallbladder mucosa, which affect its absorptive capabilities. Excess water or bile acid may be absorbed as a result. Cholesterol may then precipitate out and cause gallstones (Njeze, 2013).

There are numerous risk factors that may predispose an individual to gallstone formation (Stinton et al, 2010). Some of these are modifiable, others are not (Table 28.7) High dietary fat intake over a prolonged period may predispose a person to gallstone formation because of the constant stimulus to produce more cholesterol for bile

synthesis required in fat digestion. Rapid weight loss (as with jejunioileal and gastric bypass surgery and fasting or severe calorie restriction) is associated with a high incidence of biliary sludge and gallstone formation. Indeed, cholelithiasis and fatty liver disease share risk factors, including central obesity, insulin resistance, and diabetes mellitus (Koller et al, 2012; Weikert et al, 2010).

Risk factors for cholesterol stone formation include female gender, pregnancy, older age, family history, obesity and truncal body fat distribution, diabetes mellitus, inflammatory bowel disease, and drugs (lipid-lowering medications, oral contraceptives, and estrogens). Certain ethnic groups are at greater risk of stone formation, including Native Americans, Scandinavians, and Mexican Americans. In addition, approximately 30% of individuals with cirrhosis have gallstones (Acalovschi, 2014).

Pigmented stones typically consist of bilirubin polymers or calcium salts. They are associated with chronic hemolysis. Risk factors associated with these stones include older age, sickle cell anemia, thalassemia, biliary tract infection, cirrhosis, alcoholism, and long-term PN.

Medical and Surgical Management

Cholecystectomy is surgical removal of the gallbladder, especially if the stones are numerous, large, or calcified. The cholecystectomy may be performed as a traditional open laparotomy or as a less invasive laparoscopic procedure.

Chemical dissolution with the administration of bile salts, chenodeoxycholic acid, and ursodeoxycholic acid (litholytic therapy), or dissolution by extracorporeal shockwave lithotripsy, may also be used less often than surgical techniques. Patients with gallstones that have migrated into the bile ducts may be candidates for a diagnostic procedure using X-ray called endoscopic retrograde cholangiopancreatography.

Medical Nutrition Therapy

The role of diet in the pathogenesis of gallstones and therefore treatment recommendations remains unclear. Obesity is a risk factor, but the exact composition of the diet that results in gallstones is less clear. Diets high in cholesterol and fat seem to increase the risk of cholelithiasis. In contrast, unsaturated fats, coffee, fiber, ascorbic acid (vitamin C), calcium, and moderate consumption of alcohol reduce the risk (Shaffer, 2006).

There also may be some benefit in replacing simple sugars and refined starches with high-fiber carbohydrates. Individuals consuming refined carbohydrates have a 60% greater risk for developing gallstones, compared with those who consumed the most fiber, in particular insoluble fiber (Mendez-Sanchez et al, 2007). Thus plant-based diets may reduce the risk of cholelithiasis. Vegetarian diets are high in fiber and low in fat, consisting primarily of unsaturated fat. Vitamin C, which is generally high in vegetarian diets, affects the rate-limiting step in the catabolism of cholesterol to bile acids and inversely is related to the risk of gallstones, especially in women.

Weight cycling (repeatedly losing and regaining weight), fasting, and very-low-calorie diets increase the likelihood of cholelithiasis. Along with weight reduction, some evidence indicates that physical activity reduces the risk of cholecystitis. In cholecystitis, MNT includes a high-fiber, low-fat, plant-based diet to prevent gallbladder contractions. Data are conflicting as to whether intravenous lipids stimulate gallbladder contraction.

After surgical removal of the gallbladder, oral feedings can be advanced to a regular diet as tolerated, although a lower fat diet with adequate soluble fiber may be important at first. In the absence of the gallbladder, bile is secreted directly by the liver into the intestine. The biliary tract dilates, forming a “simulated pouch” over time to allow bile to be held in a manner similar to the original gallbladder. Some patients may develop frequent loose, watery stools if they eat fatty meals during this adaptation time frame. In most cases, the diarrhea is temporary and self-limiting.

TABLE 28.7 Risk Factors for Gallstone Formation

Modifiable	Nonmodifiable
High-fat diet	Familial/genetics
Female sex hormone use	Ethnicity
Obesity/metabolic syndrome/diabetes	Female gender
Rapid weight loss	Increasing age
Physical inactivity	
Underlying disease: cirrhosis, Crohn's disease	
Drugs	
Parenteral nutrition	

Adapted from Stinton LM, Myers RP, Shaffer EA: Epidemiology of Gallstones, *Gastroenterol Clin North Am* 39:157–169, 2010; Shaffer EA: Gallstone disease: epidemiology of gallbladder stone disease, *Best Pract Res Clin Gastroenterol* 20(6):981–996, 2006.

Cholecystitis

Pathophysiology

Inflammation of the gallbladder is known as **cholecystitis**, and it may be chronic or acute. It usually is caused by gallstones obstructing the bile ducts (calculous cholecystitis), leading to the backup of bile. Bilirubin, the main bile pigment, gives bile its greenish color. When biliary tract obstruction prevents bile from reaching the intestine, it backs up and returns to the circulation. Bilirubin has an affinity for elastic tissues (such as the eye and the skin); therefore when it overflows into the general circulation, it causes the yellow skin pigmentation and eye discoloration typical of **jaundice**.

Acute cholecystitis without stones (acalculous cholecystitis) may occur in critically ill patients or when the gallbladder and its bile are stagnant. Impaired gallbladder emptying in chronic acalculous cholecystitis appears to be due to diminished spontaneous contractile activity and decreased contractile responsiveness to CCK. The walls of the gallbladder become inflamed and distended, and infection can occur. During such episodes, the patient experiences upper-quadrant abdominal pain accompanied by nausea, vomiting, and flatulence.

Chronic cholecystitis is longstanding inflammation of the gallbladder. It is caused by repeated, mild attacks of acute cholecystitis. This leads

to thickening of the walls of the gallbladder. The gallbladder begins to shrink and eventually loses the ability to perform its function: concentrating and storing bile. Eating foods that are high in fat may aggravate the symptoms of cholecystitis because bile is needed to digest such foods. Chronic cholecystitis occurs more often in women than in men, and the incidence increases after the age of 40. Risk factors include the presence of gallstones and a history of acute cholecystitis.

Surgical Management

Acute cholecystitis requires surgical intervention unless medically contraindicated. Without surgery, the condition may either subside or progress to gangrene.

Medical Nutrition Therapy

Acute cholecystitis. In an acute attack, oral feedings are temporarily discontinued. PN may be indicated if the patient is malnourished and it is anticipated that they will not be taking anything orally for a prolonged period. When feedings are resumed, a low-fat diet is recommended to decrease gallbladder stimulation. A hydrolyzed low-fat formula or an oral low-fat diet consisting of 30 to 45 g of fat per day can be given. [Table 28.8](#) shows a fat-restricted diet.

TABLE 28.8 Fat-Restricted Diet

Food Allowed	Food to Limit or Exclude
<p>Beverages</p> <p>Skim milk or buttermilk made with skim milk; coffee, tea, Postum, fruit juice, soft drinks, cocoa made with cocoa powder and skim milk</p>	Whole milk, buttermilk made with whole milk, chocolate milk, cream in excess of amounts allowed under fats
<p>Bread and Cereal Products</p> <p>Plain, nonfat cereals; spaghetti, noodles, rice, macaroni; plain whole grain or enriched breads, air-popped popcorn, bagels, English muffins</p>	Biscuits, breads, egg or cheese bread, sweet rolls made with fat; pancakes, doughnuts, waffles, fritters, popcorn prepared with fat; muffins, natural cereals and breads to which extra fat is added
<p>Cheese</p> <p>Fat-free or low-fat cottage cheese, $\frac{1}{4}$ c to be used as substitute for 1 oz of cheese, or low-fat cheeses containing less than 5% butterfat</p>	Whole-milk cheeses
<p>Desserts</p> <p>Sherbet made with skim milk; nonfat frozen yogurt; nonfat frozen nondairy desserts; fruit ice; sorbet; gelatin; rice, bread, cornstarch, tapioca, or pudding made with skim milk; fruit whips with gelatin, sugar, and egg white; fruit; angel food cake; graham crackers; vanilla wafers; meringues</p>	Cake, pie, pastry, ice cream, or any dessert containing shortening, chocolate, or fats of any kind, unless especially prepared using part of fat allowance
<p>Eggs</p> <p>Three per week prepared only with fat from fat allowance; egg whites as desired; low-fat egg substitutes</p>	More than one/day unless substituted for part of the meat allowed
<p>Fats</p> <p>Choose up to the limit allowed among the following (1 serving in the amount listed equals 1 fat choice):</p> <ul style="list-style-type: none"> 1 tsp butter or margarine 1 tsp shortening or oil 1 tsp mayonnaise 2 tsp Italian or French dressing 1 Tbsp reduced-fat salad dressing 1 strip crisp bacon $\frac{1}{8}$ avocado (4-inch diameter) 2 Tbsp light cream 1 Tbsp heavy cream 6 small nuts 5 small olives 	Any in excess of amount prescribed on diet; all others

Continued

TABLE 28.8 Fat-Restricted Diet—cont'd

Food Allowed	Food to Limit or Exclude	
Fruits As desired	Avocado in excess of amount allowed on fat list	
Lean Meat, Fish, Poultry, and Meat Substitutes Choose up to the limit allowed among the following: poultry without skin, fish, veal (all cuts), liver, lean beef, pork, and lamb, all with visible fat removed—1 oz cooked weight equals 1 equivalent; ¼ c water-packed tuna or salmon equals 1 equivalent; tofu or tempeh—3 oz equals 1 equivalent	Fried or fatty meats, sausage, scrapple, frankfurters, poultry skins, stewing hens, spare-ribs, salt pork, beef unless lean, duck, goose, ham hocks, pig's feet, luncheon meats (unless reduced fat), gravies unless fat free, tuna and salmon packed in oil, peanut butter	
Milk Skim, buttermilk, or yogurt made from skim milk	Whole, 2%, 1%, chocolate, buttermilk made with whole milk	
Seasonings As desired	None	
Soups Bouillon, clear broth, fat-free vegetable soup, cream soup made with skim milk, packaged dehydrated soups	All others	
Sweets Jelly, jam, marmalade, honey, syrup, molasses, sugar, hard sugar candies, fondant, gumdrops, jelly beans, marshmallows, cocoa powder, fat-free chocolate sauce, red and black licorice	Any candy made with chocolate, nuts, butter, cream, or fat of any kind	
Vegetables All plainly prepared vegetables	Potato chips; buttered, au gratin, creamed, or fried potatoes and other vegetables unless made with allowed fat; casseroles or frozen vegetables in butter sauce	
Daily Food Allowances for 40-g Fat Diet		
Food	Amount	Approximate Fat Content (g)
Skim milk	2 c or more	0
Lean meat, fish, poultry	6 oz or 6 equivalents	18
Whole egg or egg yolks	3 per week	2
Vegetables	3 servings or more, at least 1 or more dark green or deep yellow	0
Fruits	3 or more servings, at least 1 citrus	0
Breads, cereals	As desired, fat free	0
Fat exchanges*	4-5 exchanges daily	20-25
Desserts and sweets	As desired from permitted list	0
	Total Fat	38-43

*Fat content can be reduced further by reducing the fat exchanges. 1 fat exchange = 5 g of fat.

After cholecystectomy, patients may experience symptoms of gastritis secondary to duodenogastric reflux of bile acids. The reflux also may be responsible for symptoms in this **postcholecystectomy syndrome**. At present, there are no well-established pharmacologic approaches in the management of postcholecystectomy gastritis. The symptoms are not caused, but exacerbated, by the cholecystectomy. The use of ursodeoxycholic acid and various Chinese herbs have been suggested (Zhang et al, 2017). However, efficacy of their use is limited. The addition of soluble fiber to the diet may act as a sequestering agent and bind the bile in the stomach between meals to avoid gastritis.

Chronic cholecystitis. Patients with chronic conditions may require a long-term, low-fat diet that contains 25% to 30% of total kilocalories as fat (see Table 28.7). Stricter limitation is undesirable because fat in the intestine is important for some stimulation and drainage of the biliary tract. Additionally, saturated fats should be replaced with fish oil and polyunsaturated fats to reduce the risk of gallstone formation (Lee and Jang, 2012; Stinton et al, 2010; Berr et al, 1992). The degree of food intolerance varies widely among persons with gallbladder disorders; many complain of foods that cause flatulence and bloating. For this reason, it is best to determine with the patient which foods should be eliminated (see Chapter 27 for a discussion of potential gas-forming

foods). Administration of water-soluble forms of fat-soluble vitamins may be of benefit in patients with chronic gallbladder conditions or in those in whom fat malabsorption is suspected.

Cholangitis

Pathophysiology and Medical Management

Inflammation of the bile ducts is known as **cholangitis**. Patients with acute cholangitis need resuscitation with fluids and broad-spectrum antibiotics. If the patient does not improve with conservative treatment, placement of a percutaneous biliary stent or cholecystectomy may be needed.

Sclerosing cholangitis can result in sepsis and liver failure. Most patients have multiple intrahepatic strictures, which makes surgical intervention difficult, if not impossible. Patients are generally on broad-spectrum antibiotics. Percutaneous ductal dilation may provide short-term bile duct patency in some patients. When sepsis is recurrent, patients may require chronic antibiotic therapy (see Primary Sclerosing Cholangitis).

COMPLEMENTARY AND INTEGRATIVE MEDICINE FOR GALLSTONES

Patients often seek complementary and integrative approaches to gallbladder disease, including various nutritional supplements, herbal medications, and gallbladder flushes. Vitamin C deficiency has been linked to gallstone formation in animal models (Jenkins, 1978). The data in humans are limited, but vitamin C supplementation has been associated with a decreased risk of gallstones in postmenopausal women who consume alcohol (Simon et al, 1998) and may protect against gallstones (Walcher et al, 2009). In a cross-sectional study of 582 elderly people, higher circulating levels of vitamin E was associated with a lower probability of gallstone disease (Waniek et al, 2018).

Choleretic (substances that increase the volume of secretion of bile from the liver) herbs such as milk thistle, dandelion root, artichoke, turmeric, greater celandine, and Oregon grape stimulate bile flow and reduce the amount of cholesterol in bile. Various herbs have been suggested as treatment options for cholestasis and other hepatobiliary disorders (Spiridonov, 2012). However, data from well-conducted randomized controlled trials is limited.

The use of acupuncture has been proposed for the treatment of gallstones (Moga, 2003). It is thought that acupuncture aids in the removal of stones. However, it may be that acupuncture aids in the relief of pain more so than the removal of stones.

PHYSIOLOGY AND FUNCTIONS OF THE EXOCRINE PANCREAS

The pancreas is an elongated, flattened gland that lies in the upper abdomen behind the stomach. The head of the pancreas is in the right upper quadrant below the liver within the curvature of the duodenum, and the tapering tail slants upward to the hilum of the spleen (see Fig. 28.6). This glandular organ has an endocrine and exocrine function. Pancreatic cells manufacture glucagon, insulin, and somatostatin for absorption into the bloodstream (endocrine function) for regulation of glucose homeostasis (see Chapter 29). Other cells secrete enzymes and other substances directly into the intestinal lumen, where they aid in digesting proteins, fats, and carbohydrates (exocrine function).

In most people, the pancreatic duct, which carries the exocrine pancreatic secretions, merges with the common bile duct into a unified opening through which bile and pancreatic juices drain into the duodenum at the ampulla of Vater. Many factors regulate exocrine

secretion from the pancreas. Neural and hormonal responses play a role, with the presence and composition of ingested foods being a large contributor. The two primary hormonal stimuli for pancreatic secretion are secretin and CCK (see Chapter 1).

Factors that influence pancreatic secretions during a meal can be divided into three phases: (1) the cephalic phase, mediated through the vagus nerve and initiated by the sight, smell, taste, and anticipation of food that leads to the secretion of bicarbonate and pancreatic enzymes; (2) gastric distention with food initiates the gastric phase of pancreatic secretion, which stimulates enzyme secretion; and (3) the intestinal phase, mediated by the release of CCK, with the most potent effect.

DISEASES OF THE EXOCRINE PANCREAS

Pancreatitis

Pathophysiology and Medical Management

Pancreatitis is an inflammation of the pancreas and is characterized by edema, cellular exudate, and fat necrosis. The disease can range from mild and self-limiting to severe, with tissue autodigestion, necrosis, and hemorrhage of pancreatic tissue. Various prognostic scoring systems have been developed such as Ranson, acute physiology and chronic health evaluation (APACHE)-II, bedside index for severity in acute pancreatitis (BISAP) scores, and computed tomography severity index (CTSI) (Banks et al, 2013; Ranson, 1974; Larvin and McMahon, 1989; Balthazar et al, 1990; Wu et al, 2008; Petrov et al, 2009). These can help predict the mortality of acute pancreatitis (Cho et al, 2015). There may be differences in these scores but they help to predict the severity of the disease. Pancreatitis is classified as either acute or chronic, the latter with pancreatic destruction so extensive that exocrine and endocrine function are severely diminished, and maldigestion and diabetes mellitus may result.

The symptoms of pancreatitis can range from continuous or intermittent pain of varying intensity to severe upper abdominal pain, which may radiate to the back. Symptoms may worsen with the ingestion of food. Clinical presentation also may include nausea, vomiting, abdominal distention, and steatorrhea. Severe cases are complicated by hypotension, oliguria, and dyspnea. There is extensive destruction of pancreatic tissue with subsequent fibrosis, enzyme production is diminished, and serum amylase and lipase may appear normal. However, absence of enzymes to aid in the digestion of food leads to steatorrhea and malabsorption. Table 28.9 describes several tests used to determine the extent of pancreatic destruction.

TABLE 28.9 Some Tests of Pancreatic Function

Test	Significance
Secretin stimulation test	Measures pancreatic secretion, particularly bicarbonate, in response to secretin stimulation
Glucose tolerance test	Assesses endocrine function of the pancreas by measuring insulin response to a glucose load
72-hr stool fat test	Assesses exocrine function of the pancreas by measuring fat absorption that reflects pancreatic lipase secretion
Fecal elastase	Enzyme most commonly used to determine pancreatic function; indirect test. Levels >200 mcg/g are considered normal; concentration <15 mcg/g of feces consistent with pancreatic exocrine insufficiency

Medical Nutrition Therapy

Alcohol use, smoking, body weight, diet, genetic factors, and medications affect the risk of developing pancreatitis. Thus diet modification has an important role after diagnosis. Dietary recommendations differ, depending on whether the condition is acute or chronic. Obesity appears to be a risk factor for the development of pancreatitis and for increased severity (Martinez et al, 2004; Katuchova et al, 2014).

Depressed serum calcium levels are common. Hypoalbuminemia occurs, with subsequent edema (also known as third spacing of fluid). The calcium, which is bound to albumin, is thus affected and may appear artificially low. Another occurrence is “soap” formation in the gut by calcium and fatty acids, created by the fat necrosis that results in less calcium absorption. Checking an ionized calcium level is a method of determining available calcium.

Acute pancreatitis. Pain associated with acute pancreatitis (AP) is partially related to the secretory mechanisms of pancreatic enzymes and bile. Therefore, nutrition therapy is adjusted to provide minimum stimulation of these systems (International Association of Pancreatology, 2013) (see *Pathophysiology and Care Management Algorithm: Pancreatitis*). The basis for nutrition therapy is to put the pancreas “at rest.” In patients with AP, early (within 24 hours) oral feeding as tolerated should be initiated rather than keeping the patient nil per os (NPO, nothing by mouth) (Crockett et al, 2018; Vege et al, 2018). Success of early feeding has been demonstrated using a variety of diets, including low fat, normal fat content, and soft or solid consistency, and thus starting with a clear liquid diet is not required (Lankisch et al, 2015). Early feeding is not successful in all AP due to pain, vomiting, or ileus (lack of peristalsis in the gut), and feeding may need to be delayed beyond 24 hours in some cases. Some patients who are intolerant of oral feeding may require placement of an enteral tube for nutritional support. The diet usually is progressed as tolerated to easily digested foods with a low-fat content with more fat added as tolerated. Foods may be better tolerated if they are divided into six small meals (see Table 28.8).

Severe acute pancreatitis (SAP) results in a hypermetabolic, catabolic state with immediate metabolic alterations in the pancreas and in remote organs. Metabolic demands are similar to those of sepsis. Amino acids are released from muscle and used for gluconeogenesis. These patients often exhibit signs of stress-induced malnutrition such as decreased serum levels of albumin, transferrin, and lymphocytes reflecting the inflammatory response (see Chapter 7). SAP is associated with significant morbidity and mortality. These patients often develop complications such as fluid collections, pseudocysts, pancreatic necrosis, and infection or multisystem organ failure.

The optimal route and timing of nutrition in SAP has been the subject of much controversy. PN and EN are equally effective in terms of days to normalization of serum amylase levels, days to resumption of oral feeding, days to clear nosocomial infections, and the clinical outcome in patients with mild to moderate pancreatitis (Wu et al, 2014). The favorable effect of either EN or PN on patient outcome may be enhanced by supplementation with modulators of inflammation such as arginine, glutamine, omega-3 fatty acids, or probiotics and systemic immunity (McClave et al, 2006; McClave et al, 2016) (see Chapter 7). However, failure to use the GIT in patients with SAP may exacerbate the stress response and disease severity, leading to more complications and prolonged hospitalization; thus EN is preferred for nutrition therapy (Al-Omran et al, 2010; McClave, 2013; Mirtallo et al, 2012; Crockett et al, 2018; Vege et al, 2018). Some data support the use of early EN in AP (Zou et al, 2014). In a meta-analysis of observational data from individuals with AP, starting EN within 24 hours after hospital admission, compared with after 24 hours, was associated with a reduction in complications (Bakker et al, 2014). Early EN in patients with AP may reduce length of hospital stay without adverse events for patients with mild to moderate pancreatitis (Vaughn et al, 2017). In

another meta-analysis, early EN was associated with a significant decrease in the incidence of multiple organ failure but was not significant for other complications and mortality compared with delayed EN (Feng et al, 2017).

Nasogastric EN has been shown to be efficacious in SAP (Nally et al, 2014). However, to minimize pancreatic stimulation it is best to place jejunal feeding tubes endoscopically as far down the intestine as possible, generally more than 40 cm past the ligament of Treitz (O’Keefe et al, 2001).

EN results in a substantial cost savings with fewer septic complications and overall reduction of morbidity and mortality (Petrov et al, 2008; Sun et al, 2013). The location of the feeding and the composition of the formula is thought to determine the degree of pancreatic stimulation. Infusion into the jejunum eliminates the cephalic and gastric phases of exocrine pancreatic stimulation which is optimal in AP. The use of jejunal feedings may be better tolerated and allow for an increase in the amount of nutrition that is delivered in the face of AP. However, no controlled trial has clearly demonstrated a significant improvement of feeding tolerance, mortality, or length of intensive care unit (ICU) stay with the use of jejunal feeding compared with gastric feedings (Zhang et al, 2013). Because the placement of a nasogastric feeding tube is easier than a jejunal tube, it is reasonable to consider gastric feedings for AP and reserve jejunal feedings for those who are intolerant to gastric feeding (Petrov, 2014). For those patients with SAP complicated by organ failure, pancreatic necrosis, or fluid collections, nasojejunal feeding is the preferred method of delivery (Seminario and O’Keefe, 2014) to minimize pancreatic stimulation (see Chapter 12 for jejunal feeding details).

Although various formulations have been used in pancreatitis, no studies have determined the relative merits of standard, partially digested, elemental, or “immune-enhanced” formulations. Polymeric formulas infused at various sections of the gut stimulate the pancreas more than elemental and hydrolyzed formulas. Peptide-based formula can be used safely and standard formulas can be tried if the patient is tolerant (Mirtallo et al, 2012). Close observation for patient tolerance is important. Tolerance may be enhanced with the use of supplemental pancreatic enzymes during enteral feeding (Berry, 2014). These can be provided by mouth, mixed with water and delivered via the feeding tube, or added directly to the enteral formula. An enteral in-line lipase cartridge is also available which has been shown to hydrolyze a majority of the fat in EN formulas to monoglycerides and free fatty acids (Freedman, 2017). When the patient is allowed to eat, supplemental pancreatic enzymes may also be required to treat steatorrhea. In severe, prolonged cases, PN may be necessary.

Patients with mild to moderate stress can tolerate dextrose-based solutions, whereas patients with more severe stress require a mixed fuel system of dextrose and lipid to avoid complications of glucose intolerance. Lipid emulsion should not be included in a PN regimen if hypertriglyceridemia is the cause of the pancreatitis (Patel et al, 2014). A serum triglyceride level should be obtained before lipid-containing PN is initiated. Lipids may be should only given to patients with triglyceride values less than 400 mg/dL. Because of the possibility of pancreatic endocrine abnormalities and a relative insulin resistance, close glucose monitoring also is warranted. H₂-receptor antagonists may be prescribed to decrease hydrochloric acid production, which reduce stimulation of the pancreas. The hormone somatostatin is considered the best inhibitor of pancreatic secretion and may be used in conjunction with PN.

Chronic pancreatitis. In contrast to SAP, chronic pancreatitis (CP) evolves insidiously over many years. CP is characterized by recurrent attacks of epigastric pain of long duration that may radiate into the back. The pain can be precipitated by meals. Associated nausea, vomiting, or diarrhea make it difficult to maintain adequate nutrition status (Verhaegh et al, 2013).

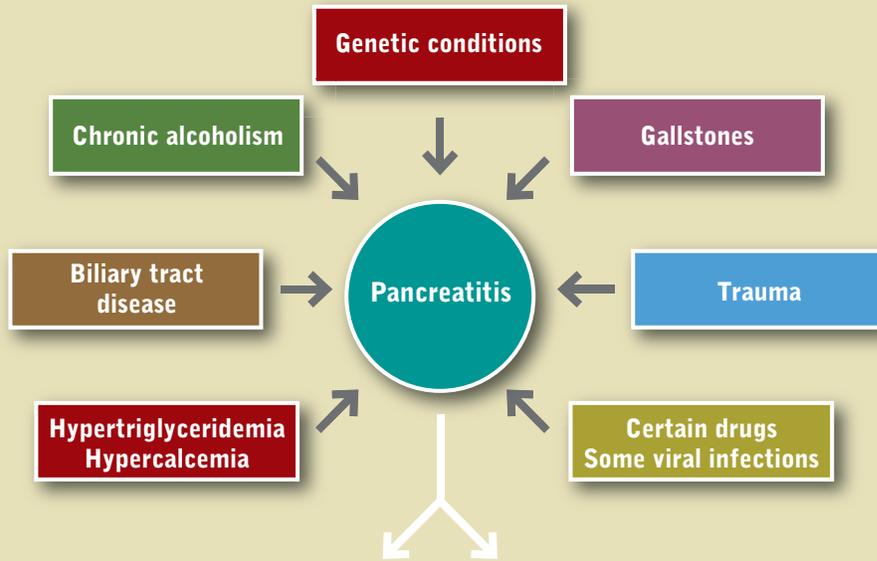

Patients with CP are at increased risk of developing protein-calorie malnutrition because of pancreatic insufficiency and inadequate oral

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Pancreatitis

ETIOLOGY

PATHOPHYSIOLOGY

Diagnosis

I: Apply Ranson’s criteria
 II: Tests of pancreatic function
 Secretin stimulation test
 Glucose tolerance test
 72-hour stool fat test
 Fecal elastase

Clinical Findings

Symptoms:

- Abdominal pain and distention
- Nausea
- Vomiting
- Steatorrhea

In severe form:

- Hypotension
- Oliguria
- Dyspnea

MANAGEMENT

Medical Management

Acute:

- Withhold oral feeding
- Give IV fluids
- Administer H₂-receptor antagonists, somatostatin

Chronic:

- Manage intestinal pH with:
 - Antacids
 - H₂-receptor antagonists
 - Proton pump inhibitors
- Administer insulin for glucose intolerance

Nutrition Management

Acute:

- Withhold oral and enteral feeding
- Support with IV fluids
- If oral nutrition cannot be initiated in 5 to 7 days, start tube feeding
- Once oral nutrition is started, provide
 - Easily digestible foods
 - Low-fat diet
 - 6 small meals
 - Adequate protein intake
 - Increased calories

Chronic:

- Provide oral diet as in acute phase
- Tube feeding (TF) can be used when oral diet is inadequate or as a treatment to reduce pain
- Prescription pancreatic enzymes
- Supplement fat-soluble vitamins and vitamin B₁₂

intake. Patients with CP admitted to a tertiary care center usually have malnutrition, increased energy requirements, weight loss, deficits of lean muscle and adipose tissue, visceral protein depletion, impaired immune function, and vitamin deficiencies (Duggan et al, 2014).

The objective of therapy for patients is to prevent further damage to the pancreas, decrease the number of attacks of acute inflammation, alleviate pain, decrease steatorrhea, and correct malnutrition. Dietary intake should be as liberal as possible, but modifications may be necessary to minimize symptoms.

The first goal of MNT is to provide optimal nutrition support, and the second is to decrease pain by minimizing stimulation of the exocrine pancreas. Because CCK stimulates secretion from the exocrine pancreas, one approach is to decrease CCK levels. If postprandial pain is a limiting factor, alternative enteral therapies, such as feeding beyond the ligament of Treitz, that minimally stimulate the pancreas are warranted. Nutrition counseling, antioxidants, and pancreatic enzymes may play a role in effective management of CP as well (Afghani et al, 2014).

When pancreatic function is diminished by approximately 90%, enzyme production and secretion are insufficient; maldigestion and malabsorption of protein and fat thus become a problem. In general, large meals with high-fat foods and alcohol should be avoided. However, there is a lot of variation among these patients and the diet should be liberalized as much as possible. For example, a gradual increase in the amount of fat and size of the meal is possible in some patients.

The patient may present with weight loss despite adequate energy intake and will complain of bulky, greasy stools. This is definitely the case with idiopathic CP associated with a cystic fibrosis gene mutation; therapies directed toward cystic fibrosis may benefit these patients (see Chapter 33). Of these therapies, pancreatic enzyme replacement has been shown to be efficacious (de la Iglesia-Garcia et al, 2016). Pancreatic enzyme replacements are given orally with meals; the dosage should be at least 30,000 units of lipase with each meal. To promote weight gain, the level of fat in the diet should be the maximum a patient can tolerate without increased steatorrhea or pain.

Additional therapies to maintain nutrition status and minimize symptoms in patients with maximum enzyme supplementation include a lower-fat diet (40 to 60 g/day) (see Table 28.7) or substitution of some dietary fat with MCT oil to improve fat absorption and weight gain (see Chapter 12). A lower-fat diet, primarily from vegetable-based oils such as olive oil may help reduce pain and ease nausea as well as eating small frequent meals. Trans fatty acids, found in commercially baked goods and other processed foods, can increase inflammation and are not recommended.

Malabsorption of the fat-soluble vitamins may occur in patients with significant steatorrhea. Also, deficiency of pancreatic protease, necessary to cleave vitamin B₁₂ from its carrier protein, potentially could lead to vitamin B₁₂ deficiency. Appropriate supplemental enzyme therapy will improve vitamin absorption; however, the patient should continue to be monitored periodically for vitamin deficiencies. Water-miscible forms of the fat-soluble vitamins or parenteral administration of vitamin B₁₂ may be necessary. Some evidence indicates that increasing intake of antioxidants (found in fruits and vegetables) may help protect against pancreatitis or alleviate symptoms of the condition (Ahmed et al, 2014).

Because pancreatic bicarbonate secretion is frequently defective, medical management also may include maintenance of an optimal intestinal pH to facilitate enzyme activation. Antacids, H₂-receptor antagonists, or proton pump inhibitors that reduce gastric acid secretion may be used to achieve this effect.

In CP with extensive pancreatic destruction, the insulin-secreting capacity of the pancreas decreases, and glucose intolerance develops. Treatment with insulin and nutrition therapy is then required (see

Chapter 29). Management is delicate and should focus on control of symptoms rather than normoglycemia.

Effort should be made to cater to the patient's tolerances and preferences for nutritional management; however, alcohol is discouraged because of the possibility of exacerbating the pancreatic disease. There is evidence that the progressive destruction of the pancreas will be slowed in the alcoholic patient who abstains from alcohol (Nordback et al, 2008; Yadav et al, 2009).

COMPLEMENTARY AND INTEGRATIVE MEDICINE FOR PANCREATIC DISORDERS

The role of complementary and integrative medicine in the treatment of pancreatic disorders remains unclear (Saxena et al, 2014). Over the counter digestive enzymes are sometimes used with pancreatic disease, but their use is not supported by evidenced-based research, the composition is often not guaranteed due to the way they are regulated, they can be costly, and they are often inactivated in the stomach due to the pH. The standard of care in pancreatic disease is prescription pancreatic enzymes such as Creon (Natural Medicines Database, 2019). There is little to no research on integrative approaches for pancreatic disease. In China, there are some studies involving herbal preparations, many of which are not readily available in other countries. Some of the studies are non-randomized and non-controlled. For traditional Chinese interventions, consider referring patients to a licensed Chinese medicine provider or licensed acupuncturist. Because chronic pancreatitis is an inflammatory condition, one of the most common integrative approaches is a nutritionally adequate anti-inflammatory diet (see Appendix 22 and chapter 7), although there is no direct scientific evidence supporting its use in the medical literature. Some studies suggest melatonin may have a protective effect and may alter the disease progression (Belyaev et al, 2011; Jaworek et al, 2012; Jin et al, 2013). See chapter 11 for more information about safely recommending dietary and herbal supplements.

PANCREATIC SURGERY

A surgical procedure often used for pancreatic carcinoma is a **pancreaticoduodenectomy (Whipple procedure)**, in which distal segment (antrum) of the stomach, the first and second portions of the duodenum, the head of the pancreas, the common bile duct, and the gallbladder are removed. The basic concept behind the pancreaticoduodenectomy is that the head of the pancreas and the duodenum share the same arterial blood supply (the gastroduodenal artery). These arteries run through the head of the pancreas, so both organs must be removed if the single blood supply is severed. If only the head of the pancreas were removed, it would compromise blood flow to the duodenum, resulting in tissue necrosis. A cholecystectomy, vagotomy, or a partial gastrectomy also may be performed during the surgery. The pancreatic duct is reanastomosed (reattached) to the jejunum. Partial or complete pancreatic insufficiency can result, depending on the extent of the pancreatic resection. Most patients who have undergone pancreatic resection are at risk for vitamin and mineral deficiencies and will benefit from vitamin and mineral supplementation. Nutrition care is similar to that for CP.

Pancreatic and Islet Cell Transplantation

There have been significant improvements in the outcomes of patients undergoing pancreatic transplants or pancreatic transplants combined with a kidney transplant (Dean et al, 2017; Laftavi et al, 2017). In

patients with unstable (brittle) diabetes mellitus who suffer from bouts of hyper- and hypoglycemia, transplantation can restore normal glucose homeostasis and prevent, halt, or reverse the progression of secondary complications (Dunn, 2014; Gruessner and Gruessner, 2013).

Pancreatic islet allotransplantation is a procedure in which islets from the pancreas of a deceased organ donor are purified, processed, and transferred into a recipient. It is performed in certain patients with type 1 diabetes mellitus whose blood glucose levels are extremely labile and difficult to control. **Pancreatic islet autotransplantation** is performed after total pancreatectomy in patients with severe and chronic, or long-lasting, pancreatitis that cannot be managed by other treatments. After pancreatectomy, islets are extracted and purified from the pancreas. The islets then are infused through a catheter into the liver. The goal is to give the body enough healthy islets to make insulin. A person who receives a pancreatic islet cell transplant should follow a meal plan designed for a person with diabetes mellitus if hyperglycemia is present. Some patients undergoing this procedure will achieve normoglycemia without exogenous insulin (see Chapter 29). Immunosuppressive medications are required for allo- but not autotransplantation; these medications can contribute to weight gain, hypertension, dyslipidemia, and labile blood glucose levels (Chhabra and Brayman, 2014).

Although pancreas transplantation has been favored for β -cell replacement, with improved outcomes following islet transplantation, the use of this minimally invasive therapy in carefully selected patients should be considered (Wisel et al, 2016; Hatipoglu, 2016; Markmann et al, 2016). Pancreas transplant remains the procedure of choice for β -cell replacement in uremic patients. Islet transplantation should be considered in nonuremic patients with low body mass index (BMI) and low insulin requirements, patients lacking the cardiovascular reserve to undergo open abdominal surgery, or patients who elect to forego the risks of a major operation in exchange for an increased risk of islet graft failure.

CLINICAL CASE STUDY 1

A 62-year-old white man is admitted to the hospital from the doctor's office with altered mental status. Past medical history reveals cirrhosis resulting from hepatitis C, esophageal varices, hepatic encephalopathy, and ascites. The patient reports missing his doses of lactulose the two previous days. Muscle wasting is noted in the form of squared shoulders, prominent clavicle, temporal wasting, and thin extremities. He has 3+ pitting edema in his lower extremities and a protuberant abdomen from ascites. His abnormal laboratory values on admission included elevated liver function enzymes and total bilirubin, sodium 127 mEq/L, glucose 68 mg/dL. Nutritional data include height, 177.8 cm; weight, 71.8 kg; dry weight, 75 kg; recent body weight range due to fluid fluctuations, 63.6 kg to 90.9 kg.

Nutrition Diagnostic Statements

- Involuntary weight loss related to cirrhosis as evidenced by 4.5% weight loss (based on dry weight) and physical signs of malnutrition.
- Altered laboratory values related to cirrhosis as evidenced by hyponatremia and hypoglycemia.

Interventions

- Initiate 2 g sodium diet with small, frequent meals.
- Ensure adequate kcals and protein.
- Fluid restriction (coordinate care with medical team).
- Initiate commercial beverage twice daily.

Monitoring and Evaluation

- Monitor food and beverage intake.
- Assess food and nutrition knowledge.
- Assess adherence to prescribed diet.

CLINICAL CASE STUDY 2

A 42-year-old Hispanic female presents with a history of chronic pancreatitis resulting from pancreatic divisum (a congenital abnormality in which there are two pancreatic ducts instead of one). The patient has had multiple hospitalizations for acute pancreatitis. Despite placement of pancreatic stents, she has developed chronic pancreatitis (confirmed by abnormal endoscopic ultrasound and low fecal elastase) and depends on chronic pain medications. She presents for evaluation of total pancreatectomy with islet autotransplantation. The patient is thin, with apparent muscle wasting, and reports that she is very fatigued and no longer able to work because of chronic pain. She describes chronic abdominal pain that worsens with eating so that she is only drinking clear soft drinks throughout the day and eating only one small meal per day. She often is constipated, but this can alternate with diarrhea with greasy, foul-smelling loose stools. Her nutritional data include height, 160 cm; weight, 40.5 kg; usual body weight, 54.5 kg (1 year ago). Her 25-hydroxy vitamin D level is <10 ng/mL.

Nutrition Diagnostic Statements

- Involuntary weight loss due to pain with eating as evidenced by 31-lb weight loss / 74% usual body weight (UBW).
- Altered nutrition-related laboratory values due to malabsorption as evidenced by vitamin D level less than 10 ng/mL.

Interventions

- Insert feeding tube (for supplemental nocturnal nutrition).
- Nutrition-related medication management (start pancreatic enzymes with meals).
- Initiate vitamin D supplement.
- Interview patient and family about culturally acceptable foods.

Monitoring and Evaluation

- Monitor total energy intake and body weight.
- Monitor enteral intake—formula/solution (for tolerance and adequacy).
- Monitor vitamin A, D, E levels.

Medical Nutrition Therapy for Diabetes Mellitus and Hypoglycemia of Nondiabetic Origin

Jessica Jones, MS, RDN, CDE

KEY TERMS

acanthosis nigricans	honeymoon phase	maturity onset diabetes of youth (MODY)
amylin	hyperglycemia	metabolic syndrome
autonomic symptoms	hyperglycemic hyperosmolar state (HHS)	microvascular diseases
basal or background insulin dose	hypoglycemia (or insulin reaction)	neuroglycopenic symptoms
C-peptide	hypoglycemia of nondiabetic origin	normoglycemia
carbohydrate counting	immune-mediated diabetes mellitus	polydipsia
continuous glucose monitoring (CGM)	impaired fasting glucose (IFG)	polyphagia
correction factor (CF)	impaired glucose tolerance (IGT)	polyuria
counterregulatory (stress) hormones	incretins	postprandial (after a meal) blood glucose
dawn phenomenon	insulin	postprandial (reactive) hypoglycemia
diabetic ketoacidosis (DKA)	insulin deficiency	prediabetes
fasting hypoglycemia	insulin resistance	preprandial (fasting/premeal) blood glucose
fasting plasma glucose (FPG)	insulin secretagogues	self-monitoring of blood glucose (SMBG)
gastroparesis	insulin to carbohydrate ratio	Somogyi effect

glycemic index (GI)	macrocosmia	
glycemic load (GL)	macrovascular diseases	
glycosylated hemoglobin (A1C)		

For most people, eating carbohydrate foods will cause blood sugar levels to rise. However, the difference between people with diabetes and those without the disease is how high the blood sugar rises, and for how long.

Diabetes mellitus is a group of diseases characterized by prolonged high blood glucose concentrations. The cause of high blood glucose—also known as **hyperglycemia**—is the result of defects in insulin secretion, insulin action, or both. **Insulin**, a hormone produced by the beta-cells of the pancreas, is necessary for the use or storage of macronutrients (think carbohydrate, protein, and fat). Since people with diabetes do not produce adequate insulin—and/or have some degree of insulin resistance—hyperglycemia occurs.

Diabetes mellitus contributes to a considerable increase in morbidity and mortality, which can be reduced by early diagnosis and treatment. Direct medical expenditures such as inpatient care, outpatient services, and nursing home care are astronomical, and indirect costs such as disability, work loss, and premature mortality are equally high. Research estimates that the total costs of diagnosed diabetes have risen to \$327 billion in 2017 from \$245 billion in 2012 (Yang et al, 2018).

Thus providing medical nutrition therapy (MNT) for prevention and treatment of diabetes has tremendous potential to reduce these costs. Fortunately, people with diabetes can take steps to control the disease and lower the risk of complications or premature death.

INCIDENCE AND PREVALENCE

It is estimated that 9.4% of the U.S. population is living with diabetes. In 2017 total prevalence of diabetes in the United States in all ages was 30.3 million people (15.3 million adult men and 14.9 adult women), or 9.4% of the population. Of these, 23.1 million are diagnosed and 7.2 million are undiagnosed. In 2015 an estimated 1.5 million new cases of diabetes were diagnosed in people age 18 years or older (Centers for Disease Control and Prevention [CDC], 2017a). Diabetes prevalence also increases with age, affecting 12 million people age 65 years and older, or 39.7% of all people in this age group.

Much of the increase in prevalence is because the prevalence of type 2 diabetes is increasing dramatically in younger age groups in the last decade, especially in minority populations. Among youth with newly diagnosed diabetes, approximately 23% have type 2 diabetes (Mayer-Davis et al, 2017). The prevalence of type 2 diabetes is highest in ethnic groups in the United States. Data indicate in people aged 20 years or older, 15.1% of American Indians and Alaska Natives, 12.7% of non-Hispanic blacks,

Portions of this chapter were written by Marion J Franz, MS, RDN, LD, CDE and Alison B Evert, MS, RDN, CDE for the previous edition of this text.

12.1% of Hispanics, and 8.0% of Asian Americans had diagnosed diabetes. Among Hispanics, rates were 13.8% for Mexicans, 12% for Puerto Ricans, and 9% for Cubans. Of great concern are the 84.1 million people (34% of adults 18 years or older and 48.3% of adults 65 years or older) with prediabetes, which includes impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) (CDC, 2017a). All are a high risk for conversion to type 2 diabetes and cardiovascular disease (CVD) if lifestyle prevention strategies are not implemented.

CATEGORIES OF GLUCOSE INTOLERANCE

Assigning a type of diabetes to an individual often depends on the circumstances present at the time of diagnosis, and many individuals do not easily fit into a single category. What is essential is the need to intercede early with lifestyle interventions, beginning with prediabetes and continuing through the disease process.

Prediabetes

Individuals with a stage of impaired glucose homeostasis that includes **impaired fasting glucose (IFG)** and **impaired glucose tolerance (IGT)** are referred to as having prediabetes, indicating their relatively high risk for the development of diabetes and CVD. **Prediabetes** is diagnosed with at least one of the following: IFG (fasting plasma glucose 100 to 125 mg/dL), IGT (2-hour postchallenge glucose of 140 to 199 mg/dL), both, or a hemoglobin A1C of 5.7% to 6.4%. Individuals diagnosed with prediabetes and should be counseled about effective diabetes prevention strategies, such as eating a balanced diet and increasing physical activity, to lower their risks (American Diabetes Association [ADA], 2018).

Type 1 Diabetes

The ADA estimates that about 1.25 million Americans have type 1 diabetes (ADA, 2018). At diagnosis, people with **type 1 diabetes mellitus (T1DM)** often experience excessive thirst, frequent urination, and significant weight loss. The primary defect is pancreatic beta-cell destruction, usually leading to absolute **insulin deficiency** and resulting in hyperglycemia, **polyuria** (excessive urination), **polydipsia** (excessive thirst), **polyphagia** (excessive hunger), unexpected weight loss, dehydration, electrolyte disturbance, and **diabetic ketoacidosis (DKA)**—a serious complication of diabetes characterized by extreme hyperglycemia and a buildup of ketones in the blood and urine. The rate of beta-cell destruction is variable, proceeding rapidly in infants and children and slowly in others (mainly adults.) The capacity of a healthy pancreas to secrete insulin is far in excess of what is needed normally. Therefore the clinical onset of diabetes may be preceded by an extensive asymptomatic period of months to years, during which beta-cells are undergoing gradual destruction.

T1DM accounts for 5% of all diagnosed cases of diabetes (CDC, 2017a). People with T1DM are dependent on exogenous insulin—meaning insulin produced outside of the body—to prevent ketoacidosis and death. T1DM can develop at any age. Although more cases are diagnosed in people before the age of 30 years, it also occurs in older individuals. Most individuals are lean but some are diagnosed without any (or with more subtle) symptoms and may be at a higher weight.

T1DM has two forms: immune-mediated and idiopathic (ADA, 2018). **Immune-mediated diabetes mellitus** results from an autoimmune destruction of the beta-cells of the pancreas, the only cells in the body that make the hormone insulin. Idiopathic T1DM refers to forms of the disease that have no known etiology. Although only a minority of individuals with T1DM fall into this category, of those who do, most are of African or Asian ancestry (ADA, 2018). At this time there is no known cure for T1DM.

Since autoimmune thyroid disease and celiac disease occur with increased frequency in people with T1DM, the ADA suggests screening for thyroid disease in people diagnosed with T1DM. Other autoimmune conditions, such as celiac disease, Addison's disease, autoimmune hepatitis, autoimmune gastritis, dermatomyositis, and myasthenia gravis, also occur more commonly in people with T1DM compared with the general pediatric population. Individuals with celiac disease that has been confirmed by a biopsy should be placed on a gluten-free diet by a registered dietitian nutritionist (RDN) experienced in managing diabetes and celiac disease (ADA, 2018).

Pathophysiology

As mentioned previously, people with T1DM experience destruction of the pancreatic beta cells, which results in decreased insulin production and prolonged elevation of blood glucose levels. Markers of the immune destruction of the beta-cells include islet cells autoantibodies; autoantibodies to insulin; autoantibodies to glutamic acid decarboxylase (GAD65) (a protein on the surface of the beta-cells); and autoantibodies to the tyrosine phosphatases IA-2, IA-2beta, and ZnT8. T1DM is defined by the presence of one or more of these autoimmune markers. It is important to note that T1DM also has strong genetic factors, which involve the association between T1DM and histocompatibility locus antigen (HLA) with linkage to the DQA and DQB and the DRB genes. These HLA-DR/DQ alleles can be either predisposing or protective (ADA, 2018). In T1DM, the rate of clinical beta-cell destruction is variable, being rapid in some individuals (mainly infants and children) and slow in others (mainly adults). Children and adolescents, for example, may present with DKA as the first manifestation of the disease. Adults can often retain sufficient b-cell function to prevent DKA for many years. Note that although T1DM commonly occurs in childhood and adolescence, it can occur at any age (ADA, 2018).

Frequently after diagnosis and the correction of hyperglycemia, metabolic acidosis, and ketoacidosis, endogenous insulin secretion—or insulin secreted inside the body—recovers. During this **honeymoon phase**, exogenous (outside the body) insulin requirements decrease dramatically for up to 1 year or longer, and good metabolic control may be easily achieved (Fonolleda et al, 2017). However, the need for increasing exogenous insulin replacement is inevitable and always should be anticipated. Intensive insulin therapy along with attention to MNT and self-monitoring of glucose from early diagnosis has been shown to prolong insulin secretion. One study found that children who were diagnosed with T1DM early in life—specifically before the age of 7 years—had a much greater loss of β -cells compared with those who are diagnosed with the illness in their teenage years or beyond (Leete et al, 2016).

Latent autoimmune diabetes of the adult (LADA)—also known as type 1.5 diabetes—is an autoimmune diabetes that occurs in adulthood. It is defined by adult-onset, presence of diabetes associated autoantibodies, and no insulin treatment requirement for a period after diagnosis. With genetic features of both type 1 and type 2 diabetes, LADA is the most prevalent form of adult-onset autoimmune diabetes (and possibly the most common form of autoimmune diabetes in general). LADA may be controlled initially with nutrition therapy, but within a relatively short period of time glucose-lowering medication and progression to insulin treatment are required (Laugesen et al, 2015).

Type 2 Diabetes

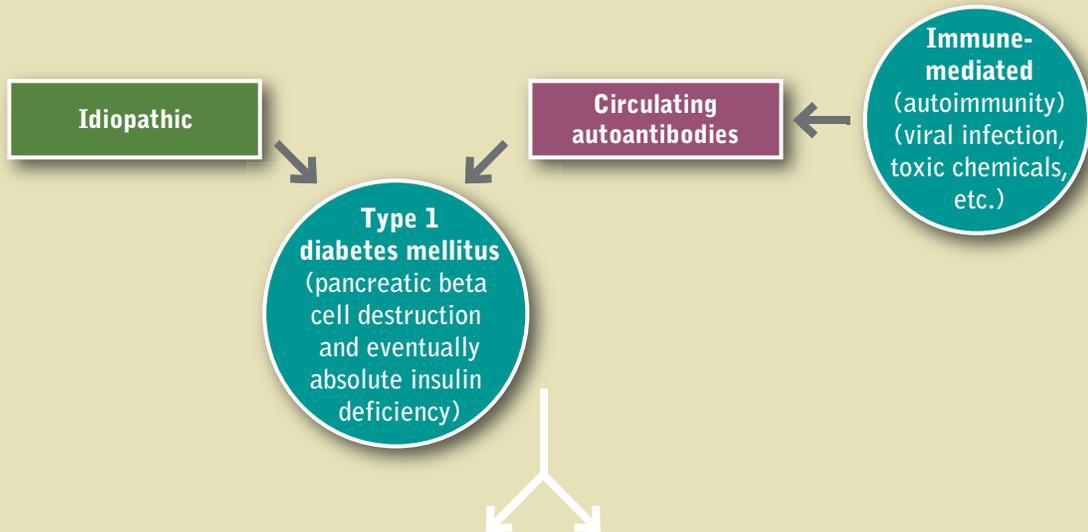

Type 2 diabetes mellitus (T2DM) accounts for 90% to 95% of all diagnosed cases of diabetes and is a progressive disease that, in many cases, is present long before it is diagnosed (ADA, 2018). Hyperglycemia develops gradually and is often not severe enough in the early stages for the person to notice any of the classic symptoms of diabetes. Although undiagnosed, these individuals are at increased risk of developing macrovascular and microvascular complications (CDC, 2017a).

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Type 1 Diabetes Mellitus

ETIOLOGY

PATHOPHYSIOLOGY

Symptoms

- Hyperglycemia
- Excessive thirst
- Frequent urination
- Significant weight loss
- Electrolyte disturbances

Complications

Ketoacidosis

Macrovascular diseases

- Coronary heart disease
- Peripheral vascular disease
- Cerebrovascular disease

Microvascular diseases

- Retinopathy
- Nephropathy

Neuropathy

MANAGEMENT

Medical Management

Medical nutrition therapy

Medications

- Insulin by injection or insulin infusion pumps

Monitoring

- Self-monitoring of blood glucose (SMBG)
- A1C testing
- Lipids
- Blood pressure
- Ketones
- Weight and growth in children

Self-management education

Medical Nutrition Therapy (MNT)

- Integrate insulin regimen into preferred eating and physical activity schedule; consistency in timing and amount of carbohydrate eaten if on fixed insulin doses
- Adjust premeal insulin dose based on insulin-to-carbohydrate ratios
- Adequate energy and nutrient intake to promote growth and development in children
- Cardioprotective nutrition interventions

Most people with T2DM are obese (defined as body mass index [BMI] >30 kg/m²), yet most obese individuals do not develop T2DM. Being at a higher weight may increase insulin resistance and can contribute to the destruction of the pancreatic beta-cells; however the exact mechanism of action remains unclear. Therefore obesity combined with a genetic predisposition may be necessary for T2DM to occur. Other risk factors include genetic and environmental factors, including a family history of diabetes, older age, physical inactivity, a prior history of gestational diabetes, prediabetes, hypertension or dyslipidemia, and race or ethnicity (Eckel et al, 2011).

Pathophysiology

T2DM is characterized by a combination of **insulin resistance** (decreased tissue sensitivity or responsiveness to insulin) and beta-cell failure. Endogenous insulin levels may be normal, depressed, or elevated, but they are inadequate to overcome concomitant insulin resistance. As a result, hyperglycemia ensues. At the time T2DM is diagnosed, there is an estimated 24% to 65% reduction in beta-cell function (Chen et al, 2017).

Insulin resistance is demonstrated first in target tissues, mainly muscle, liver, and adipose cells. Initially there is a compensatory increase in insulin secretion (hyperinsulinemia), which maintains glucose concentrations in the normal or prediabetic range. However, in many people, the pancreas is unable to continue to produce adequate insulin, which results in chronic hyperglycemia followed by a diabetes diagnosis.

Hyperglycemia is first exhibited as an elevation of **postprandial (after a meal) blood glucose** caused by insulin resistance at the cellular level and is followed by an elevation in fasting glucose concentrations. As insulin secretion decreases, hepatic glucose production increases, causing the increase in **preprandial (fasting/premeal) blood glucose levels**. The insulin response is also inadequate in suppressing alpha-cell **glucagon** secretion, resulting in glucagon hypersecretion and increased hepatic glucose production. Compounding the problem is **glucotoxicity**, the deleterious effect of hyperglycemia on insulin sensitivity and insulin secretion; hence the importance of achieving near-euglycemia in people with T2DM (Hædersdal et al, 2018).

Insulin resistance also is demonstrated at the adipocyte level, leading to lipolysis and an elevation in circulating free fatty acids. In particular, excess intraabdominal obesity, characterized by an excess accumulation of visceral fat around and inside abdominal organs, results in an increased flux of free fatty acids to the liver, leading to an increase in insulin resistance. Increased fatty acid levels (**lipotoxicity**) also cause a further decrease in insulin sensitivity at the cellular level, impair pancreatic insulin secretion, and disrupt hepatic glucose production. The above defects contribute to the development and progression of T2DM and are also primary targets for pharmacologic therapy.

People with T2DM may or may not experience the classic symptoms of uncontrolled diabetes (polydipsia, polyuria, polyphagia, weight loss) and they are not prone to develop ketoacidosis except during times of severe stress. The progressive loss of beta-cell secretory function means that people with T2DM require more medication(s) over time to maintain the same level of glycemic control; eventually exogenous insulin will be required. Insulin is also required sooner for control during periods of stress-induced hyperglycemia, such as during illness or surgery.

If at diagnosis it is not clear whether T1DM or T2DM is present, **C-peptide** may be measured. When the pancreas produces insulin, it begins as a large molecule—proinsulin. This molecule splits into two equal-sized pieces: insulin and C-peptide. A person with T1DM has a

low level of C-peptide, whereas as a person with T2DM can have a normal or high level of C-peptide. As T2DM progresses, C-peptide also may be measured to see if endogenous insulin is still being produced by the pancreas. If it is not, exogenous insulin is needed (Leighton et al, 2017).

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is a type of diabetes that occurs during pregnancy. About 2% to 10% of all pregnancies in the United States are affected by this condition (CDC, 2017b). Gestational diabetes increases a mother's risk of both hypertension during pregnancy and having a large baby requiring a cesarean section (C-section). Gestational diabetes also increases the baby's risk of premature labor (causing breathing and other problems), having low blood sugar, and developing diabetes later in life. Women of low socioeconomic status and those of Hispanic, Native American, Asian, and African American descent are more likely to experience GDM (Phelan, 2016).

For many women, blood sugar levels will revert back to normal after pregnancy. Others will end up developing diabetes. It is estimated that 15% to 25% of women with prior GDM will develop T2DM within 1 to 2 years after pregnancy, and that 35% to 70% will develop T2DM 10 to 15 years after pregnancy (Phelan, 2016).

Treatment for GDM includes checking blood sugar regularly (and making sure the numbers are within a healthy range), eating a balanced diet, being active (regular, moderate physical activity is recommended), and monitoring the baby's growth and development. Most women will be able to manage GDM with lifestyle changes, but some will require medications to achieve optimal blood glucose ranges (Kelley et al, 2015). Insulin is the preferred agent for management of both T1DM and T2DM in pregnancy because it does not cross the placenta. Furthermore, oral agents, such as metformin, are typically not sufficient in overcoming the insulin resistance in T2DM and are ineffective in T1DM (ADA, 2018). Previously GDM was defined as any degree of glucose intolerance with onset or first recognition during pregnancy. However, the number of pregnant women with undiagnosed diabetes has increased, and therefore it has now been recommended that women with risk factors for diabetes should be screened for undiagnosed T2DM at the first prenatal visit, using standard diagnostic criteria. Women found to have diabetes in the first trimester should receive a diagnosis of overt, not gestational, diabetes (ADA, 2018).

All women not previously known to have diabetes should be screened for GDM at 24 to 28 weeks of gestation. GDM is diagnosed most often during the second or third trimester of pregnancy because of the increase in insulin-antagonist hormone levels and insulin resistance that normally occurs at this time. Laboratory assessment of hemoglobin A1C, previously known as Hb A1C, at 24 to 28 weeks of gestation as a screening for GDM does not function as well as the glucose tolerance test (GTT). GDM screening can be accomplished with either of two strategies (for more details, see Table 14.5 in Chapter 14):

1. "One-step" 75-g oral glucose tolerance test (OGTT) or
2. "Two-step" approach with a 50-g (nonfasting) screen followed by a 100-g OGTT for those who screen positive.

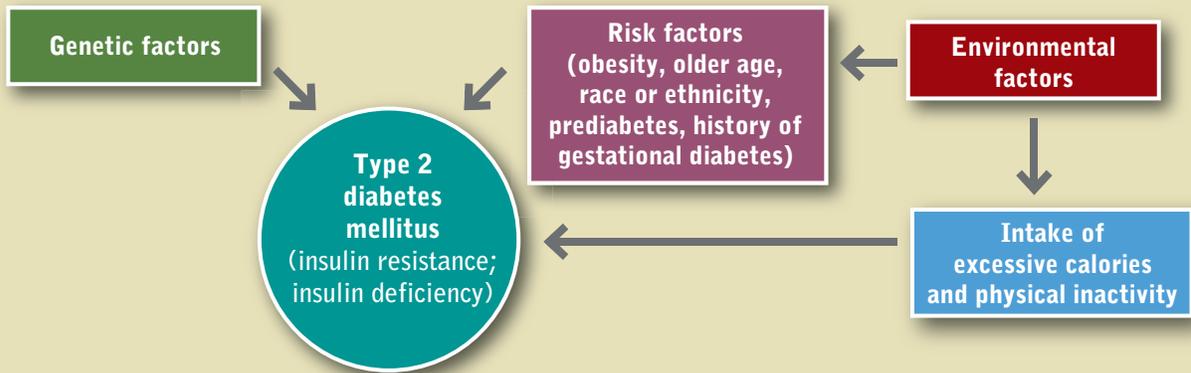

For a comprehensive multisystem checklist for people with diabetes, please refer to the document *American Diabetes Association Standards of Medical Care in Diabetes*, which is published yearly online for free.

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Type 2 Diabetes Mellitus

ETIOLOGY

PATHOPHYSIOLOGY

Symptoms (variable)

- Hyperglycemia
- Fatigue
- Excessive thirst
- Frequent urination

Clinical Findings

- Abnormal patterns of insulin secretion and action
- Decreased cellular uptake of glucose and increased postprandial glucose
- Increased release of glucose by liver (gluconeogenesis) resulting in fasting hyperglycemia
- Central obesity
- Hypertension
- Dyslipidemia

MANAGEMENT

Medical Management

Medical nutrition therapy

Physical activity

Medications

- Glucose-lowering medications
- Insulin

Monitoring

- Self-monitoring of blood glucose (SMBG)
- A1C testing
- Lipids
- Blood pressure
- Weight

Self-management education

Medical Nutrition Therapy (MNT)

- Lifestyle strategies (food/eating and physical activity) that improve glycemia, dyslipidemia, and blood pressure
- Nutrition education (regular balanced meal pattern, carbohydrate counting, fat modification) and counseling for health behavior change
- Blood glucose monitoring to determine adjustments in food or medications
- Cardioprotective nutrition interventions

During pregnancy, treatment to normalize maternal blood glucose levels reduces the risk of adverse maternal, fetal, and neonatal outcomes. Extra glucose from the mother crosses the fetal placenta and the fetus' pancreas responds by releasing extra insulin to cope with the excess glucose. The excess glucose is converted to fat, which results in **macrosomia** (a larger than normal baby). The fetus may become too large for a normal birth resulting in the need for C-section. Neonatal hypoglycemia at birth is another common problem. The above-normal levels of maternal glucose have caused the fetus to produce extra insulin. However, after birth the extra glucose is no longer available to the fetus, but until the pancreas can adjust, the neonate may require extra glucose through intravenous feedings for a day or two to keep blood glucose levels normal.

GDM does not cause congenital anomalies. Such malformations occur in women with diabetes before pregnancy who have uncontrolled blood glucose levels during the first 6 to 8 weeks of pregnancy when fetal organs are being formed. Because GDM does not appear until later in pregnancy, the fetal organs were formed before hyperglycemia became a problem.

When optimal blood glucose levels are not being maintained with MNT or the rate of fetal growth is excessive, pharmacologic therapy is needed (ADA, 2018). Research supports the use of insulin, insulin analogs, metformin, and glyburide during pregnancy. Women with GDM should be screened for diabetes 4 to 12 weeks postpartum and should have lifelong screening for the development of diabetes or prediabetes at least every 3 years (ADA, 2018). See Table 29.1 for a criteria for the diagnosis of diabetes and prediabetes.

Other Types of Diabetes

This category includes diabetes associated with specific genetic syndromes (such as neonatal diabetes and **maturity onset diabetes of youth (MODY)**), genetic defects in insulin action, diseases of the exocrine pancreas (such as cystic fibrosis), endocrinopathies, (such as acromegaly or Cushing's syndrome), drug or chemical induced (such as in the treatment of HIV/AIDS or after organ transplantation), infections, and other illnesses. Monogenic defects that cause b-cell dysfunction, such as neonatal diabetes and MODY, represent a small fraction of patients with diabetes (<5%) (ADA, 2018).

SCREENING AND DIAGNOSTIC CRITERIA

Screening for Diabetes

1. Testing should be considered in overweight or obese (BMI greater than or equal to 25 kg/m² or greater than or equal to 23 kg/m² in Asian Americans) adults who have one or more of the following risk factors:
 - First-degree relative with diabetes
 - High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
 - History of CVD
 - Hypertension (greater than or equal to 140/90 mm Hg or on therapy for hypertension)
 - High-density lipoprotein (HDL) cholesterol level <35 mg/dL (0.90 mmol/L) and/or a triglyceride level >250 mg/dL (2.82 mmol/L)
 - Women with polycystic ovary syndrome (PCOS)
 - Physical inactivity
 - Other clinical conditions associated with insulin resistance (e.g., severe obesity; **acanthosis nigricans**, a condition in which dark raised areas appear on the sides of the neck and in body folds and creases).

TABLE 29.1 Criteria for the Diagnosis of Diabetes Mellitus and Increased Risk for Diabetes (Prediabetes)

Diagnosis	Criteria
Diabetes	A1C $\geq 6.5\%$ (≥ 48 mmol/mol). The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay.* OR FPG ≥ 126 mg/dL (≥ 7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hr.* OR 2-h PG ≥ 200 mg/dL (≥ 11.1 mmol/L) during an OGTT. The test should be performed as described by the WHO, using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.* OR In patients with classic symptoms of hyperglycemia or hyperglycemic crisis, a random PG ≥ 200 mg/dL (≥ 11.1 mmol/L)
Prediabetes*	FPG 100-125 mg/dL (5.6-6.9 mmol/L) (impaired fasting glucose) OR 2-h PG during 75-g OGTT 140-199 mg/dL (7.8-11.0 mmol/L) (impaired glucose tolerance) OR A1C 5.7%-6.4% (39-47 mmol/mol)

*In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing.

*For all three tests, risk is continuous, extending below the lower limit of the range and becoming disproportionately greater at the higher end of the range.

DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; 2-h PG, 2-hour plasma glucose level (measured 2 hours after an oral glucose tolerance test [OGTT] with administration of 75 g of glucose); NGSP, National Glycohemoglobin Standardization Program; WHO, World Health Organization.

Modified from American Diabetes Association: Classification and of diabetes: standards of medical care in diabetes—2018, *Diabetes Care* 41(S1):S15-17, 2018.

2. Patients with prediabetes (A1C greater than or equal to 5.7% [39 mmol/mol], IGT, or IFG) should be tested yearly.
3. Women who were diagnosed with GDM should have lifelong testing at least every 3 years.
4. For all other patients, testing should begin at age 45 years.
5. If results are normal, testing should be repeated at a minimum of 3-year intervals, with consideration of more frequent testing depending on initial results and risk status.

Risk-based screening for T2DM or prediabetes in asymptomatic children and adolescents in a clinical setting (Persons aged <18 years):

Criteria

- Overweight (BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal for height)

Plus one or more additional risk factors based on the strength of their association with diabetes as indicated by evidence grades:

- Maternal history of diabetes or GDM during the child's gestation
- Family history of T2DM in first- or second-degree relative
- Race/ethnicity (Native American, African American, Latino, Asian American, Pacific Islander)
- Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, PCOS, or small-for-gestational-age birth weight) (ADA, 2018)

Diagnostic Criteria

There are four methods used to diagnose diabetes. In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing (ADA, 2018). Diagnostic criteria for diabetes and prediabetes are summarized in Table 29.1.

1. Fasting plasma glucose (FPG) 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours. (In the absence of unequivocal hyperglycemia, results should be confirmed by repeat testing [ADA, 2018].)
2. OR 2-h plasma glucose 200 mg/dL (11.1 mmol/L) during OGTT. The test should be performed as described by the World Health Organization (WHO), using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.*
3. OR A1C 6.5% (48 mmol/mol). The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the Diabetes Control and Complications Trial (DCCT) assay.*
4. OR in a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose <200 mg/dL (11.1 mmol/L).

Plasma glucose criteria, either the **fasting plasma glucose (FPG)** or the 2-hr plasma glucose after a 75-g OGTT, was the method usually used to diagnosis diabetes. However, the A1C assay now is highly standardized and is a reliable measure of chronic glucose levels. The A1C test reflects longer-term glucose concentrations and is assessed from the results of **glycosylated hemoglobin (A1C)** tests. When hemoglobin and other proteins are exposed to glucose, the glucose becomes attached to the protein in a slow, nonenzymatic, and concentration-dependent fashion (Fig. 29.1). Measurements of A1C therefore reflect a weighted average of plasma glucose concentration over the preceding weeks. In nondiabetic persons A1C values are 4% to 6%; these values correspond to mean blood glucose levels of about 70 to 126 mg/dL (3.9 to 7.0 mmol/L) (Table 29.2). A1C values vary less than FPG, and testing is more convenient because patients are not required to be fasting or to undergo an OGTT. However, A1C levels may vary with a person's race/ethnicity as glycation rates may differ by race (ADA, 2018). It is also unclear if the same A1C cutoff point should be used to diagnose children or adolescents with diabetes because studies used to recommend A1C to diagnose diabetes have all been performed in adult populations. For conditions with abnormal red cell turnover, such as hemolysis (blood loss), pregnancy, or iron deficiency, the diagnosis of diabetes must use glucose criteria exclusively (ADA, 2018). The A1C test should be performed using a method certified by the NGSP.

MANAGEMENT OF PREDIABETES

In no other disease does lifestyle—healthy food choices and physical activity—play a more important role in prevention and treatment than

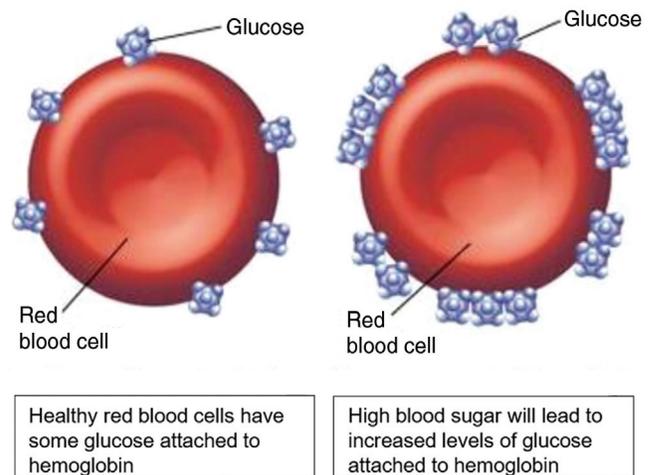

Fig. 29.1 Glycosylated Hemoglobin: Hemoglobin A1C. Glycosylated hemoglobin or A1C is the amount of glucose attached to the hemoglobin protein in a red blood cell. As blood sugar increases, the amount of glucose attached to hemoglobin increases. Because red blood cells last for 3 months in circulation, the A1C test is used to estimate average blood glucose over a 3-month time frame.

in diabetes. Studies comparing lifestyle modifications to medication have provided support for the benefit of weight loss (reduced energy intake) and physical activity as the first choice to prevent or delay diabetes. Clinical trials comparing lifestyle interventions to a control group have reported risk reduction for T2DM from lifestyle interventions ranging from 29% to 67% (Youssef, 2012). Two frequently cited

TABLE 29.2 A1C and Estimated Average Glucose

A1C (%)	Estimated Average Glucose (mg/dL)
4	68
4.5	82
5.0	97
5.5	111
6.0	126
6.5	140
7.0	154
7.5	169
8.0	183
8.5	197
9.0	212
9.5	226
10.0	240
10.5	255
11.0	269
11.5	283
12.0	298

The A1C test measures the percentage of red blood cells that have glucose bound to hemoglobin. This number correlates to blood glucose levels (mg/dL).

American Diabetes Association. *eAG / A1C Conversion Calculator* (website) https://professional.diabetes.org/diapro/glucose_calc.

studies are the Finnish Diabetes Prevention Study (FDPS) and the Diabetes Prevention Program (DPP), in which lifestyle interventions focused on a weight loss of 5% to 10%, physical activity of at least 150 min/week of moderate activity, and ongoing counseling and support. Both reported a 58% reduction in the incidence of T2DM in the intervention group compared with the control group and persistent reduction in the rate of conversion to T2DM within 3 to 14 years postintervention follow-up (DPP Research Group, 2009; Li et al, 2008; Lindström et al, 2006).

Medical Management

Use of the pharmacologic agents metformin, alpha-glucosidase inhibitors, orlistat, glucagon-like peptide-1 (GLP-1) receptor agonist, and thiazolidinediones has been shown to decrease incidence of diabetes by various degrees. However, none are approved by the U.S. Food and Drug Administration (FDA) specifically for diabetes prevention (ADA, 2018). Metformin has the strongest evidence base and has also demonstrated long-term safety as pharmacologic therapy for diabetes prevention. Keep in mind that diet and lifestyle modifications have been shown to be more effective than metformin when it comes to preventing and/or delaying diabetes (ADA, 2018).

Physical Activity

Physical activity helps to improve blood glucose control in T2DM, reduces cardiovascular risk factors, and may contribute to well-being. It is also important to note that physical activity, independent of weight loss, improves insulin sensitivity (ADA, 2018). Recommendations include moderate-intensity aerobic physical activity a minimum of 30 minutes 5 days per week (150 min/week) (i.e., walking 3 to 4 miles/hr) or vigorous-intensity aerobic physical activity a minimum of 20 minutes 3 days per week (90 min/week). Muscle-strengthening activities involving all major muscle groups two or more days per week are also recommended (U.S. Department of Health and Human Services and U.S. Department of Agriculture, 2015).

Medical Nutrition Therapy for Prediabetes

There is no one-size-fits-all meal plan for people living with prediabetes. One of the most important considerations for creating diabetes-centered goals around MNT is an emphasis on patient-centered care. This means the approach should be individualized and take into account a patient's health status, food preferences, food security, and housing situation (ADA, 2018). The ADA states that it is important to maintain the pleasure of eating by providing nonjudgmental messages about food choices. Adhering to a combination of healthy lifestyle habits (developing a healthy eating pattern, participating in regular physical activity, achieving and maintaining body weight goals, moderating alcohol intake, and being a nonsmoker) was shown to reduce the risk of developing T2DM by as much as 84% for women and 72% for men (Reis et al, 2011). More recently, moderate to high adherence to a Mediterranean-style eating pattern characterized by high levels of MUFAs such as olive oil, high intake of plant-based foods (vegetables, legumes, fruits, and nuts), moderate amounts of fish and wine, and a low intake of red and processed meat and whole-fat dairy products has been associated with a lower incidence of diabetes (Youssef, 2012; ADA, 2018).

In addition, whole grains and dietary fiber are associated with reduced risk of diabetes. Increased intake of whole grain-containing foods improves insulin sensitivity independent of body weight, and increased intake of dietary fiber has been associated with improved

insulin sensitivity and improved ability to secrete insulin adequately to overcome insulin resistance. Moderate consumption of alcohol (1 to 3 drinks per day [15 to 45 g alcohol]) is linked with decreased risk of T2DM, coronary heart disease, and stroke. But the data do not support recommending alcohol consumption to people at risk for diabetes who do not already drink alcoholic beverages.

High consumption of sugar-sweetened beverages, which includes soft drinks, fruit drinks, and energy and vitamin water-type drinks containing sucrose, high-fructose corn syrup, and/or fruit juice concentrates is associated with the development of T2DM (Malik et al, 2010). Studies also have reported that an eating pattern high in saturated fatty acids and trans fatty acids is associated with increased markers of insulin resistance and risk for T2DM, whereas unsaturated fatty acid intake is associated inversely with risk of diabetes (Youssef, 2012). Therefore individuals at increased risk for T2DM should be encouraged to limit their intake of sugar-sweetened beverages and decrease saturated fat intake (ADA, 2018).

MANAGEMENT OF DIABETES

Achieving glycemic control is the most important MNT goal in people with diabetes. Two classic clinical trials have demonstrated beyond a doubt the clear link between glycemic control and the development of complications in people with both T1DM and T2DM. The first is the DCCT, which studied approximately 1400 people with T1DM. Each individual involved in the study was treated with either intensive (multiple injections of insulin or use of insulin infusion pumps guided by blood glucose monitoring results) or conventional (one or two insulin injections per day) regimens. A 30-year follow-up of the DCCT demonstrated that an intervention that aimed to achieve **normoglycemia**, as close to the nondiabetic range as safely possible, reduced all of the microvascular and cardiovascular complications of diabetes and should be implemented as early as possible after diagnosis (Nathan, 2014). Another study, known as the United Kingdom Prospective Diabetes Study (UKPDS), demonstrated conclusively that glucose and blood pressure control decreased the risk of long-term complications in T2DM (Holman et al, 2008). Both of these trials emphasize importance of nutrition therapy in achieving continued glycemic control.

Medical Management

The management of all types of diabetes includes MNT, physical activity, blood glucose monitoring, medications, and self-management education and support. An important goal of medical treatment is to provide the individual with diabetes with the necessary tools to achieve the best possible control of glucose, lipids, and blood pressure to prevent, delay, or manage the microvascular (diabetic nephropathy, neuropathy, and retinopathy) and macrovascular complications (coronary artery disease, peripheral arterial disease, and stroke) while minimizing hypoglycemia and excess weight gain. Insulin, the primary hormone in glucose control is also antidiabetic and anabolic and facilitates cellular transport (Table 29.3). In general, the **counterregulatory (stress) hormones** (glucagon, growth hormone, cortisol, epinephrine, and norepinephrine) have the opposite effect of insulin.

The ADA's glycemic treatment goals for people with diabetes are listed in Table 29.4. Achieving goals requires open communication between the health care provider and the individual with diabetes and appropriate self-management education. Patients can assess day-to-day glycemic control by **self-monitoring of blood glucose (SMBG)** and measurement of urine or blood ketones. Longer-term glycemic

TABLE 29.3 Action of Insulin on Carbohydrate, Protein, and Fat Metabolism

Effect	Carbohydrates	Protein	Fat
Anticatabolic (prevents breakdown)	Decreases breakdown and release of glucose from glycogen in the liver	Inhibits protein degradation, diminishes gluconeogenesis	Inhibits lipolysis, prevents excessive production of ketones and ketoacidosis
Anabolic (promotes storage)	Facilitates conversion of glucose to glycogen for storage in liver and muscle	Stimulates protein synthesis	Facilitates conversion of pyruvate to free fatty acids, stimulating lipogenesis
Transport	Activates the transport system of glucose into muscle and adipose cells	Lowers blood amino acids in parallel with blood glucose levels	Activates lipoprotein lipase, facilitating transport of triglycerides into adipose tissue

TABLE 29.4 Recommendations for Glycemic Control for Many Nonpregnant Adults With Diabetes

Glycemic Control	Criteria
A1C	<7.0% (<53 mmol/mol)*
Preprandial capillary plasma glucose	80-130 mg/dL* (4.4-7.2 mmol/L)
Peak postprandial capillary plasma glucose†	<180 mg/dL* (<10.0 mmol/L)

*More or less stringent glycemic goals may be appropriate for individual patients. Goals should be individualized based on duration of diabetes, age/life expectancy, comorbid conditions, known CVD or advanced microvascular complications, hypoglycemia unawareness, and individual patient considerations.

†Postprandial glucose may be targeted if A1C goals are not met despite reaching preprandial glucose goals. Postprandial glucose measurements should be made 1 to 2 h after the beginning of the meal, generally peak levels in patients with diabetes.

Modified from American Diabetes Association: Glycemic Targets: Standards of medical care in diabetes—2018, *Diabetes Care* 41(S1):S60, 2018.

control (3-month average) is assessed by A1C testing. Cardiovascular risk factors should be assessed at least annually in all patients with diabetes. These risk factors include hypertension, dyslipidemia, smoking, a family history of premature coronary disease, chronic kidney disease, and the presence of albuminuria (ADA, 2018).

Patients with T1DM or T2DM who have hypertension should be treated to achieve blood pressure targets that are greater than or equal to 140/90 mm Hg (ADA, 2018). The ADA states that in adults with diabetes, it is reasonable to obtain a lipid profile (total cholesterol, low-density lipoprotein [LDL] cholesterol, HDL cholesterol, and triglycerides) at the time of diagnosis, at the initial medical evaluation, and at least every 5 years thereafter in patients under the age of 40 years. In patients who have had the disease for a longer period of time (typically younger patients with youth-onset T1DM), more frequent lipid profiles may be preferred (ADA, 2018). Providers should consider intensifying lifestyle therapy and optimizing glycemic control for patients with elevated triglyceride levels (≥ 150 mg/dL [1.7 mmol/L]) and/or low HDL cholesterol (<40 mg/dL [1.0 mmol/L] for men, <50 mg/dL [1.3 mmol/L] for women) (ADA, 2018).

Optimal control of diabetes also requires the restoration of normal carbohydrate, protein, and fat metabolism. It is important that people with diabetes receive medical care from a team that ideally includes physicians, dietitians, nurses, pharmacists, and mental health

professionals with expertise in diabetes. Individuals with diabetes also must assume an active role in their care. For T1DM a flexible, individualized management program using the principles of intensive insulin therapy is essential. T2DM is a progressive disease. In this instance it is not the diet that fails; rather, the pancreas is no longer able to secrete enough insulin to maintain adequate glucose control. As the disease progresses, MNT alone is not enough to keep A1C level at 7% or less. Therapy must intensify over time. Medications, and eventually insulin, need to be combined with nutrition therapy for optimal blood glucose control. Through the collaborative development of individualized nutrition interventions and ongoing support of behavior changes, health care professionals can facilitate the achievement of health goals for the person with diabetes.

Medical Nutrition Therapy for Diabetes

MNT is integral to total diabetes care and management. To integrate MNT effectively into the overall management of diabetes requires an RDN who is knowledgeable and skilled in implementing current nutrition therapy recommendations into the medical management of diabetes. Often times, RDNs acquire a specialized diabetes certification, known as a Certified Diabetes Educator (CDE) credential. CDEs are health professionals who possess comprehensive knowledge of and experience in diabetes management and prevention.

MNT requires an individualized approach and effective nutrition, self-management education, counseling, and support. Monitoring glucose, A1C and lipid levels, blood pressure, weight, and quality-of-life issues is essential in evaluating the success of nutrition-related recommendations. Effective nutrition therapy interventions may be implemented in individualized sessions or in a comprehensive diabetes education program.

Since T2DM is a progressive disease, nutrition and physical activity interventions alone (i.e., without medications) are generally not adequate in maintaining glycemic control overtime. However, even after medications are initiated, nutrition therapy and proper education should continue to be an important component of the individualized treatment plan. For example, individuals with T1DM using multiple daily injections or continuous subcutaneous insulin infusion should focus on how to adjust insulin doses based on planned carbohydrate intake. For individuals using fixed daily insulin doses, carbohydrate intake on a day-to-day basis should be consistent with respect to time and amount. Retrospective studies reveal durable A1C reductions with these types of programs, with a significant improvement in quality of life over time. Finally, nutritional approaches for reducing CVD risk, including optimizing serum lipids and blood pressure, can effectively reduce CVD events and mortality (Evert et al, 2014).

The Academy of Nutrition and Dietetics (AND) published evidence-based nutrition practice guidelines (EBNPG) for T1DM and T2DM in adults in their Evidence Analysis Library and in print (AND, 2017; Franz et al, 2017). The ADA nutrition recommendations are published in a position statement and are summarized in their annual standards of care.

Goals and Desired Outcomes

The goals for MNT for diabetes emphasize the role of lifestyle in improving glucose control, lipid and lipoprotein profiles, and blood pressure. Goals of MNT are summarized in Box 29.1. Medicare reimburses qualified RDN providers for providing evidence-based MNT for diabetes management to eligible participants. Improving health through food choices and physical activity is the basis of all nutrition recommendations for the treatment of diabetes.

Besides being skilled and knowledgeable in assessing and implementing MNT, RDNs also must be aware of expected outcomes from MNT, when to assess outcomes, and what feedback (including recommendations) should be given to referral sources. Furthermore, the effect of MNT on A1C will be known by 6 weeks to 3 months, at which time the RDN must assess whether the goals of therapy have been met by changes in lifestyle or whether changes or additional medications are needed (Evert et al, 2014; AND, 2017).

Multiple research studies support MNT as an effective therapy in reaching diabetes treatment goals. MNT implemented by RDNs reduced A1C levels by 1.0% to 1.9% for people with T1DM and 0.3% to 2% for people with T2DM (ADA, 2018).

These outcomes are similar or greater to those from glucose-lowering medications. MNT also is reported to improve lipid profiles, decrease blood pressure, promote weight loss, decrease need for medications, and decrease risk of onset and progression to diabetes-related comorbidities. A variety of nutrition therapy interventions such as individualized MNT, portion control, sample menus, carbohydrate counting, exchange lists, simple meal plans, and low-fat vegan diets can be implemented (Franz and MacLeod, 2018). Individualized MNT, implemented in collaboration with the individual with diabetes, is essential because a variety of nutrition interventions are effective. A common focus of MNT for individuals with T2DM is reduced energy

intake. Additionally, MNT may encourage the consumption of dietary fiber from fruit, vegetables, whole grains and legumes due to their overall health benefits. Sodium may also be a nutrient of focus. The recommendation for the general public to reduce sodium to <2300 mg/day is also appropriate for people with diabetes. However, if the individual has both diabetes and hypertension, additional reductions in sodium intake may be indicated (Franz and MacLeod, 2018). For individuals with T1DM, a common focus is using carbohydrate counting to determine premeal insulin boluses (Franz et al, 2017).

Energy Balance and Weight

Children/Adolescents

Historically, achieving and maintaining body weight goals has been a focus of MNT for diabetes. This is particularly true for children with T1DM. Provision of adequate calories for normal growth and development for children and adolescents with T1DM is a key component of MNT. Therefore height and weight should be measured at each visit and tracked via appropriate height and weight growth charts (Chiang et al, 2018) (See Appendix 4).

For youth with T2DM, traditional nutrition therapy goals included prevention of excessive weight gain while encouraging normal linear growth. However, the 2016 American Academy of Pediatrics (AAP) guidelines recommended shifting the focus from weight to healthy lifestyle behaviors. The guidelines state that while obesity may be a risk factor for T2DM in youth, obesity prevention efforts may lead to the development of an eating disorder (Golden et al, 2016). Furthermore, longitudinal research found that children whose parents used restrictive feeding have a higher likelihood of eating in the absence of hunger and an elevated BMI later in childhood (Birch et al, 2003).

Adults

Overweight and obesity are common in people both at risk for and with T2DM. Some research suggests that reduced calorie intake can lead to reductions in A1C of 0.3% to 2.0% in adults with T2DM. If appropriate for the individual, a reduction in caloric intake may also lead to improvements in medication doses and quality of life (ADA, 2018). Similarly, weight loss interventions implemented in people with prediabetes and newly diagnosed with T2DM have been shown to be effective in improving glycemic control, but the benefit of weight loss interventions in T2DM of longer duration is mixed (Franz et al, 2017). Substantial evidence suggests that weight loss diets are not sustainable. A review of over 30 long-term studies concluded that the more diets an individual has tried, the more weight they regain (Mann et al, 2007).

Furthermore, the AND EBNPG reported that approximately half of the weight loss intervention studies in people with T2DM improved A1C at 1 year and one-half did not (AND, 2008a). In the weight loss studies lasting 1 year or longer reviewed by the ADA, only 2 study groups achieved weight losses of 5% or greater. The first were people newly diagnosed with T2DM who followed a Mediterranean-style eating pattern (−6.2 kg) and the second were those who participated in an intensive lifestyle intervention as part of the Look AHEAD (Action for Health in Diabetes) study (−8.4 kg) (Esposito et al, 2009; Look AHEAD Research Group, 2010). Other weight loss interventions resulted in weight losses of less than 5% (4.8 kg or less) at 1 year (Evert et al, 2013). Weight losses greater than 5% resulted in consistent improvements in A1C, lipids, and blood pressure; however, weight losses less than 5% did not result in consistent 1-year improvements in A1C,

BOX 29.1 Goals of Medical Nutrition Therapy That Apply to Adults With Diabetes

1. To promote and support healthful eating patterns, emphasizing a variety of nutrient-dense foods in appropriate portion sizes, to improve overall diet and specifically to:
 - Attain individualized glucose, blood pressure, and lipids goals
 - Achieve and maintain body weight goals
 - Delay or prevent complications of diabetes
2. To address individual nutrition needs based on personal and cultural preferences, health literacy and numeracy, access to healthful food choices, willingness and ability to make behavioral changes.
3. To maintain the pleasure of eating by providing positive messages about food choices while limiting food choices only when indicated by scientific evidence.
4. To provide the individual with diabetes with practical tools for day-to-day meal planning rather than focusing on individual macronutrients, micronutrients, or single foods.

Adapted from Evert AB et al: Nutrition therapy recommendations for the management of adults with diabetes, *Diabetes Care* 36:3821, 2013.

lipids, or blood pressure (AND, 2008a; Franz, 2013). One approach that has recently gained popularity within the dietetics community is the Health at Every Size (HAES) weight neutral paradigm, which focuses on health gain/promotion rather than weight loss. A systematic review of 16 studies looking at the impact of nondiet approaches (such as HAES) on attitudes, behaviors, and health outcomes found that nondiet interventions resulted in statistically significant improvements in disordered eating patterns, self-esteem, and depression. Additionally, none of the interventions resulted in significant weight gain or worsening of blood glucose levels, cholesterol, or blood pressure. In two of the studies, biochemical measures improved significantly compared with the control or diet group. The researchers did note that there were limitations due to the inconsistent definitions of nondiet approaches and the use of various assessment instruments to measure outcomes. However, they concluded that “because of the long-term ineffectiveness of weight-focused interventions, the psychological improvements seen in weight-neutral, nondiet interventions warrant further investigation” (Clifford et al, 2015). It is important to keep in mind that potential weight discrimination may have an effect on health outcomes. One study found that weight discrimination, or negative weight-related attitudes toward individuals at higher weights or obesity, exacerbated the effects of waist-to-hip ratio on A1C, such that people who had higher waist-to-hip ratios and reported weight discrimination had the highest A1C levels (Tsenkova et al, 2011). Therefore the RDN should collaborate with individuals who have diabetes to integrate nutrient-dense eating patterns (which may or may not lead to weight loss) and regular physical activity and should not make assumptions on eating habits and lifestyle patterns based on weight.

Bariatric Surgery

Bariatric surgery can be an effective weight loss treatment for severely obese patients with T2DM and can result in marked improvements in glycemia (Schauer et al, 2014). The ADA states that metabolic surgery should be recommended as an option to treat T2DM in appropriate surgical candidates with BMI greater than or equal to 40 kg/m² (BMI greater than or equal to 37.5 kg/m² in Asian Americans), regardless of the level of glycemic control or complexity of glucose-lowering regimens, and in adults with BMI 35.0–39.9 kg/m² (32.5–37.4 kg/m² in Asian Americans) when hyperglycemia is inadequately controlled despite lifestyle and optimal medical therapy (ADA, 2018). In 4434 adults with T2DM, gastric bypass surgery resulted in 68.2% initial complete diabetes remission within 5 years after surgery (Arterburn et al, 2013). However, 35.1% had redeveloped diabetes within the next 5 years and the median duration of remission was 8.3 years. Predictors of relapse were poor preoperative glycemic control, insulin use, and longer diabetes duration.

Macronutrient Percentages and Eating Patterns

Although numerous studies have attempted to identify the optimal percentages of macronutrients for the eating plan of persons with diabetes, review of the evidence shows clearly that there is not an ideal percentage of calories from carbohydrate, protein, and fat for all persons with diabetes (Evert et al, 2014). Macronutrient distribution should be based on an individualized assessment of current eating patterns, preferences, and metabolic goals. In addition to metabolic goals, the RDN should consider personal preferences (including tradition, culture, religion, health beliefs and goals, economics) when working with individuals to determine the best eating pattern for them (ADA, 2018). Individualization of the macronutrient composition will depend on the metabolic status of the

individual (including lipid profile, renal function) and/or personal food preferences.

The ADA also reviewed research on eating patterns (Mediterranean-style, vegetarian and vegan, low-fat, low-carbohydrate, and Dietary Approaches to Stop Hypertension [DASH]) implemented for diabetes management and concluded that a variety of eating patterns are acceptable (ADA, 2018). The RDN must take into consideration personal preferences and metabolic goals when recommending one eating pattern over another.

Although numerous factors influence glycemic response to foods, monitoring total grams of carbohydrates, whether by use of carbohydrate counting or experienced based estimation, remains a key strategy in achieving glycemic control (Evert et al, 2013). While some evidence suggests that the type of carbohydrate eaten may influence blood glucose levels, the total amount of carbohydrate eaten is the primary predictor of glycemic response. Day-to-day consistency in the amount of carbohydrate eaten at meals and snacks is reported to improve glycemic control, especially in persons on either MNT alone, glucose-lowering medications, or fixed insulin regimens. In people with T1DM or T2DM who are on insulin pump therapy, insulin doses should be adjusted to match carbohydrate intake (Evert et al, 2013).

Carbohydrate counting is an eating plan method based on the principle that all types of carbohydrate (except fiber) are digested, and that the majority of carbohydrates are absorbed into the bloodstream as molecules of glucose. Carbohydrate foods include starches, such as breads, cereals, pasta, rice, beans and lentils, starchy vegetables, crackers, and snack chips; fruits and fruit juices; milk, milk substitutes, and yogurt; and sweets and desserts. One carbohydrate exchange (or serving) is a portion of food containing 15 grams of carbohydrate (see Appendix 18).

It is important for the RDN to ensure that the individual with diabetes has an understanding of which foods contain carbohydrates and the relationship between carbohydrate intake and blood glucose levels. It is equally important for the RDN to avoid vilifying carbohydrates, which unfortunately occurs too frequently in health care centers that work with patients who have diabetes. The RDN's role should include helping the individual understand that carbohydrates are part of a healthy diet, and collaboratively create an eating plan that lists the number of carbohydrate choices recommended for meals and, if desired, snacks. Individuals are encouraged to keep protein and fat food sources as consistent as possible because they do not greatly affect blood glucose levels even though they require insulin for metabolism.

There are two main eating plans using carbohydrate counting. The first uses insulin-to-carbohydrate ratios to adjust premeal insulin doses for variable carbohydrate intake (physiologic insulin regimens). Note that the insulin-to-carbohydrate ratio is typically calculated by dividing 500 by the total daily dose of insulin. For example, if a patient is taking 50 units of insulin per day, you would divide 500 by 50 to get 10. This means that 1 unit of rapid-acting insulin will cover the spike in blood glucose after the patient eats 10 grams of carbohydrate.

The second eating plan is following a consistent carbohydrate eating plan when using fixed insulin regimens. Testing premeal and postmeal glucose levels is important for making adjustments in either food intake or medication to achieve glucose goals.

Carbohydrate Intake

As noted earlier, blood glucose levels after eating are determined primarily by the speed of digestion and absorption of glucose into the

bloodstream and the ability of insulin to clear glucose from the circulation. Low-carbohydrate diets may seem to be a logical approach to lowering postprandial glucose. However, foods that contain carbohydrates (whole grains, legumes, fruits, vegetables, and low-fat milk) are excellent sources of vitamins, minerals, dietary fiber, and energy and are encouraged over other sources of carbohydrates (namely highly processed carbohydrate with low fiber, added sugars and fats, or high sodium) to improve overall nutrient intake (ADA, 2018).

The long-held belief that sucrose—also known as common table sugar—must be restricted based on the assumption that sugars are more rapidly digested and absorbed than starches is not justified. The total amount of carbohydrate eaten at a meal, regardless of whether the source is starch or sucrose, is the primary determinant of postprandial glucose levels. The glycemic effect of carbohydrate foods cannot be predicted based on their structure (i.e., starch vs. sugar) owing to the efficiency of the human digestive tract in reducing starch polymers to glucose. Starches are rapidly metabolized into 100% glucose during digestion, in contrast to sucrose, which is metabolized into only approximately 50% glucose and approximately 50% fructose. Fructose has a lower glycemic response, which has been attributed to its slow rate of absorption and its storage in the liver as glycogen. Sucrose-containing foods can be substituted for isocaloric amounts of other carbohydrate foods. However, as for the general population, care should be taken to avoid excess energy intake and to avoid displacing nutrient-dense food choices (Ludwig et al, 2018). The ADA advises that people with or at risk for diabetes avoid sugar-sweetened beverages (soft drinks, fruit drinks, energy and vitamin-type water drinks containing sucrose, high-fructose corn syrup, and/or fruit juice concentrates) to reduce the risk of worsening the cardiometabolic risk profile and to prevent weight gain (ADA, 2018).

Glycemic Index and Glycemic Load

The **glycemic index (GI)** of food was developed to compare the physiologic effects of carbohydrates on glucose. The GI ranks carbohydrate foods according to how they affect blood glucose levels (for example, the GI of glucose = 100; the GI of white bread = 70).

The estimated **glycemic load (GL)** of foods, meals, and dietary patterns is calculated by multiplying the GI by the amount of available carbohydrate (divided by 100) in each food and then totaling the values for all foods in a meal or dietary pattern. For example, two slices of white bread with a GI of 75 and 30 g of carbohydrate has a GL of 22.5 ($75 \times 30/100 = 22.5$) (see Appendix 28 for GI and GL of foods).

The ADA conducted a systematic review of GI and GL diets in the management of diabetes and found that studies longer than 12 weeks report no significant impact of GI or GL, independent of weight loss, on A1C. However, mixed results were reported regarding fasting glucose levels and endogenous insulin levels. If GI or GL is proposed as a glycemia-lowering strategy, the RDN can advise adults with diabetes that lowering the GI or GL may or may not have a significant effect on glycemic control.

Fiber and Whole Grains

There is evidence to suggest that dietary fiber intake may lead to decreased all-cause mortality in individuals with diabetes (Evert et al, 2014). Additionally, a meta-analysis reviewing 15 studies that examined the relationship between fiber and diabetes found that an intervention involving fiber supplementation for T2DM can reduce fasting blood glucose (FBG) and A1C. Compared with the placebo, individuals who consumed dietary fiber as an intervention had an overall mean difference of a decrease in A1C of 0.26%. While this evidence is promising, one of the limitations is that the studies used a

variety of grams of fiber per day in their interventions, from as low as an additional 4 g/day to 40 g/day (Post et al, 2012).

As with the general population, consuming 25 g fiber per day for adult women and 38 g per day for adult men is encouraged (Evert et al, 2014). It is also recommended that individuals with diabetes, along with the general population, consume at least half of all grains as whole grains.

Grams of fiber (and sugar alcohols) are included on food labels and are calculated as having about half the energy (2 kcal/g) of most other carbohydrates (4 kcal/g). However, for most people it is not necessary to subtract the amount of dietary fiber (or sugar alcohols) when carbohydrate counting (Evert et al, 2014). Adjustments in carbohydrate intake values is practical only if the amount per serving is more than 5 g. In that case, counting half of the carbohydrate grams from fiber (and sugar alcohols) would be useful in calculating food choices for food labels or recipes.

Nonnutritive and Hypocaloric Sweeteners

Reduced calorie sweeteners approved by the FDA include sugar alcohols (erythritol, sorbitol, mannitol, xylitol, isomalt, lactitol, and hydrogenated starch hydrolysates) and tagatose. All FDA-approved nonnutritive sweeteners, when consumed within the established daily intake levels, can be used by people with diabetes, including pregnant women. Furthermore, nonnutritive sweeteners could facilitate reductions in added sugars intake, thereby resulting in decreased total energy intake (ADA, 2018). However, although the use of nonnutritive sweeteners appears to be safe, some people report gastric discomfort after eating foods sweetened with these products, and consuming large quantities may cause diarrhea, especially in children.

Keep in mind that the intake of nutritive sweeteners, when substituted isocalorically for other carbohydrates, will not have a significant effect on A1C or insulin levels; however, they can reduce overall calorie and carbohydrate intake (ADA, 2018).

Protein Intake

According to the ADA, there is no evidence that adjusting the daily level of protein intake (typically 1 to 1.5 g/kg body weight/day or 15% to 20% total calories) will improve health in individuals without diabetic kidney disease. For people with diabetes, evidence is inconclusive to recommend an ideal amount of protein intake for optimizing glycemic control or improving CVD risk factors; therefore, goals should be individualized to reflect current eating patterns. Some research does suggest that slightly higher protein intake (20% to 30% of total calories) may lead to increased satiety in people with diabetes.

Although nonessential amino acids undergo gluconeogenesis, in well-controlled diabetes the glucose produced does not appear in the general circulation; the glucose produced is likely stored in the liver as glycogen. When glycolysis occurs, it is unknown if the original source of glucose was carbohydrate or protein. Although protein is just as potent a stimulant of acute insulin release as carbohydrate, it has no long-term effect on insulin needs. Adding protein to the treatment of hypoglycemia does not prevent subsequent hypoglycemia, due to the potential simultaneous rise in endogenous insulin (ADA, 2018).

Fat Intake

Evidence is also inconclusive for an ideal amount of total fat for people with diabetes and therefore goals should be individualized. The type of fat consumed appears to be more important than total fat in terms of metabolic and cardiovascular risk.

Monounsaturated fatty acid (MUFA)-rich foods as a component of the Mediterranean-style eating pattern are associated with improved

glycemic control and improved CVD risk factors in persons with T2DM. Controversy exists on the best ratio of omega-6 to omega-3 fatty acids; however, polyunsaturated fatty acids (PUFAs) and MUFAs are recommended as substitutes for saturated fatty acids (SFAs) or trans fatty acids. The amount of SFAs, cholesterol, and trans fat recommended for people with diabetes is the same as for the general population.

There is evidence from the general population that foods containing omega-3 fatty acids have beneficial effects on lipoproteins and prevention of heart disease. Therefore the recommendations for the general public to eat fish (particularly fatty fish) at least two times (two servings) per week is also appropriate for people with diabetes. However, evidence from randomized controlled trial (RCTs) does not support recommending omega-3 supplements for people with diabetes for the prevention or treatment of CVD (ADA, 2018).

Alcohol

Small amounts of alcohol ingested with food have minimum, if any, acute effect on glucose and insulin levels. If individuals choose to drink alcohol, daily intake should be limited to one drink or less for adult women and two drinks or less for adult men (1 drink = 12 oz beer, 5 oz wine, or 1.5 oz distilled spirits). Each drink contains 15 grams of alcohol. The type of alcoholic beverage consumed does not make a difference. The same precautions that apply to alcohol consumption for the general population apply to persons with diabetes. Abstention from alcohol should be advised for people with a history of alcohol abuse or dependence; for women during pregnancy; and for people with medical problems such as liver disease, pancreatitis, advanced neuropathy, or severe hypertriglyceridemia (ADA, 2018).

Moderate to high alcohol consumption may place people with diabetes who take insulin or **insulin secretagogues** (medications that increase insulin production) at increased risk for delayed hypoglycemia (ADA, 2018). Consuming alcohol with food can minimize the risk of nocturnal hypoglycemia, or low blood sugar that occurs overnight when an individual is asleep. Education and awareness of delayed hypoglycemia after consuming alcoholic beverages is important. Alcoholic beverages should be considered an addition to the regular food and meal plan for all persons with diabetes. No food should be omitted, given the possibility of alcohol-induced hypoglycemia and because alcohol does not require insulin to be metabolized (ADA, 2018). Excessive amounts of alcohol (three or more drinks per day) on a consistent basis, contribute to hyperglycemia, which improves as soon as alcohol use is discontinued.

Small amounts of alcohol, in particular red wine, may be safe and potentially decrease cardiometabolic risk. One long-term RCT suggested that among well-controlled people with diabetes, initiating modest wine intake, especially red wine, as part of a healthy diet is probably safe and modestly decreases cardiometabolic risk (Blomster et al, 2014). However, chronic ingestion of alcohol does raise blood pressure and may be a risk factor for stroke (O'Keefe et al, 2018).

Micronutrients and Herbal Supplements

The evidence examining the effect of dietary supplements on blood glucose regulation are mixed; therefore the ADA does not endorse the use of routine vitamin or mineral supplementation in people with diabetes (compared with the general population) who do not have underlying deficiencies (ADA, 2018).

There is, however, some emerging evidence that suggests certain supplements may be helpful in lowering blood sugar levels. These include cinnamon, chromium, alpha-lipoic acid (ALA), and berberine.

A 2013 systematic review and meta-analysis found that cinnamon doses of 120 mg/day to 6 g/day for 4 to 18 weeks reduced levels of FPG, total cholesterol (−15.60 mg/dL), LDL cholesterol (−9.42 mg/dL), and triglycerides (−29.59 mg/dL) while increasing levels of HDL cholesterol (1.66 mg/dL). However, despite the reductions observed in FBG, no significant effect on hemoglobin A1C (HbA1C) levels (−0.16%) was seen (Allen et al, 2013).

A narrative review published in the *Journal of the Academy of Nutrition and Dietetics* had similar findings. The review analyzed 11 RCTs and found that all the studies reported some reductions in FPG during the cinnamon intervention. Of the studies measuring A1C, very modest decreases were also apparent with cinnamon, whereas changes in the placebo groups were minimal (Costello et al, 2016). It is important to use caution when combining cinnamon (in pill form) with other blood glucose-lowering herbs and supplements, as taking cinnamon with some antidiabetes drugs may cause hypoglycemic effects.

Chromium is an essential trace mineral required by the body in small amounts. Some research suggests that the mineral may be used to improve glycemic control for diabetes (types 1 and 2), prediabetes, PCOS, reactive hypoglycemia, metabolic syndrome, and other glucose regulation disorders (Natural Medicines Database, 2018). One study examined the effects of 42 µg Cr/day of chromium supplementation in a small number of people with newly diagnosed diabetes. After 3 months of chromium supplementation, the control group experienced a significant reduction in FBG. Additionally, A1C values improved significantly from 9.51% to 6.86%, indicating better glycemic control. In the experimental group, total cholesterol, triglycerides and LDL levels were also significantly reduced. These data demonstrate a possible beneficial effect of chromium supplementation on glycemic control and lipid variables in subjects with newly onset T2DM (Sharma et al, 2011). It should be noted that cell culture studies suggest a possibility of DNA damage with long-term chromium supplementation, however this has not been shown in living organisms (Linus Pauling Institute, 2018).

ALA is an essential cofactor in mitochondrial enzymes related to energy production that may improve glucose utilization in those with T2DM (Linus Pauling Institute, 2018b).

One trial randomized 105 people with diabetes to two groups. The first was instructed to take a supplement containing 600 mg of ALA (along with L-carnosine, zinc, and vitamins of group B). The second was given a placebo. The study found that after 3 months, there was a reduction of FPG, postprandial glucose, and A1C in the group that supplemented with ALA compared the placebo. The study also observed a reduction of LDL cholesterol, and triglycerides in the ALA group (Derosa et al, 2016).

Berberine is an alkaloid found in a variety of medicinal plants, including *Hydrastis canadensis* (goldenseal) and *Berberis aristata* (tree turmeric). It has been used for medicinal purposes in Chinese and Ayurvedic medicine and as a dye, thanks to its vibrant yellow color. In one clinical study, berberine significantly lowered FBG, A1C, triglyceride, and insulin levels in patients with T2DM. The FBG and A1C-lowering effects of berberine were similar to those of metformin and rosiglitazone. Liver function was improved greatly in these patients by showing reduction of liver enzymes (Ziegler et al, 2011). In another study, 36 adults with newly diagnosed T2DM were randomly assigned to treatment with berberine or metformin (0.5 g three times per day). After the 3 months, the hypoglycemic effect of berberine was similar to that of metformin. Significant decreases in A1C (9.5% to 7.5%), FBG (10.6 mmol/L to 6.9 mmol/L), postprandial blood glucose (19.8 mmol/L to 11.1 mmol/L), and triglycerides (1.13 mmol/L to 0.89 mmol/L) were observed in the berberine group (Yin et al, 2008).

Note that berberine may be contraindicated during lactation and pregnancy, and in children. Additionally, it can cause hypoglycemia in individuals on blood sugar-lowering medications (insulin, Amaryl, etc.) and may potentially lower blood pressure. Therefore it should be used with caution in people with low blood pressure or in people on blood sugar-lowering medications. Berberine can also inhibit activity of enzymes that break down certain drugs (Neoral, Sandimmune), which can lead to increased blood levels and increased risk of adverse effects. Other potential adverse effects include nausea, bloating, constipation, diarrhea, hypertension, respiratory failure, headache, bradycardia, jaundice, and paresthesias.

Even though there is some emerging evidence to suggest that herbal supplements may help with blood glucose regulation, it is important to remember that herbal products are not standardized and vary in their content of active ingredients (see Chapter 11). They have the potential to interact with and alter the effect of other medications. Therefore people with diabetes should always report the use of supplements and herbal products to their health care provider/RDN.

Metformin is associated with vitamin B₁₂ deficiency. Because of this, a recent report from the Diabetes Prevention Program Outcomes Study (DPPOS) suggests that periodic testing of vitamin B₁₂ levels should be considered in patients taking metformin, especially if the individual has a history of anemia or peripheral neuropathy.

Physical Activity/Exercise

Physical activity should be an integral part of the treatment plan for persons with diabetes. Exercise helps improve insulin sensitivity, reduce cardiovascular risk factors, control weight, and improve well-being. Given appropriate guidelines, the majority of people with diabetes can exercise safely. Individual activity plans will vary, depending on interest, age, general health, and level of physical fitness.

There are two types of exercise: aerobic and anaerobic. Both are important in people with diabetes. Aerobic exercise consists of rhythmic, repeated, and continuous movements of the same large muscle groups for at least 10 minutes at a time. Examples include walking, bicycling, jogging, swimming, and many sports. Anaerobic exercise, also known as resistance exercise, consists of activities that use muscular strength to move a weight or work against a resistive load. Examples include weight lifting and exercises using resistance-providing machines.

Despite the increase in glucose uptake by muscles during exercise, glucose levels change little in individuals without diabetes. Muscular work causes insulin levels to decline, while counterregulatory hormones (primarily glucagon) rise. As a result, the increased glucose use by the exercising muscles is matched with increased glucose production by the liver. This balance between insulin and counterregulatory hormones is the major determinant of hepatic glucose production, underscoring the need for insulin adjustments in addition to adequate carbohydrate intake during exercise for people with diabetes.

In people with T1DM, the glycemic response to exercise varies, depending on overall diabetes control, plasma glucose, and insulin levels at the start of exercise; timing, intensity, and duration of the exercise; previous food intake; and previous conditioning. An important variable is the level of plasma insulin during and after exercise. Hypoglycemia can occur because of insulin-enhanced muscle glucose uptake by the exercising muscle.

In people with T2DM, blood glucose control can improve with physical activity, largely because of decreased insulin resistance and increased insulin sensitivity, which results in increased peripheral use

of glucose not only during but also after the activity (Colberg et al, 2016). This exercise-induced enhanced insulin sensitivity occurs independent of any effect on body weight. Structured exercise interventions of at least 8 weeks in duration are reported to lower A1C. Exercise also decreases the effects of counterregulatory hormones, which reduces the hepatic glucose output, contributing to improved glucose control.

Potential Problems with Exercise

Hypoglycemia is a potential problem associated with exercise in people taking insulin or insulin secretagogues. Hypoglycemia can occur during, immediately after, or many hours after exercise, and is more common in people with T1DM (Colberg et al, 2016). Hypoglycemia has been reported to be more common after exercise—especially exercise of long duration. This can include strenuous activity, play, or sporadic exercise. Hypoglycemia in this instance is typically due to increased insulin sensitivity after exercise, requiring repletion of liver and muscle glycogen, which can take up to 24 to 30 hours (see Chapter 22).

Blood glucose levels before exercise reflect only the value at that time, and it is unknown if this is a stable blood glucose level or a blood glucose level that is dropping. If blood glucose levels are dropping before exercise, adding exercise can contribute to hypoglycemia during the activity.

Hyperglycemia also can result from exercise of high intensity, likely because the effects of counterregulatory hormones. When a person participates in a high level of exercise intensity, there is a greater-than-normal increase in counterregulatory hormones. As a result, hepatic glucose release exceeds the rise in glucose use. The elevated glucose levels also may extend into the postexercise state. Hyperglycemia and worsening ketosis also can result in people with T1DM who are deprived of insulin for 12 to 48 hours and are ketotic. Vigorous activity should be avoided in the presence of ketosis (ADA, 2018). It is not, however, necessary to postpone exercise based simply on hyperglycemia, provided the individual feels well and urine and/or blood ketones are negative.

Exercise Guidelines

The variability of glucose responses to exercise contributes to the difficulty in giving precise guidelines for exercising safely. Frequent blood glucose monitoring before, during, and after exercise helps individuals identify their response to physical activities. To meet their individual needs, it is important to modify general guidelines to reduce insulin doses before (or after) exercise. Additionally, an individual may choose to ingest carbohydrates before (or after) any physical activity. Similar to the general population without diabetes, it is also important for individuals with diabetes to stay hydrated when performing physical activities.

Carbohydrate recommendations for insulin or insulin secretagogue users. During moderate-intensity exercise, glucose uptake is increased by 8 to 13 g/hr; this is the basis for the recommendation to add 15 g carbohydrate for every 30 to 60 minutes of activity (depending on the intensity) over and above normal routines. Moderate exercise for less than 30 minutes usually does not require any additional carbohydrate or insulin adjustment, unless the individual is hypoglycemic before the start of exercise. Added carbohydrates should be ingested if preexercise glucose levels are less than 100 mg/dL (5.6 mmol/L). Supplementary carbohydrate is generally not needed in individuals with T2DM who are not treated with insulin or insulin secretagogues; it simply adds unnecessary calories (ADA, 2018).

In all people, blood glucose levels decline gradually during exercise, and ingesting carbohydrate during prolonged exercise can improve performance by maintaining the availability and oxidation of blood

glucose. For the exerciser with diabetes whose blood glucose levels may drop sooner and lower than the exerciser without diabetes, ingesting carbohydrate after 40 to 60 minutes of exercise is important and also may assist in preventing hypoglycemia. Drinks containing 2% to 4% glucose empty from the stomach as quickly as water and have the advantage of providing both needed fluids and carbohydrates (Leiper, 2015). Consuming carbohydrates immediately after exercise optimizes repletion of muscle and liver glycogen stores. For the exerciser with diabetes, this takes on added importance because of increased risk for late-onset hypoglycemia.

Insulin Guidelines

It is often necessary to adjust the insulin dosage to prevent hypoglycemia. This occurs most often with moderate to strenuous activity lasting more than 45 to 60 minutes. For most persons a modest decrease (of about 1 to 2 units) in the rapid- (or short-) acting insulin during the period of exercise is a good starting point. For prolonged vigorous exercise, a larger decrease in the total daily insulin dosage may be necessary. After exercise, insulin dosing also may have to be decreased.

Precautions for Persons with Diabetes

Persons with T2DM may have a lower Vo_2max and therefore need a more gradual training program. Rest periods may be needed, but this does not impair the training effect from physical activity.

Exercise Recommendations

Adults with diabetes should be advised to perform at least 150 min/week of moderate-intensity aerobic physical activity spread over at least 3 days/week with no more than 2 consecutive days without physical activity. In the absence of contraindications, adults with T2DM should be encouraged to perform resistance exercise at least twice per week with each session consisting of at least one set of five or more different resistance exercises involving large muscle groups. There is an additive benefit of combined aerobic and resistance training in adults with T2DM. Children with diabetes or prediabetes should be encouraged to engage in at least 60 min/day of physical activity with vigorous muscle-strengthening and bone-strengthening activities at least 3 days/week (ADA, 2018).

Routine screening preexercise is not recommended. Providers should use clinical judgment in this area. High-risk patients should be encouraged to start with short periods of low-intensity exercise and increase the intensity and duration slowly (ADA, 2018).

Medications

A consensus statement on the approach to management of hyperglycemia in T2DM has been published by the ADA and the European Association for the Study of Diabetes (Inzucchi et al, 2015). Interventions at the time of diagnosis include healthy eating, weight control, physical activity, and diabetes education. Metformin is the preferred initial pharmacologic agent for T2DM, either in addition to lifestyle counseling and physical activity, or when lifestyle efforts alone have not achieved or maintained glycemic goals. If A1C target goals are not reached after approximately 3 months, a second oral agent, a GLP-1 receptor agent, or basal insulin is added. If A1C goals are not reached after 3 additional months, a three-drug intervention is implemented. If combination therapy that includes a long-acting insulin does not achieve A1C goals, a more complex insulin therapy involving multiple daily doses is started—usually in combination with one or more noninsulin agents. A patient-centered approach is always ideal, and should include patient preferences, cost, and potential side effects (ADA, 2018). The overall objective is to achieve and maintain glycemic control and to change interventions (including the use of insulin) when therapeutic goals are not being met.

All people with T1DM and many people with T2DM who no longer produce adequate endogenous insulin need replacement of insulin. Circumstances that require the use of insulin in T2DM include the failure to achieve adequate control with administration of glucose-lowering medications and periods of acute injury, infection, extreme heat exposure, surgery, or pregnancy.

Glucose-Lowering Medications for Type 2 Diabetes

Understanding that T2DM is a progressive disease is important for the understanding of treatment choices. Assisting individuals with diabetes to understand the disease process also helps them to understand and accept changes in medications that occur over time. Diabetes is first diagnosed when there is insufficient insulin available to maintain euglycemia, and as insulin deficiency progresses, medications and eventually insulin will be required to achieve glycemic goals.

Glucose-lowering medications target different aspects of the pathogenesis of T2DM—insulin resistance at the cellular level, incretin system defects, endogenous insulin deficiency, elevated levels of glucagon, and excessive hepatic glucose release. Because the mechanisms of action differ, the medications can be used alone or in combination. Table 29.5 lists the generic and brand names of glucose-lowering medications and their principal sites of action for persons with T2DM. Appendix 13 lists the nutrition implications of common drugs.

Biguanides

Metformin is the most widely used first-line type 2 medication. It suppresses hepatic glucose production, is not associated with hypoglycemia, may cause small weight losses when therapy begins, and is relatively inexpensive. The most common side effects are gastrointestinal (GI), which often disappear with time. To minimize these effects, the medication should be taken with food consumption and the smallest dose (500 mg) given twice a day for a week and gradually increased to maximum doses. If that does not help, Metformin XR (or extended release) is a good alternative that can help minimize GI side effects. This should also be taken with meals (Levy et al, 2010). A rare side effect of Metformin is severe lactic acidosis, which can be fatal. The acidosis usually occurs in patients who use alcohol excessively, have renal dysfunction, or have liver impairments. Metformin may also cause a decrease in B_{12} , so patients need to make sure to have adequate intake (ADA, 2018).

Sulfonylureas

The sulfonylureas (glyburide [DiaBeta], glipizide [Glucotrol], glimepiride [Amaryl]) are insulin secretagogues and promote insulin secretion by the beta-cells of the pancreas. First- and second-generation sulfonylurea drugs differ from one another in their potency, pharmacokinetics, and metabolism. Disadvantages of their use include weight gain, GI side effects—nausea, diarrhea, and constipation—and the potential to cause hypoglycemia. They also have the advantage of being inexpensive.

Thiazolidinediones (TZDs)

Thiazolidinediones (TZDs) or glitazones (pioglitazone [Actos] and rosiglitazone [Avandia]) decrease insulin resistance in peripheral tissues and thus enhance the ability of muscle and fat cells to take up glucose. TZDs also have a favorable effect on lipids and do not independently cause hypoglycemia. Adverse effects include weight gain, fluid retention leading to edema and/or heart failure, and increased risk of bone fractures.

Glucagon-like Peptide-1 (GLP-1) Receptor Agonists

Incretins are hormones made by the GI tract and include GLP-1. GLP-1 is released during nutrient absorption, which increases glucose-dependent

TABLE 29.5 Glucose-Lowering Medications for Type 2 Diabetes

Class	Compound(s)	Mechanism(s)	Effects/ Considerations
Biguanides	Metformin (Glucophage) Metformin Extended Release (Glucophage XR)	Decrease hepatic glucose production	Low cost, potential ASCVD benefit, contraindicated w/eGFR <30, gastrointestinal side effects common (nausea, diarrhea), potential for vitamin B ₁₂ and folate deficiency
Sulfonylureas (2nd generation)	Glipizide (Glucotrol) Glipizide (Glucotrol XL) Glyburide (Glynase PresTabs) Glimepiride (Amaryl)	Increase insulin secretion	Low cost, hypoglycemia, weight gain, glyburide not recommended with diabetic kidney disease, FDA special warning on increased risk of cardiovascular mortality
Meglitinides (Glinides)	Repaglinide (Prandin) Nateglinide (Starlix)	Increases insulin secretion	Hypoglycemia
Thiazolidinediones	Pioglitazone (Actos) Rosiglitazone (Avandia)	Increases insulin sensitivity	Low cost, weight gain, potential ASCVD benefit (pioglitazone), generally not recommended in renal impairment, fluid retention (edema, heart failure), FDA black box: May cause or worsen congestive heart failure, benefit in NASH, risk of bone fractures, bladder cancer (pioglitazone), raises LDL cholesterol (rosiglitazone)
Glucagon-like peptide-1 (GLP-1) receptor agonists	Exenatide (Byetta) Exenatide Extended Release (Bydureon) Liraglutide (Victoza) Albiglutide (Tanzeum) Dulaglutide (Trulicity)	Increases glucose-dependent insulin secretion Suppresses glucagon secretion (glucose dependent) Slows gastric emptying Increases satiety/activates GLP-1 receptors	High cost, weight loss, benefit ASCVD and progression of DKD (liraglutide), increased risk of side effect in patients with renal impairment, FDA black box: Risk of thyroid C-cell tumors, gastrointestinal side effects common (nausea, vomiting, diarrhea), injection site reactions, acute pancreatitis risk
Dipeptidyl peptidase-4 (DPP-4) inhibitors	Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin (Tradjenta) Alogliptin (Nesina)	Increases insulin secretion (glucose dependent) and decreases glucagon secretion (glucose dependent)/Inhibits DPP-4 activity, increasing postprandial incretin (GLP-1, GIP) concentrations	High cost, CHF potential risk (saxagliptin, alogliptin), can be used in renal impairment, potential risk of acute pancreatitis, joint pain
Bile acid sequestrants	Colesevelam (Welchol)	Decreases hepatic glucose and increases incretin levels/Binds bile acids in intestinal tract, increasing hepatic bile acid production	Do not use if history of bowel obstruction, triglycerides >500, or pancreatitis. Can decrease absorption of certain meds, soluble vitamins. Side effects GI in nature
Dopamine-2 agonists	Bromocriptine quick release QR (Cycloset)	Modulates hypothalamic regulation of metabolism, increases insulin sensitivity/activates dopaminergic receptors	Side effects: nausea, headache, fatigue, hypotension, syncope, somnolence
Alpha glucosidase inhibitors	Acarbose (Precose) Miglitol (Glyset)	Inhibits intestinal alpha glucosidase/slowly slows intestinal carbohydrate digestion and absorption	Diarrhea, gas, and nausea If mild to moderate hypoglycemia occurs in combination with another antidiabetic drug such as a sulfonylurea or insulin, the hypoglycemia should be treated with oral glucose (dextrose) instead of sucrose (table sugar) because the drug blocks the digestion of sucrose to glucose.
Amylin mimetics	Pramlintide (Symlin)	Decreases glucagon secretion, slows gastric emptying, increases satiety/activates amylin receptors	FDA black box: severe hypoglycemic risk 3 hours post injection, consider decreasing insulin dose when starting. Side effects: nausea, weight loss

Continued

TABLE 29.5 Glucose-Lowering Medications for Type 2 Diabetes—cont'd

Class	Compound(s)	Mechanism(s)	Effects/ Considerations
Sodium-glucose transport 2 inhibitors (SGLT2)	Canagliflozin (Invokana) Dapagliflozin (Farxiga) Empagliflozin (Jardiance)	Blocks reabsorption of glucose in the kidneys, increasing glucosuria/SGLT2 inhibition in the proximal nephron	High cost, weight loss, benefits ASCVD/CHF/progression of DKD (canagliflozin not <45 eGFR, empagliflozin contraindicated with eGFR <30), FDA black box: risk of amputation (canagliflozin), risk of bone fractures (canagliflozin), DKA risk (rare in T2DM), risk of volume depletion/hypotension, raises LDL cholesterol, genitourinary infections
Insulins	See Table 29.6	Increases glucose disposal, decreases hepatic glucose production, suppresses ketogenesis/activates insulin receptors	Human insulin-low cost, analogs-high cost, hypoglycemia (higher risk with human insulin), weight gain, lower dose required with decreased eGFR, injection site reactions

Modified from American Diabetes Association: Pharmacologic approaches to glycemic treatment: Standards of medical care in diabetes—2018, *Diabetes Care* 41(S1):S77, S79-80, 2018.

insulin secretion, slows gastric emptying, decreases glucagon production, and enhances satiety. Exenatide (Byetta) and liraglutide (Victoza) are synthetic drugs that have many of the same glucose-lowering effects as the body's naturally occurring incretin, GLP-1. A primary benefit is weight loss (liraglutide has also been approved as a weight-loss drug). Typically exenatide is injected twice a day, at breakfast and at the evening meal, and liraglutide is injected once a day, at any time, independent of meals. There are three once-weekly injection GLP-1s: exenatide extended (Bydureon), dulaglutide (Trulicity), and semaglutide (Ozempic).

Dipeptidyl Peptidase 4 Inhibitors (DPP-4)

GLP-1 and glucose-dependent insulinotropic peptide (GIP), the main intestinal stimulants of insulin are rapidly degraded by the enzyme DPP-4. As a result, incretins have very short half-lives of 2 to 3 minutes. DPP-4 inhibitors prolong their half-lives. Oral DPP-4 inhibitors are sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina). They have a modest effect on A1C; however, advantages include being weight neutral and relatively well tolerated. Furthermore, they do not cause hypoglycemia when used as monotherapy.

Alpha Glucosidase Inhibitors

Acarbose (Precose) and miglitol (Glyset) are alpha-glucosidase inhibitors that work in the small intestine to inhibit enzymes that digest carbohydrates, thereby delaying carbohydrate absorption and lowering postprandial glycemia. They do not cause hypoglycemia or weight gain when used alone, but they can frequently cause flatulence, diarrhea, cramping, or abdominal pain. Symptoms may be alleviated by initiating therapy at a low dose and gradually increasing the dose to therapeutic levels.

Meglitinides (Glinides)

The meglitinides repaglinide (Prandin) and nateglinide (Starlix) differ from the sulfonylureas in that they have short metabolic half-lives, which result in brief episodic stimulation of insulin secretion. They are given before meals, decreasing postprandial glucose excursions and less risk of hypoglycemia. Nateglinide only works in the presence of glucose and is a somewhat less potent secretagogue. Possible weight gain is similar to sulfonylureas.

Sodium-Glucose Transporter 2 (SGLT-2) Inhibitors

Canagliflozin (Invokana), dapagliflozin (Farxiga), empagliflozin (Jardiance), and ertugliflozin (Steglatro) are drugs in a new class that target

blood glucose-lowering action in the kidneys. SGLT-2 inhibitors block a transporter protein that returns glucose to the bloodstream after it is filtered through the kidneys. Blocking this protein causes more glucose to be flushed out in the urine. Used independently it does not cause hypoglycemia or weight gain.

Amylin Agonists (Pramlintide)

Pramlintide (Symlin) is a synthetic analog of the hormone amylin, a hormone normally cosecreted with insulin by the beta-cell in response to food that is deficient in people with T1DM and T2DM. It is injected before meals, slowing gastric emptying and inhibiting glucagon production and resulting in a decrease in postprandial glucose excursions, which is related to a decrease in glucagon production from the pancreatic alpha cells. It must be injected separately from insulin.

Insulin

Insulin strategies for persons with T2DM may begin with basal insulin at bedtime to suppress nocturnal hepatic glucose production and to normalize fasting glucose levels. Glucose-lowering medications usually are continued during the day. The next step is to add one mealtime rapid-acting insulin with the basal insulin or use of premixed insulin, which is a combination of two insulins mixed together, twice daily. Premixed insulin is typically a combination of a short or rapid-acting insulin and an intermediate or long-acting insulin. If A1C goals are not achieved, mealtime rapid-acting insulin is used before each meal. Insulin secretagogues usually are stopped, but other glucose-lowering agents may be continued.

Insulin has three characteristics: onset, peak, and duration (Table 29.6). U-100 is the concentration of insulin used in the United States. This means it has 100 units of insulin per milliliter of fluid (100 units/mL). U-100 syringes deliver U-100 insulin; however, insulin pens are now being used more frequently as an alternative to the traditional syringe-needle units. Humulin R U-500 (500 units/mL) is useful in the treatment of insulin-resistant patients who require daily doses more than 200 units.

Rapid-acting insulins include lispro (Humalog), insulin aspart (Novolog), and insulin glulisine (Apidra) and are used as bolus (pre-meal or prandial) insulins. They are insulin analogs that differ from human insulin in amino acid sequence but bind to insulin receptors and thus function in a manner similar to human insulin. To determine

TABLE 29.6 Action Times of Human Insulin Preparations

Type of Insulin	Onset of Action	Peak Action	Usual Effective Duration	Monitor Effect In
Rapid-Acting				
Insulin lispro	<0.25-0.5 hr	0.5-2.5 hr	3-6.5 hr	1-2 hr
Insulin aspart	<0.25 hr	0.5-1.0 hr	3-5 hr	1-2 hr
Insulin glulisine	<0.25 hr	1-1.5 hr	3-5 hr	1-2 hr
Inhaled insulin				
Short-Acting				
Human Regular	0.5-1 hr	2-3 hr	3-6 hr	4 hr (next meal)
Intermediate-Acting Analogs				
Human neutral protamine hagedorn (NPH)	2-4 hr	4-10 hr	10-16 hr	8-12 hr
Basal Insulin Analogs				
Insulin glargine (Lantus)	2-4 hr	Peakless	20-24 hr	10-12 hr
Insulin detemir (Levemir)	0.8-2 hr (dose dependent)	Peakless	12-24 hr (dose dependent)	10-12 hr
Degludec				
Premixed Insulin Products				
70/30 (70% NPH, 30% regular)	0.5-1 hr	Dual	10-16 hr	
Humalog Mix (Lispro) 75/25 (75% neutral protamine lispro [NPL], 25% lispro)	<0.25 hr	Dual	10-16 hr	
Humalog Mix (Lispro) 50/50 (50% protamine lispro, 50% lispro)	<0.25 hr	Dual	10-16 hr	
NovoLog Mix 70/30 (70% neutral protamine aspart [NPA], 30% aspart)	<0.25 hr	Dual	15-18 hr	

Data from American Diabetes Association: Pharmacologic approaches to glycemic treatment: Standards of medical care in diabetes—2018, *Diabetes Care* 41(S1):S80, 2018.

the accuracy of the dose, blood glucose checking is done before meals and 2 hours after the start of the meals.

Regular insulin includes short-acting insulin with a slower onset of action and later activity peak. For best results the slow onset of regular insulin requires it to be taken 30 to 60 minutes before meals.

Neutral protamine hagedorn (NPH) is the only available intermediate-acting insulin and is cloudy in appearance. This type of insulin contains substrates that work over a long period of time, usually with an effective duration of 10 to 16 hours.

Long-acting insulins include insulin glargine (Lantus) and insulin detemir (Levemir). Insulin glargine is an insulin analog that, because of its slow dissolution at the injection site, results in a relatively constant and peakless delivery over 24 hours. Because of its acidic pH, it cannot be mixed with any other insulin in the same syringe before injection and usually is given at bedtime. However, glargine can be given before any meal. Keep in mind that consistency is key, as the dose must be administered consistently at whichever time is chosen. Basal insulin analogs decrease the chances of hypoglycemia, especially nocturnal hypoglycemia.

Premixed insulins include 70% NPH/30% regular, 75% lispro protamine (NPL [addition of neutral protamine to lispro to create an intermediate-acting insulin])/25% lispro, 50% lispro protamine and 50% lispro, and 70% protamine (addition of neutral protamine to aspart to create an immediate-acting insulin)/30% aspart (ADA, 2018). People using premixed insulins must eat at specific times and be consistent in carbohydrate intake to prevent hypoglycemia.

Insulin Regimens

All persons with T1DM and those with T2DM who no longer produce adequate endogenous insulin need replacement of insulin that mimics normal insulin action. After individuals without diabetes eat, their plasma glucose and insulin concentrations increase rapidly, peaking in 30 to 60 minutes, and return to basal concentrations within 2 to 3 hours. To mimic this, rapid-acting (or short-acting) insulin is given before meals, and this is referred to as bolus or mealtime insulin.

Mealtime insulin doses are adjusted based on the amount of carbohydrate in the meal. An insulin-to-carbohydrate ratio can be established for an individual that will guide decisions on the amount of mealtime insulin to inject based on grams of carbohydrate consumed. The **basal or background insulin dose** is that amount of insulin required in the postabsorptive state to restrain endogenous glucose output primarily from the liver, which helps maintain normal glucose levels between meals. Basal insulin also limits lipolysis and excess flux of free fatty acids to the liver. Long-acting insulins are used for basal insulin (Fig. 29.2).

These physiologic insulin regimens allow increased flexibility in the type and timing of meals. For nonobese persons with T1DM, the required insulin dosage is about 0.5 to 1 unit/kg of body weight per day. About 50% of the total daily insulin dose is used to provide for basal or background insulin needs. The remainder (rapid-acting insulin) is divided among the meals either proportionately to the carbohydrate content or by giving about 1 to 1.5 units of insulin per 10 to 15 g of carbohydrates consumed (**insulin to carbohydrate ratio**). As a result of the presence in the morning of higher levels of counterregulatory

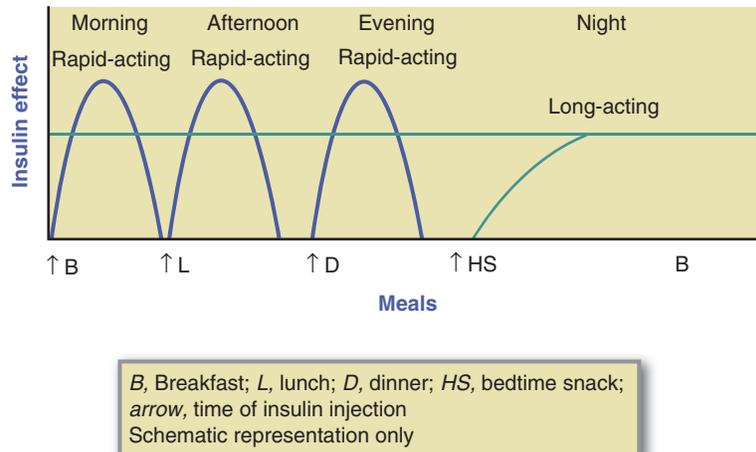

Fig. 29.2 Time actions of flexible insulin regimens. (Modified from Kaufman FR, editor: *Medical management of type 1 diabetes*, ed 6, Alexandria, VA, 2012, American Diabetes Association.)

hormones, many individuals may require larger doses of mealtime insulin for carbohydrates consumed at breakfast than meals later in the day. Persons with T2DM may require insulin doses in the range of 0.5 to 1.2 units/kg of body weight daily. Large doses, even more than 1.5 units/kg of body weight daily, may be required at least initially to overcome prevailing insulin resistance. The type and timing of insulin regimens should be individualized, based on eating and exercise habits and blood glucose concentrations.

Insulin Regimens: Continuous Sustained Insulin Infusion (CSII) or Insulin Pump Therapy

The insulin (usually a rapid-acting insulin) is pumped continuously by a mechanical device in micro amounts through a subcutaneous catheter (Fig. 29.3). The pump delivers insulin in two ways: in a steady, measured, and continuous dose (basal insulin) and as a surge (bolus) dose before meals.

The individual also should be educated about carbohydrate counting/estimation. Mealtime boluses are dependent on carbohydrate intake as well as circadian variation in insulin sensitivity, current blood glucose levels, and planned physical activity. Regularly scheduled

outpatient follow-up with diabetes care providers knowledgeable in the use of CSII is recommended to optimize glycemic control long term. Although there is an initial learning curve, insulin pump therapy provides many benefits, including eliminating the need for individual insulin injections. Using an insulin pump may also result in fewer large swings in blood glucose levels as well as allow users to be more flexible about when and what they eat.

Self-Management Education

Diabetes management is a team effort. Persons with diabetes must be at the center of the team because they have the responsibility for day-to-day management. RDNs, nurses, physicians, and other health care providers contribute their expertise to developing therapeutic regimens that help the person with diabetes achieve the best metabolic control possible. The goal is to provide patients with the knowledge, skills, and motivation to incorporate self-management into their daily lifestyles. The AND EBNPG recommends that individuals with diabetes be referred for MNT early after the diagnosis of diabetes. MNT is to be provided by an RDN in an initial series of three to four encounters, each lasting 45 to 90 minutes. This series should be completed within 3 to 6 months, and the RDN should determine whether additional encounters are needed after the initial series based on the nutrition assessment of learning needs and progress toward desired outcomes. At least one follow-up encounter is recommended annually to reinforce lifestyle changes and to evaluate and monitor outcomes that affect the need for changes in MNT or medication(s). The RDN should again determine whether additional MNT encounters are needed. Although glycemic control is the primary focus for diabetes management, cardioprotective nutrition interventions for the prevention and treatment of CVD also should be implemented in the initial series of encounters (AND, 2008a; Franz et al, 2010).

Dietitians can demonstrate their specialized diabetes knowledge by obtaining certification beyond the RDN credential. Two diabetes care certifications available to registered dietitians (RDs) are the CDE, a specialty certification, and board certified-advanced diabetes management (BC-ADM), an advanced practice certification.

Monitoring

The health care team, including the individual with diabetes, should work together to implement blood glucose monitoring and establish individual target blood glucose goals (see Table 29.4). Several methods

Fig. 29.3 A child is wearing an insulin pump. (From www.istockphoto.com.)

are available to assess the effectiveness of the diabetes management plan on glycemic control: SMBG or **continuous glucose monitoring (CGM)** of interstitial glucose and A1C. SMBG is used on a day-to-day basis to manage diabetes effectively and safely; however, measurement of A1C levels provides the best available index of overall diabetes control.

Self-Monitoring of Blood Glucose (SMBG)

The ADA recommendations state that persons on multiple-dose insulin (MDI) or insulin pump therapy should do SMBG before meals and snacks, occasionally postprandially at bedtime, before exercise, when they suspect low blood glucose, after treating low blood glucose until they are normoglycemic, and before critical tasks such as driving. For people using less-frequent insulin injections or noninsulin therapies, SMBG results may be helpful to guide treatment decisions (ADA, 2018).

The AND EBNPG for diabetes reviewed the evidence on glucose monitoring and recommended that for persons with T1DM or T2DM on insulin therapy, at least three to four glucose tests per day are needed to determine the accuracy of the insulin dose(s) and to guide adjustments in insulin dose(s), food intake, and physical activity. Once established some insulin regimens require less-frequent SMBG. For persons on MNT alone or MNT in combination with glucose-lowering medications, frequency and timing are dependent on diabetes management goals and therapies.

Self-management education and training are necessary to use SMBG devices and data correctly (ADA, 2018). Individuals must be taught how to adjust their management program based on the results of SMBG. The first step in using such records is to learn how to identify patterns in blood glucose levels taken at the same time each day that are outside the target range—generally high readings for 3 or more days in a row or low readings 2 days in a row. The next step is to determine whether a lifestyle factor (meal times, carbohydrate intake, quantity and time of physical activity) or medication dose adjustment is needed.

If changes in medication doses such as insulin are needed, adjustments should be made to the insulin/medications at the time of the problem glucose readings. After pattern management is mastered, algorithms for insulin dose changes to compensate for an elevated or low glucose value can be used. A commonly used formula determines the insulin sensitivity, or **correction factor (CF)**, which defines how many milligrams per deciliter a unit of rapid-insulin (or short-acting) will lower blood glucose levels over a 2- to 4-hr period (Kaufman, 2012). The CF is determined by using the “1700 rule,” in which 1700 is divided by the total daily dose (TDD) of insulin the individual typically takes. For example, if the TDD is 50 units of insulin, the $CF = 1700/50 = 35$. In this case 1 unit of rapid-acting insulin should lower the individual’s blood glucose level by 35 mg/dL (2 mmol/L).

In using blood glucose monitoring records, remember that factors other than food affect blood glucose concentrations. An increase in blood glucose can be the result of insufficient insulin or insulin secretagogue; too much food; or increases in glucagon and other counter-regulatory hormones as a result of stress, illness, or infection. Factors that contribute to hypoglycemia include too much insulin or insulin secretagogue, not enough food, unusual amounts of exercise, and skipped or delayed meals. Urine glucose testing, which has been used in the past, has so many limitations that it should not be used.

Continuous Glucose Monitoring (CGM)

CGM systems include a tiny glucose-sensing device called a sensor that is inserted under the skin in the subcutaneous fat tissue for several days at a time. The sensor measures glucose in interstitial fluid and

transmits readings every 5 minutes to a monitor that is worn or carried externally. CGM devices also provide information not just on current glucose level but also on the trend and rate of change in glucose levels (i.e., whether the glucose level is rising or falling and how quickly). Other features include alerts for glucose highs and lows and the ability to download data and track trends over time. The ADA recommends that CGM in conjunction with intensive insulin regimens can be a useful tool to lower A1C in selected adults with T1DM. Evidence is less strong for A1C lowering in children, teens, and younger adults; however, CGM may be also helpful in these groups (ADA, 2018).

A1C Monitoring

A1C tests should be done at least twice a year in persons who are meeting treatment goals and have stable glycemic control. They should be done quarterly in persons whose therapy has changed or who are not meeting glycemic goals. In persons without diabetes, A1C values are 4% to 6%. These values correspond to mean plasma glucose levels of approximately 70 to 126 mg/dL (3.9 to 7.0 mmol/L). Correlation between A1C levels and average glucose levels has recently been verified. An A1C of 6% reflects an average glucose level of 126 mg/dL (7.0 mmol/L) (See Table 29.2). Lowering A1C to below or around 7% is a reasonable goal for many nonpregnant adults with diabetes. An A1C less than 7% has been shown to reduce cardiovascular complications of diabetes and is associated with long-term reduction of macrovascular disease (ADA, 2018). Less stringent goals, such as less than 8%, may be appropriate for elderly individuals or individuals with advanced macrovascular and microvascular complications, history of severe hypoglycemia, or other extensive comorbid conditions (ADA, 2018).

Ketone, Lipid, and Blood Pressure Monitoring

Urine or blood testing can be used to detect ketones. Testing for ketonuria or ketonemia should be performed regularly during periods of illness and when blood glucose levels consistently exceed 240 mg/dL (13.3 mmol/L). The presence of persistent, moderate, or large amounts of ketones, along with elevated blood glucose levels, requires insulin adjustments. People with T2DM rarely have ketosis; however, ketone testing should be done when the person is seriously ill.

For most adults, lipids should be measured at least annually; however, in adults with low-risk lipid values (100 mg/dL [2.6mmol/L]), assessments may be repeated every 5 years. Blood pressure should be measured at every routine diabetes visit (ADA, 2018).

IMPLEMENTING THE NUTRITION CARE PROCESS

The nutrition care process (NCP) is a systematic and standardized approach to providing high-quality nutrition care. This system was adopted by the AND’s House of Delegates in 2003 in an effort to provide dietetics professionals with a framework for critical thinking and decision making. The AND found that the use of the NCP can lead to more efficient and effective care and greater recognition of the role of dietetic professionals in all care settings.

There are two ways to deliver MNT using the NCP: individual or group sessions. While providing nutrition interventions in groups is becoming increasingly popular, it is important that group interventions allow for individualization of MNT and evaluation of outcomes. The NCP consists of four distinct, interrelated steps.

Nutrition Assessment

The AND EBNPG for diabetes recommends that the RDN assess the following domains in adults with T1DM and T2DM to formulate the nutrition care plan. The first is biomedical data, medical tests, and medication uses (including type of diabetes, glycemic control and

targets, lipid profiles, blood pressure, renal function, and use of medications). The second is nutrition-focused physical findings (including height, weight, BMI and waist circumference, injection sites, and the relative importance of weight management). Third is the client history, which includes general health and demographic information, social history, cultural preferences, health literacy and numeracy, education and occupation, physical activity, patient or family nutrition-related medical and health history, and any other medical or surgical treatments. This section also includes knowledge, beliefs, attitudes, motivation, readiness to change, self-efficacy, and willingness and ability to make behavioral changes. Last but not least is the food and nutrition-related history. Here the RDN will gather information on food, beverage and nutrient, intake, including energy intake, serving sizes, meal-snack patterns, carbohydrate, fiber, types and amounts of fat, protein, micronutrient intake, and alcohol intake. It is also important to gather information on experience with food, previous and current food and nutrition history, eating environment, access to healthy foods, and eating out (Box 29.2).

Nutrition Diagnosis

The nutrition diagnosis identifies and describes a specific nutrition problem that can be resolved or improved through treatment/intervention by an RDN. Patients often have more than one nutrition diagnoses, in which case the RDN will need to prioritize them in the nutrition intervention step. Examples of diabetes-related nutrition diagnoses are listed in Box 29.3.

Nutrition Interventions

Nutrition Therapy Interventions for All People with Diabetes

The first priority is to promote and support a healthful eating pattern, emphasizing a variety of nutrient-dense foods in appropriate portion sizes. However, monitoring carbohydrate intake also can be an important

BOX 29.2 Nutrition Assessment

Nutrition Assessment Categories

- Biochemical data, medical tests, and procedures, which include laboratory data such as for A1C, glucose, lipids, kidney function, and blood pressure measurements
- Anthropometric measurements, which include height, weight, body mass index (BMI), waist circumference, growth rate, and rate of weight change
- Client history, which includes:
 - General patient information, such as age, gender, race/ethnicity, language, literacy, and education
 - Medical/health history and medical treatment, including goals of medical therapy and prescribed medications related to medical condition for which medical nutrition therapy (MNT) is being implemented
 - Readiness to change nutrition-related behaviors
 - Weight management goals
 - Physical activity history and goals
 - Social history, such as social and medical support, cultural and religious beliefs, and socioeconomic status
 - Other medical or surgical treatments, therapy, and alternative medicine
 - Food/nutrition history
 - Food intake, nutrition and health knowledge and beliefs
 - Food availability
 - Supplement use

Modified from Franz MJ et al: *ADA pocket guide to lipid disorders, hypertension, diabetes, and weight management*, Chicago, 2012, Academy of Nutrition and Dietetics.

BOX 29.3 Examples of Problem, Etiology, and Signs and Symptoms (PES) Statements Related to Diabetes Mellitus

Nutrition Diagnosis: Inconsistent Carbohydrate Intake

- Inconsistent carbohydrate intake (P) related to incorrect application of carbohydrate counting (E) as evidenced by food records revealing 2 additional carbohydrate servings for many meals and wide fluctuations in blood glucose levels, most days of the week (S).

Nutrition Diagnosis: Inconsistent Carbohydrate Intake

- Inconsistent carbohydrate intake (P) related to inconsistent timing of meals (E) as evidenced by wide fluctuations in blood glucose levels (S).

Nutrition Diagnosis: Excessive Carbohydrate Intake

- Excessive carbohydrate intake (P) compared with insulin dosing related to inaccurate carbohydrate counting (E) as evidenced by the number of carbohydrate servings per meal noted in food record and postmeal glucose levels consistently greater than 200 mg/dL (S).

Nutrition Diagnosis: Inappropriate Intake of Food Fats

- Excessive saturated fat intake (P) related to lack of knowledge of saturated fat content of foods (E) as evidenced by self-report of high saturated fat intake (S).

Nutrition Diagnosis: Altered Laboratory Values

- Altered blood glucose values (P) related to insufficient insulin (E) as evidenced by hyperglycemia despite very good eating habits (S).

Nutrition Diagnosis: Food- and Nutrition-Related Knowledge Deficit

- Food- and nutrition-related knowledge deficit (P) related to lack of exposure to information (E) as evidenced by new diagnosis of diabetes (or prediabetes, lipid disorder, hypertension) (S).

Nutrition Diagnosis: Not Ready for Lifestyle Change

- Not ready for lifestyle change (P) related to denial of need to change in precontemplation (E) as evidenced by reluctance to begin participation in physical activity program (S).

Modified from Franz MJ et al: *ADA pocket guide to lipid disorders, hypertension, diabetes, and weight management*, Chicago, 2012, Academy of Nutrition and Dietetics.

nutrition therapy strategy for persons with all types of diabetes. It is important that individuals with diabetes know which foods contain carbohydrates (starchy vegetables, grains, fruit, milk and milk products, vegetables, and sweets). They should also be educated on portion sizes and how many servings they should select for meals, and if they desire, snacks. When choosing carbohydrates, nutrient-dense, high-fiber foods are recommended whenever possible instead of processed foods with added sodium, fat, and sugars. Sugar-sweetened beverages and juice should also be minimized or avoided.

Nutrition Therapy Interventions for Specific Populations

For people with T1DM and insulin-requiring T2DM, the first priority is to integrate an insulin regimen into the usual eating habits and physical activity schedule. With the many insulin options now available (rapid- and long-acting insulins), an insulin regimen can be planned that will conform to an individual's preferred meal routines and food choices. While a medical doctor typically prescribes insulin, nurses and CDEs will often suggest modifications, depending on their scope of practice.

Physiologic insulin regimens that mimic natural insulin secretion involve multiple injections (three or more insulin injections per day) or use of insulin pump therapy. These types of insulin regimens allow increased flexibility in choosing when and what to eat. Mealtime insulin doses are adjusted to match carbohydrate intake (insulin-to-carbohydrate ratios). Therefore it is important that individuals learn how to count carbohydrates or use another meal planning approach to quantify carbohydrate intake. The insulin action times of the currently available rapid-acting insulin analogs are as follows: onset 5 to 15 minutes, a peak between 30 to 90 minutes, and a duration of approximately 4 to 6 hours. **Lag time** is defined as the amount of time that elapses between the injection of rapid-acting insulin and the meal; it is critical in control of postprandial hyperglycemia and in later risk of hypoglycemia. Given the pharmacodynamics of insulin analogs, a sufficient lag time of approximately 10 to 15 minutes before start of meal helps to decrease postprandial hyperglycemia.

Fixed insulin regimens are used for a variety of reasons, including age, cost, fewer required injections, lack of access to insulin analogs, personal preference, or prescribing habits of the health care provider. For people who receive fixed insulin regimens, such as premixed insulin formulas, day-to-day consistency in the timing and amount of carbohydrates eaten is key. This also applies to those who do not adjust their daily mealtime insulin doses. Carbohydrate intake can be individualized to meet the person's nutritional needs. The amount of mealtime insulin (rapid- or short-acting) that the person takes only changes based on the blood glucose level reading.

Persons with type 2 diabetes using mnt alone or with glucose-lowering medications. The first priority is to adopt lifestyle interventions that improve the metabolic abnormalities of glycemia, dyslipidemia, and hypertension. Lifestyle interventions independent of weight loss that can improve glycemia include reduced energy intake and increased energy expenditure through physical activity. Because many people with diabetes also have dyslipidemia and hypertension, a cardioprotective eating pattern also is recommended. These interventions should be implemented as soon as the diagnosis of diabetes is made.

MNT interventions for established T2DM differ from interventions for prevention. Some studies suggest that modest weight loss is beneficial in persons with insulin resistance; however, as the disease progresses to insulin deficiency, medications usually have to be combined with MNT. Emphasis should be on blood glucose control, improved food choices, increased physical activity, and moderate energy restriction rather than weight loss alone, as it is unclear whether weight loss alone may improve glycemic control. Additionally, reduction of caloric intake may result in nutritional inadequacies; therefore, special attention should be paid to maintaining adequate intake of vitamins and minerals.

The first step in food and meal planning is teaching which foods are sources of carbohydrate, what are appropriate portion sizes, and how many servings to select at meals (and snacks, if desired). Important components of successful MNT for T2DM include teaching that unsaturated fats should be substituted for foods high in saturated and trans fats, encouraging physical activity, and using blood glucose monitoring to adjust food and eating patterns. Medications are also important components of successful MNT for T2DM. Frequent follow-up with an RDN can provide the problem-solving techniques, encouragement, and support that lifestyle changes require.

Physical activity improves insulin sensitivity, acutely lowers blood glucose in people with diabetes, and also may improve cardiovascular status. By itself it has only a modest effect on weight; however, it is essential for long-term weight maintenance.

Youth with type 1 diabetes. Involvement of a multidisciplinary team, including a physician, RDN, nurse, and behavioral specialist, all trained in pediatric diabetes, is the best means of achieving optimal diabetes management in youth. However, the most important team members are the child or adolescent and the family members and caregivers.

A major nutrition goal for children and adolescents with T1DM is maintenance of normal growth and development. Possible causes of poor weight gain and linear growth include poor glycemic control, inadequate insulin, and overrestriction of calories. The last may be a consequence of the common erroneous belief that restricting food, rather than adjusting insulin, is the way to control blood glucose. Additional reasons for poor weight gain unrelated to diabetes management may include other autoimmune conditions such as thyroid abnormalities (Hashimoto's thyroiditis), malabsorption syndromes (celiac disease), or disordered eating behaviors. Some adolescents will even use less insulin in an effort to lose weight, an eating disorder known as diabulimia. Excessive weight gain can be caused by excessive caloric intake, overtreatment of hypoglycemia, or overinsulinization. Other causes include low physical activity levels and hypothyroidism, accompanied by poor linear growth (Corbin et al, 2018).

The nutrition prescription is based on the nutrition assessment. Newly diagnosed children often present with weight loss and hunger; as a result, the initial meal plan must be based on adequate calories to restore and maintain appropriate body weight. In about 4 to 6 weeks the initial caloric level may need to be modified to meet more usual caloric requirements. Nutrient requirements for children and adolescents with diabetes appear to be similar to those of children and adolescents without diabetes. The dietary reference intakes (DRIs) can be used to determine energy requirements (Institute of Medicine [IOM], 2011). However, it may be preferable to use a food and nutrition history of typical daily intake, providing that growth and development are normal, to determine an individual child's or adolescent's energy needs.

Consultation with an RDN to develop and discuss the eating plan is encouraged (Chiang et al, 2014). Because energy requirements change with age, physical activity, and growth rate, an evaluation of height, weight, BMI, and the eating plan must be updated at least every year. Height and weight should be recorded on a CDC pediatric growth charts every 3 months. Good metabolic control is essential for normal growth and development (for growth charts see Appendices 4–11). Linear growth can be affected by an insulin prescription that is not adjusted as the child grows. Chronic undertreatment with insulin along with longstanding poor diabetes control often leads to poor growth and weight loss. However, withholding food or having the child eat consistently without an appetite for food in an effort to control blood glucose should be discouraged.

Individualized eating plans, insulin regimens using basal (background) and bolus (mealtime) insulins, and insulin algorithms or insulin pumps can provide flexibility for children with T1DM as well as their families. This approach accommodates irregular meal times and schedules and varying appetites and activity levels. Blood glucose records are essential to assist in making appropriate changes in insulin regimens. Daily eating patterns in young children generally include three meals and two or three snacks, depending on the length of time between meals and the child's physical activity level. Children often prefer smaller meals and snacks. Snacks can prevent hypoglycemia between meals and provide adequate calories. Older children and teens may prefer only three meals. Blood glucose monitoring data are then used to integrate an insulin regimen into the meal, snack, and exercise schedules.

After the appropriate nutrition prescription has been determined, the meal planning approach can be selected. Keep in mind that a number of meal planning approaches can be used. Carbohydrate counting for food planning provides youth and their families with guidelines that facilitate glycemic control while still allowing the choice of many common foods that children and adolescents enjoy. However, whatever approach to food planning is used, the youth and family must find it understandable and applicable to their lifestyle.

Youth with type 2 diabetes. Childhood obesity has been accompanied by an increase in the prevalence of T2DM among children and adolescents. IGT has been shown to be highly prevalent in obese youth and is associated with insulin resistance. Once T2DM develops, beta-cell failure is also a factor. Thus T2DM in youth follows a progressive pattern similar to T2DM in adults. However, because of the increase in overweight and obesity in children and adolescents, it can be difficult to determine immediately whether a youth has T1DM or T2DM. Because of this, testing for islet antibodies is recommended, but it may take weeks to get the results of the test. Therefore guidelines for the management of T2DM in youth recommend starting the youth on insulin if it is unclear whether the youth has T1DM or T2DM (Springer et al, 2013). When the youth has been diagnosed with T2DM, metformin and lifestyle changes, including nutrition therapy and physical activity, are recommended (ADA, 2018).

Successful lifestyle treatment of T2DM in children and adolescents involves cessation of excessive weight gain, promotion of normal growth and development, and the achievement of blood glucose and A1C goals (ADA, 2018). Nutrition guidelines also should address comorbidities such as hypertension and dyslipidemia. Offer behavior modification strategies to decrease intake of high-caloric, high-fat, and high-carbohydrate foods and sugar-sweetened beverages, while encouraging healthy eating habits and regular physical activity for the entire family. Youth with T2DM should be encouraged to exercise at least 60 minutes a day and to limit their nonacademic “screen time” (video games, television) to less than 2 hours a day (Springer et al, 2013). The guidelines also emphasize the importance of a team effort using not only the physician but also the skills of an RDN, diabetes educator, and a psychologist or social worker to deal with the emotional and/or behavioral problems that may accompany T2DM.

Women with preexisting diabetes and pregnancy. Normalization of blood glucose levels during pregnancy is very important for women who have preexisting diabetes or who develop GDM. Table 29.7 lists glucose goals for pregnancy. The MNT goals are to assist in achieving and maintaining optimal blood glucose control and to provide adequate maternal and fetal nutrition throughout pregnancy, energy intake for appropriate maternal weight gain, and necessary vitamins and minerals (Reader, 2012). Nutrition recommendations during pregnancy and lactation appear to be similar for women with and without diabetes; therefore, the DRIs can be used to determine energy and nutrient requirements during pregnancy and for lactation (IOM, 2002) (see Chapter 14).

Preconception counseling and the ability to achieve near-normal blood glucose levels before pregnancy have been shown to be effective in reducing the incidence of anomalies in infants born to women with preexisting diabetes to nearly that of the general population. As a result of hormonal changes during the first trimester, blood glucose levels are often erratic. Although caloric needs do not differ from those preceding pregnancy, the eating plan may have to be adjusted to accommodate the metabolic changes. Women should be educated about the increased risk of hypoglycemia during pregnancy and cautioned against overtreatment.

TABLE 29.7 Plasma Glucose Goals During Pregnancy

Gestational diabetes AND Pregnancy with preexisting type 1 or type 2 diabetes	Fasting: <95 mg/dL (5.3 mmol/L) and EITHER 1-h postmeal: <140 mg/dL (7.8 mmol/L) OR 2-h postmeal: <120 mg/dL (6.7 mmol/L) A1C: 6-6.5% (42-48 mmol/mol)
---	--

Data from American Diabetes Association, Management of Diabetes in Pregnancy: Standards of Medical Care in Diabetes—2018, *Diabetes Care* 41(S1):S138, 2018.

The need for insulin increases during the second and third trimesters of pregnancy. At 38 to 40 weeks' postconception, insulin needs and levels peak at two to three times prepregnancy levels. Pregnancy-associated hormones that are antagonistic to the action of insulin lead to elevated blood glucose levels. For women with preexisting diabetes, this increased insulin need must be met with increased exogenous insulin.

Eating plan adjustments are necessary to provide the additional calories required to support fetal growth, and weight should be monitored. During pregnancy the distribution of energy and carbohydrate intake should be based on the woman's food intake, eating habits, and blood glucose responses. Insulin regimens can be matched to food intake, but maintaining consistent eating times and intake is essential to avoid hypoglycemia caused by the continuous fetal draw of glucose from the mother. Smaller meals and more frequent snacks are often needed. Similarly, a late-evening snack is often necessary to decrease the likelihood of overnight hypoglycemia and fasting ketosis. Records of food intake and blood glucose values are essential for determining whether glycemic goals are being met and for preventing and correcting ketosis.

Regular follow-up visits during pregnancy are needed to monitor caloric and nutrient intake, blood glucose control, and whether starvation ketosis is present. Urine or blood ketones during pregnancy may signal ketosis that can be caused by inadequate energy or carbohydrate intake, omission of meals or snacks, or prolonged intervals between meals (e.g., more than 10 hours between the bedtime snack and breakfast). Ketonemia during pregnancy has been associated with fetal brain injury and may have long-term developmental impact, and women should be instructed to test for ketones periodically before breakfast (Mohan et al, 2017).

Women with gestational diabetes mellitus. MNT for GDM involves primarily a carbohydrate-controlled meal plan that promotes optimal nutrition for maternal and fetal health with adequate energy for appropriate gestational weight gain, achievement and maintenance of normoglycemia, and absence of ketosis. Specific nutrition and food recommendations are determined and modified based on individual assessment and blood glucose records. Monitoring blood glucose, fasting ketones, appetite, and weight gain can aid in developing an appropriate, individualized meal plan and in adjusting the meal plan throughout pregnancy.

Nutrition practice guidelines for gestational diabetes have been developed and tested (Academy of Nutrition and Dietetics Evidence Analysis Library, 2016). All women with GDM should receive MNT at

diagnosis of GDM. Monitoring records guide nutrition therapy and are used to determine whether additional therapy is needed. Insulin, metformin, or glyburide therapy is added if glucose goals exceed target range (see Table 29.7) on two or more occasions in a 1- to 2-week period without some obvious explanation (Mohan et al, 2017). Inadequate weight gain and ketone testing can be useful in determining when women are undereating to keep glucose levels within target range in an effort to avoid insulin therapy.

Carbohydrates should be distributed throughout the day into three small-to-moderate size meals and two to four snacks. All pregnant women require a minimum of 175 g of carbohydrates daily (Academy of Nutrition and Dietetics Evidence Analysis Library, 2016). An evening snack usually is needed to prevent accelerated ketosis overnight. Carbohydrates are not as well tolerated at breakfast as they are at other meals because of increased levels of cortisol and growth hormones. To compensate for this, the initial eating plan may have approximately 30 g of carbohydrate at breakfast. To satisfy hunger, protein foods can be added because they do not affect blood glucose levels.

According to the EBNPG, the RDN should individualize the calorie prescription based on a thorough nutrition assessment with guidance from relevant references (DRIs, the IOM) and encourage adequate caloric intake to promote fetal/neonatal and maternal health, achieve glycemic goals, and promote appropriate gestational weight gain. Weight gain during pregnancy for women with GDM should be similar to that of women without diabetes.

Exercise assists in overcoming peripheral resistance to insulin and in controlling fasting and postprandial hyperglycemia and may be used as an adjunct to nutrition therapy to improve maternal glycemia. The ideal form of exercise is unknown, but a brisk walk after meals is often recommended.

Women with GDM (and women with preexisting diabetes) should be encouraged to breastfeed because breastfeeding is associated with a reduced incidence of future T2DM (ADA, 2018) (see Chapter 14). For women with GDM who are overweight/obese or with above-recommended weight gain during pregnancy, weight loss is advised after delivery. Weight loss may aid in reducing the risk of recurrent GDM or future development of T2DM (Reader, 2012).

Older adults. The prevalence of diabetes and IGT increases dramatically as people age. Many factors predispose older adults to diabetes: age-related decreases in insulin production, adiposity, decreased physical activity, multiple prescription medications, genetics, and coexisting illnesses. A major factor appears to be insulin resistance. Controversy persists as to whether the insulin resistance is a primary change or whether it is attributable to reduced physical activity, decreased lean body mass (sarcopenia), and increased adipose tissue, which are common in older adults. Furthermore, medications used to treat coexisting diseases may complicate diabetes therapy in older adults.

Despite the increase in glucose intolerance with age, aging should not be a reason for suboptimal control of blood glucose. Persistent hyperglycemia has deleterious effects on the body's defense mechanisms against infection. It also increases the pain threshold by exacerbating neuropathic pain, and it has a detrimental effect on the outcome of cerebrovascular accidents.

However, while it is important to control blood glucose levels in this population, the recommendations in blood glucose targets for older adults with diabetes have changed. Older adults who are otherwise healthy with few coexisting chronic illnesses and intact cognitive function and functional status should have lower glycemic goals (A1C <7.5% [58 mmol/mol]), while those with multiple coexisting chronic

illnesses, cognitive impairment, or functional dependence should have less stringent glycemic goals (A1C <8.0% to 8.5% [64 to 69 mmol/mol]) (ADA, 2018).

Nutrition recommendations for older adults with diabetes should include meeting the DRI for age for nutrients, drinking adequate fluid, avoiding significant weight loss, and being sensitive to individual preferences and longstanding food habits while advocating good nutrition (Stanley, 2012) (see Chapter 19). Restrictive diets are contraindicated. Physical activity can reduce the decline in aerobic capacity significantly that occurs with age, improve risk factors for atherosclerosis, slow the decline in age-related lean body mass, decrease central adiposity, and improve insulin sensitivity; thus it should be encouraged. Flexibility training and balance training are recommended two to three times per week for older adults with diabetes. Yoga and tai chi may be included based on individual preferences to increase flexibility, muscular strength, and balance (ADA, 2018).

Malnutrition, not obesity, is the more prevalent nutrition-related problem in older adults. It often remains subclinical or unrecognized because the result of malnutrition—excessive loss of lean body mass—resembles the signs and symptoms of the aging process. Malnutrition and diabetes adversely affect wound healing and defense against infection, and malnutrition is associated with depression and cognitive deficits. The most reliable indicator of poor nutrition status in older adults is a change in body weight; involuntary weight gain or loss of more than 10 pounds or 10% of body weight in less than 6 months indicates a need to evaluate the reason.

It is essential that older adults, especially those in long-term care settings, focus on enjoyment of the meal experience in addition to meeting nutritional needs. Dietary restriction is not warranted for older residents in long-term health facilities. Residents should be served the regular, unrestricted menu. Strict carbohydrate control and use of sugar-free foods has not been shown beneficial in this population; however, routine meals with consistent portion sizes can assist with blood sugar control (Swift, 2012).

Hyperglycemia and dehydration can lead to a serious complication of diabetes in older adults: **hyperglycemic hyperosmolar state (HHS)**. Patients with HHS have a very high blood glucose level (>600 mg/dL [33.3mmol/L]) without ketones (Pasquel and Umpierrez, 2014). Patients are markedly dehydrated, and mental alterations range from mild confusion to hallucinations or coma. Patients who have HHS have sufficient insulin to prevent lipolysis and ketosis. Treatment consists of hydration and small doses of insulin to control hyperglycemia.

The Nutrition Prescription

To develop, educate, and counsel individuals regarding the nutrition prescription, it is essential to learn about their lifestyle and eating habits. Food and eating histories can be done several ways, with the objective of determining a schedule and pattern of eating that will be the least disruptive to the lifestyle of the individual with diabetes and, at the same time, will facilitate improved metabolic control. With this objective in mind, asking the individual either to record or report what, how much, and when he or she typically eats during a 24-hour period may be the most useful. Another approach is to ask the individual to keep and bring a 3-day or 1-week food intake record (see Chapter 4 and Figs. 4.5 and 4.6). The request to complete a food record can be made when an appointment with the RDN is scheduled. It is also important to learn about daily routine and schedule. The following information is needed: (1) time of waking; (2) usual meal and eating times; (3) work schedule or school hours; (4) type, amount, and timing of exercise; (5) usual

Food Group	Meal/Snack/Time						Total servings/day	CHO (g)	Protein (g)	Fat (g)	Calories
	Breakfast	Snack	Lunch	Snack	Dinner	Snack					
Starches							15	3	1	80	
Fruit							15			60	
Milk							12	8	1	100	
Vegetables							5	2		25	
Meats/ Substitutes								7	5(3)	75(55)	
Fats									5	45	
CHO Choices							Total grams				
							Calories/gram	X4=	X4=	X9=	Total calories
							Percent calories				

Calculations are based on medium-fat meats and skim/very low-fat milk. If diet consists predominantly of low-fat meats, use the factor 3 g instead of 5 g fat; if predominantly high-fat meats, use 8 g fat. If low-fat (2%) milk is used, use 5 g fat; if whole milk is used, use 8 g fat.

Fig. 29.4 Worksheet for assessment and design of a meal or food plan. CHO, Carbohydrate.

sleep habits; (6) type, dosage, and timing of diabetes medication; and (7) SMBG data.

Using the assessment data and food and nutrition history information, a preliminary eating plan can then be designed and, if the individual desires, sample menus provided. Developing an eating plan does not begin with a set calorie or macronutrient prescription; instead it is determined by modifying the individual's usual food intake as necessary. The worksheet in Fig. 29.4 can be used to record the usual foods eaten and to modify the usual food and nutrient intake as necessary. The macronutrient and caloric values for the food lists are listed on the form and in Table 29.8; see Appendix 18 for portion sizes of the foods on the food lists. These tools are useful in evaluating nutrition assessments.

Using the form in Fig. 29.4, the RDN begins by totaling the number of servings from each food list and multiplying this number by the grams of carbohydrate, protein, and fat contributed by each. Next, the grams of carbohydrate, protein, and fat are totaled from each column. Then the grams of carbohydrates and protein are multiplied by 4 (4 kcal/g of carbohydrates and protein), and the grams of fat are multiplied by 9 (9 kcal/g of fat). Total calories and percentage of calories from each macronutrient can then be determined. Numbers derived from these calculations are then rounded off. Fig. 29.5 provides an example of a preliminary eating plan. In this example the nutrition prescription would be the following: 1900 to 2000 calories, 230 g of carbohydrates (50%), 90 g of protein (20%), and 65 g of fat (30%). The number of carbohydrate choices for each meal and snack is the total of the starch, fruit, and milk

servings. Vegetables, unless starchy or eaten in very large amounts (three or more servings per meal), generally are considered "free foods." The carbohydrate choices are circled under each meal and snack column.

The next step is to evaluate the preliminary eating plan. First and foremost, is the eating plan feasible and will it fit into the individual's lifestyle? Second, is it appropriate for diabetes management? Third, does it encourage healthful eating? Fourth, if the individual is taking diabetes medicine, is the eating plan coordinated with the medication plan to reduce risk of hypoglycemia and/or minimize postprandial hyperglycemia?

To discuss feasibility, the eating plan is reviewed with the individual in terms of general food intake. Timing of meals and snacks and approximate portion sizes and types of foods are discussed. Calorie levels are only approximate, and adjustments in calories can be made during follow-up visits. A meal-planning approach can be selected later that will assist the patient in making food choices. At this point it must be determined whether this eating plan is reasonable.

To determine the appropriateness of the eating plan for diabetes management, distribution of the meals or snacks must be assessed along with the types of medications prescribed and treatment goals. Often the eating plan begins with three or four carbohydrate servings per meal for adult women and four or five for adult men and, if desired, one or two for a snack. Eating snacks when not hungry simply provides unnecessary calories. Adding protein to a snack may promote meal balance and optimize daily intake of macronutrients; however,

Food Group	Meal/Snack/Time						Total servings/day	CHO (g)	Protein (g)	Fat (g)	Calories	
	Breakfast 7:30 AM	Snack 10:00	Lunch 12:00	Snack 3:00	Dinner 6:30	Snack 10:00						
Starches	2	1	2-3	1	2-3	1-2	10	150	30	10	80

research does not support the need for protein for optimal glucose control (ADA, 2018). Results of blood glucose monitoring before the meal and 2 hours after the meal, plus feedback from the person with diabetes, are used to assess if these recommendations are feasible and realistic and to determine whether target glucose goals are being achieved.

Another strategy for meal planning is the U.S. Department of Agriculture (USDA) MyPlate method, which recommends making half your plate nonstarchy vegetables, one quarter protein, and one quarter carbohydrates. Many patients find this style of eating more flexible and user friendly.

For people who require insulin, the timing of eating is important, as insulin must be synchronized with food consumption (see Medications earlier in the chapter). If the eating plan is determined first, an insulin regimen can be selected that will fit with it. The best way to ensure that the eating plan promotes healthful eating is to encourage individuals to eat a variety of foods from all the food groups. The Dietary Guidelines for Americans, which includes a suggested number of servings from each food group, can be used to compare the individual's eating plan with the nutrition recommendations for all Americans (see Chapter 10).

Nutrition Education and Counseling

Implementation of MNT begins with the RDN selecting from a variety of interventions (reduced energy and fat intake, carbohydrate counting, simplified meal plans, healthy food choices, individualized meal planning strategies, insulin-to-carbohydrate ratios, physical activity, and behavioral strategies) (Pastors and Franz, 2012). All of the above interventions have been shown to lead to improved metabolic outcomes. Furthermore, nutrition education and counseling must be sensitive to the individual with diabetes, including personal needs, willingness to change, and ability to make changes (Fig. 29.6). Assessing the individual's health literacy and numeracy also may be beneficial. No single eating plan approach has been shown to be more effective than any other, and the eating plan approach selected should allow individuals with diabetes to select appropriate foods for meals and snacks.

A popular approach to meal planning is carbohydrate counting. Carbohydrate-counting educational tools are based on the concept that the carbohydrate in foods is the major predictor of postprandial

Fig. 29.6 A woman with type 1 diabetes mellitus is learning about carbohydrate counseling from her RDN counselor.

blood glucose levels. One carbohydrate serving contributes 15 g of carbohydrates. Basic carbohydrate counting emphasizes the following topics: basic facts about carbohydrates, primary food sources of carbohydrate, average portion sizes and the importance of consistency and accurate portions, amount of carbohydrates that should be eaten, and label reading. Advanced carbohydrate counting emphasizes the importance of record keeping, calculating insulin-to-carbohydrate ratios, and pattern management.

An important goal of nutrition counseling is to facilitate changes in existing food and nutrition-related behaviors and the adoption of new ones. The combined use of behavior change theories may potentially have a greater impact than any individual theory or technique used alone (Franz et al, 2012). The following five A's can guide the education/counseling sessions: step 1: ask; step 2: assess; step 3: advise; step 4: agree; and step 5: arrange. The "ask" step emphasizes the importance of questions as the RDN aims to develop a relationship with the client. Motivational interviewing techniques are used initially and throughout all of the encounters. In the "assess" step, the RDN evaluated the client's readiness to change. Different intervention strategies may be needed for individuals at different stages of the change process (see Chapter 13).

Nutrition Monitoring and Evaluation

Food intake, medication, metabolic control (glycemia, lipids, and blood pressure), anthropometric measurements, and physical activity should be monitored and evaluated. Medical and clinical outcomes should be monitored after the second or third visit to determine whether the individual is making progress toward established goals. If no progress is evident, the individual and RDN must reassess and perhaps revise nutrition interventions. Blood glucose monitoring results can be used to determine whether adjustments in foods and meals will be sufficient to achieve blood glucose goals or if medication additions or adjustments have to be combined with MNT. Nutrition care must be coordinated with an interdisciplinary team.

Documentation in the individual's medical record serves as a communication tool for members of the health care team. The medical record also serves as a legal document of what was done and not done and supports reimbursement of nutrition services billed to insurance carriers. There are many different formats available for medical record documentation. The appropriate format depends on where the RDN practices and whether electronic health records are used. Regardless of the specific format, the RDN can document using the assessment, diagnosis, interventions, monitoring, and evaluation (ADIME) content (Box 29.4).

Follow-Up Encounters

Successful nutrition therapy involves a process of assessment, problem solving, adjustment, and readjustment. Food records can be compared with the eating plan, which will help to determine whether the initial eating plan needs changing, and can be integrated with the blood glucose-monitoring records to determine changes that can lead to improved glycemic control.

Nutrition follow-up visits should provide encouragement and ensure realistic expectations for the individual with diabetes. A change in eating habits is not easy for most people, and they become discouraged without appropriate recognition of their efforts. Individuals should be encouraged to speak freely about problems they are having with their eating plan. Furthermore there may be major life changes that require changes in the eating plan. Job and schedule changes, travel, illness, and other factors all have an impact on the meal plan.

BOX 29.4 Nutrition Care Documentation**Nutrition Assessment**

- Date and time of assessment
- Pertinent data collected and comparisons with standards (e.g., food and nutrition history, biochemical data, anthropometric measurements, client history, medical therapy, and supplement use)
- Patient's readiness to learn, food and nutrition-related knowledge, and potential for change
- Physical activity history and goals
- Reason for discontinuation of nutrition therapy, if appropriate

Nutrition Diagnoses

- Date and time
- Concise written statement of nutrition diagnosis (or nutrition diagnoses) written in the problem, etiology, signs and symptoms (PES) format. If there is no existing or predicted nutrition problem that requires a nutrition intervention, state "no nutrition diagnosis at this time"

Nutrition Interventions

- Date and time
- Specific treatment goals and expected outcomes
- Recommended nutrition prescription and nutrition interventions (individualized for the patient)
- Any adjustments to plan and justifications
- Patient's receptivity regarding recommendations
- Changes in patient's level of understanding and food-related behaviors
- Referrals made and resources used
- Any other information relevant to providing care and monitoring progress over time
- Plans for follow-up and frequency of care

Nutrition Monitoring and Evaluation

- Date and time
- Specific nutrition outcomes indicators and results relevant to the nutrition diagnosis (or diagnoses) and intervention plans and goals, compared with previous status or reference goals
- Progress toward nutrition intervention goals
- Factors facilitating or hindering progress
- Other positive or negative outcomes
- Future plans for nutrition care, monitoring, and follow-up or discharge

ACUTE COMPLICATIONS

Hypoglycemia and DKA are the two most common acute complications related to diabetes.

Hypoglycemia

A low blood glucose, or **hypoglycemia (or insulin reaction)**, is a common side effect of insulin therapy, although individuals taking insulin secretagogues also can be affected. **Autonomic symptoms** arise from the action of the autonomic nervous system and are often the first signs of mild hypoglycemia. Adrenergic symptoms include shakiness, sweating, palpitations, anxiety, and hunger. **Neuroglycopenic symptoms**, related to an insufficient supply of glucose to the brain, also can occur at similar glucose levels as autonomic symptoms but with different manifestations. The earliest signs of neuroglycopenia include a

BOX 29.5 Common Causes of Hypoglycemia**Medication Errors**

- Inadvertent or deliberate errors in medication (generally insulin) dosages
- Excessive insulin or oral secretagogue dosages
- Reversal of morning or evening insulin doses
- Improper timing of insulin in relation to food intake

Nutrition Therapy or Exercise

- Omitted or inadequate food intake
- Timing errors; delayed meals or snacks
- Unplanned or increased physical activities or exercise
- Prolonged duration or increased intensity of exercise

Alcohol and Drugs

- Alcohol intake without food
- Impaired mentation associated with alcohol, marijuana, or other illicit drugs

Adapted from Kaufman F: *Medical management of type 1 diabetes*, ed 6, Alexandria, VA, 2012, American Diabetes Association.

slowing down in performance and difficulty concentrating and reading. As blood glucose levels drop further, the following symptoms occur: confusion and disorientation, slurred or rambling speech, irrational or unusual behaviors, extreme fatigue and lethargy, seizures, and unconsciousness. While symptoms differ from person to person, they tend to be consistent from episode to episode for any one individual. Several common causes of hypoglycemia are listed in [Box 29.5](#).

In T1DM and T2DM it has been demonstrated that counterregulatory responses to hypoglycemia steadily decline with frequent and repetitive episodes. It can become a vicious cycle as hypoglycemic episodes impair defenses against a subsequent hypoglycemic episode and thus can result in recurrent hypoglycemia. Hypoglycemia causes increased morbidity in most people with T1DM and many with long-duration T2DM.

In general, a blood glucose of 70 mg/dL (3.9 mmol/L) or lower should be treated immediately. Treatment of hypoglycemia requires ingestion of glucose or carbohydrate-containing food. Although any carbohydrate will raise glucose levels, glucose is the preferred treatment. The form of carbohydrates (i.e., liquid or solid) used to treat does not make a difference. Commercially available glucose tablets have the advantage of being premeasured to help prevent overtreatment. Ingestion of 15 to 20 g of glucose is an effective but temporary treatment. Note that pure glucose is the preferred treatment, but any form of carb that contains glucose will increase blood glucose levels. Initial response to treatment should be seen in about 10 to 20 minutes; however, blood glucose should be evaluated again in about 60 minutes as additional carbohydrate may be necessary ([Box 29.6](#)) ([ADA, 2018](#)).

Severely low blood glucose can cause loss of consciousness or seizures. If individuals are unable to swallow, administration of subcutaneous or intramuscular glucagon may be needed. Parents, siblings, friends, and spouses should be taught how to mix, draw up, and administer glucagon so that they are properly prepared for emergency situations. Kits that include a syringe prefilled with diluting fluid are available. After the injection, turn the patient on their side to prevent choking in case of vomiting. Nausea and vomiting are common side effects of glucagon. The patient should be given food or beverage containing carbohydrate as soon as they regain consciousness and can swallow.

SMBG is essential for prevention and treatment of hypoglycemia. Changes in insulin injections, eating, exercise schedules, and travel routines warrant increased frequency of monitoring. Some patients

BOX 29.6 Treatment of Hypoglycemia

- Immediate treatment with carbohydrates is essential. If the blood glucose level falls below 70 mg/dL (3.9 mmol/L), treat with 15 g of carbohydrates, which is equivalent to:
 - 15 g carbohydrate from glucose tablets (4) or glucose gel
 - 4-6 ounces of fruit juice or regular soft drinks
 - 6 ounces (1/2 can) of regular soda pop (not sugar-free)
 - 8 ounces (1 cup) of sports drink (not sugar-free)
 - 1 tablespoon of sugar, syrup or honey
- Retest in approximately 10-15 minutes. If the blood glucose level remains <70 mg/dL (<3.9 mmol/L), treat with an additional 15 g of carbohydrates.
- Repeat testing and treatment until the blood glucose level returns to within normal range.
- If it is more than 1 hour to the next meal, test again 60 minutes after treatment as additional carbohydrate may be needed.

Adapted from Kaufman F: *Medical management of Type 1 diabetes*, ed 6, Alexandria, VA, 2012, American Diabetes Association.

experience hypoglycemia unawareness, which means that they do not experience the usual symptoms of hypoglycemia. Patients must be reminded of the need to treat hypoglycemia, even in the absence of symptoms. Hypoglycemia unawareness, or one or more episodes of severe hypoglycemia, warrants reevaluation of the treatment regimen. A CGM may be a useful tool in those with hypoglycemia unawareness and/or frequent hypoglycemic episodes (ADA, 2018).

Hyperglycemia and Diabetic Ketoacidosis

Hyperglycemia can lead to DKA, a life-threatening but reversible complication, which occurs when the body produces high levels of blood acids called ketones. DKA is always the result of inadequate insulin for glucose use. As a result, the body depends on fat for energy, and ketones are formed. Acidosis results from increased production and decreased use of acetoacetic acid and 3-beta-hydroxybutyric acid from fatty acids. Ketones spill into the urine; hence the reliance on urine testing for ketones.

DKA is characterized by an elevated serum glucose level (greater than 250 mg/dL [13.88 mmol/L]), an elevated serum ketone level, a pH less than 7.3, and a serum bicarbonate level less than 18 mEq/L (18 mmol/L) (Westerberg, 2013). Symptoms include polyuria, polydipsia, hyperventilation, dehydration, the fruity odor of ketones, and fatigue. SMBG, testing for ketones, and medical intervention can help prevent DKA. If left untreated, DKA can lead to coma and death. Treatment includes supplemental insulin, fluid and electrolyte replacement, and medical monitoring. Acute illnesses such as flu, colds, vomiting, and diarrhea, if not managed appropriately, can lead to the development of DKA. Patients need to know the steps to take during acute illness to prevent DKA (Box 29.7). During acute illness, oral ingestion of about 150 to 200 g of carbohydrates per day (45 to 50 g every 3 to 4 hr) should be sufficient, along with medication adjustments, to keep glucose in the goal range and to prevent starvation ketosis.

Fasting hyperglycemia is a common finding in persons with diabetes. The amount of insulin required to normalize blood glucose levels during the night is less in the predawn period (from 1 AM to 3 AM) than at dawn (from 4 AM to 8 AM). The increased need for insulin at dawn causes a rise in FBG levels referred to as the **dawn phenomenon**. It results if insulin levels decline between predawn and dawn or if overnight hepatic glucose output becomes excessive as is common in T2DM. To identify the dawn phenomenon, blood glucose levels are monitored at bedtime and at 2 AM to 3 AM. With the dawn phenomenon, predawn blood glucose levels will be in the low range of normal but not in the

BOX 29.7 Sick-Day Guidelines for Persons With Diabetes

1. During acute illnesses, usual doses of insulin and other glucose-lowering medications are required. The need for insulin continues, or may even increase, during periods of illness. Fever, dehydration, infection, or the stress of illness can trigger the release of counterregulatory or “stress” hormones, causing blood glucose levels to become elevated.
2. Blood glucose levels and urine or blood testing for ketones should be monitored at least four times daily (before each meal and at bedtime). Blood glucose readings exceeding 250 mg/dL and the presence of ketones are danger signals indicating that additional insulin is needed.
3. Ample amounts of liquid need to be consumed every hour. If vomiting, diarrhea, or fever is present, small sips—1 or 2 tablespoons every 15-30 min—can usually be consumed. If vomiting continues and the individual is unable to take fluids for longer than 4 hr, the health care team should be notified.
4. If regular foods are not tolerated, liquid or soft carbohydrate-containing foods (such as regular soft drinks, soup, juices, and ice cream) should be eaten. Eating about 10-15 g of carbohydrate every 1-2 hr (or 50 g of carbohydrate every 3-4 hr) is usually sufficient.
5. The health care team should be called if illness continues for more than 1 day.

Adapted from Kaufman F: *Medical management of type 1 diabetes*, ed 6, Alexandria, VA, 2012, American Diabetes Association.

hypoglycemic range. For patients with T2DM, metformin often is used because it decreases hepatic glucose output. For persons with T1DM, administering insulin that does not peak at 1 AM to 3 AM, such as a long-acting insulin, should be considered.

Hypoglycemia followed by rebound hyperglycemia is called the **Somogyi effect**. This phenomenon originates during hypoglycemia with the secretion of counterregulatory hormones (glucagon, epinephrine, growth hormone, and cortisol) and usually is caused by excessive exogenous insulin doses. Hepatic glucose production is stimulated, thus raising blood glucose levels. If rebound hyperglycemia goes unrecognized and insulin doses are increased, a cycle of overinsulinization may result. Decreasing evening insulin doses or, for the dawn phenomenon, taking a long-acting insulin should be considered.

LONG-TERM COMPLICATIONS

Long-term complications of diabetes include macrovascular diseases, microvascular diseases, and neuropathy. **Macrovascular diseases** involve diseases of large blood vessels. In contrast, **microvascular diseases** associated with diabetes involve the small blood vessels and include nephropathy and retinopathy.

Common consequences of diabetic neuropathy and/or peripheral arterial disease (PAD) include foot ulcers and amputation, and both represent major causes of morbidity and mortality in people with diabetes. Early detection is key in treatment of patients with diabetes and feet at risk for ulcers and amputations. Risk factors include poor glycemic control, peripheral neuropathy with loss of protective sensation (LOPS), cigarette smoking, foot deformities, preulcerative callus or corn, PAD, history of foot ulcer or amputation, visual impairment, and diabetic kidney disease (especially patients on dialysis) (ADA, 2018).

MNT is important in managing several long-term complications of diabetes. Nutrition therapy is also a major component in reducing risk factors for chronic complications, especially those related to macrovascular disease.

Macrovascular Diseases

Insulin resistance, which may precede the development of T2DM and macrovascular disease by many years, induces numerous metabolic changes known as the **metabolic syndrome** (see Chapter 20). It is characterized by intraabdominal obesity or the android distribution of adipose tissue (waist circumference greater than 102 cm [40 in] in men and greater than 88 cm [35 in] in women) and is associated with dyslipidemia, hypertension, glucose intolerance, and increased prevalence of macrovascular complications. Other risk factors include genetics, smoking, sedentary lifestyle, high-fat diet, renal failure, and microalbuminuria.

Macrovascular diseases including atherosclerotic cardiovascular disease (ASCVD), peripheral vascular disease (PVD), and cerebrovascular disease are more common, tend to occur at an earlier age, and are more extensive and severe in people with diabetes. People with diabetes have the CVD risk equivalent to persons with preexisting CVD and no diabetes (Low Wang et al, 2016). Furthermore, in women with diabetes the increased risk of mortality from heart disease is greater than in men, in contrast to the nondiabetic population, in which heart disease mortality is greater in men than in women (Recarti et al, 2015).

Dyslipidemia

Patients with diabetes have an increased prevalence of lipid abnormalities that contribute to higher rates of CVD. For example, in T2DM the prevalence of an elevated cholesterol level is about 28% to 34%. Similarly, about 5% to 14% of patients with T2DM have high triglyceride levels. Lower HDL cholesterol levels are common. People with T2DM typically have smaller, denser LDL particles, which increase atherogenicity even if the total LDL cholesterol level is not significantly elevated. Lifestyle intervention, including MNT, along with weight loss (if indicated) through reduced energy intake and increased physical activity and smoking cessation should be considered. Evidence is inconclusive for the ideal amount of total fat intake; fat quality may as important as quantity (Evert et al, 2013). Diet should be focused on reduction of saturated fat, trans fat, and cholesterol and increased intake of omega-3 fat (in food, not as supplements), viscous fiber, and plant stanols/sterols (ADA, 2018). In people with T2DM, a Mediterranean-style, MUFA-rich eating pattern may benefit glycemic control and CVD risk factors. Other CVD nutrition recommendations for people with diabetes are the same as for the general public. The most current American College of Cardiology (ACC)/American Heart Association (AHA) recommendations are for use of the DASH diet eating pattern (see Chapter 32). In addition to nutrition therapy, statin therapy is typically recommended, regardless of lipid levels, for all adults over 40 with diabetes (ADA, 2018) (Table 29.9).

Hypertension

Hypertension is a common comorbidity of diabetes, with about 74% of adults with diabetes having blood pressure of 140/90 mm Hg or higher or using prescription medications for hypertension (CDC, 2018). In order to reduce the risk of macrovascular and microvascular disease, treatment of hypertension in people with diabetes should be vigorous. Blood pressure should be measured at every routine visit, with a goal for blood pressure control of less than 140/80 mm Hg. MNT interventions for people with hypertension include weight loss (if overweight), DASH-style eating pattern (Appendix 17), reducing sodium intake and increasing potassium intake, moderation of alcohol intake, and increased physical activity (see Chapter 32). The recommendation for the general population to reduce sodium to less than 2300 mg/day is also appropriate for people with diabetes and hypertension (ADA, 2018). For individuals with both diabetes

TABLE 29.9 Recommendations for Lipid and Blood Pressure for Most Adults With Diabetes

Lipids/Blood Pressure	Criteria
LDL cholesterol	<100 mg/dL (<2.6 mmol/l)*
HDL cholesterol	Men: >40 mg/dL (>1.0 mmol/l) Women: >50 mg/d (>1.3 mmol/l)
Triglycerides	<150 mg/dL (<1.7 mmol/l)
Blood pressure	<140/90 mm Hg

*For patients with diabetes and atherosclerotic cardiovascular disease, if LDL cholesterol is greater than or equal to 70 mg/dL on maximally tolerated statin dose, consider adding additional LDL lowering therapy (such as ezetimibe or PCSK9 inhibitor).

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

Data from American Diabetes Association: Cardiovascular disease and risk management: Standards of medical care in diabetes—2018, *Diabetes Care* 41(S1):S86-104, 2018.

and hypertension, further reduction in sodium intake should be individualized. Consideration must be given to issues such as the availability, palatability, and additional cost of low sodium food products. Pharmacologic therapy for hypertension includes either an angiotensin-converting enzyme (ACE) inhibitor, angiotensin receptor blockers, thiazide-like diuretics, and/or dihydropyridine calcium channel blockers (ADA, 2018). See Table 29.9.

Microvascular Diseases

Diabetic Kidney Disease

Diabetic kidney disease (DKD) or diabetic nephropathy occurs in 20% to 40% of patients with diabetes and is the single leading cause of end-stage renal disease (ESRD). Because of the much greater prevalence of T2DM, such patients constitute over half of the patients with diabetes currently starting on dialysis (see Chapter 34).

An annual screening to quantitate urine albumin excretion rate should be performed in patients who have had T1DM for more than 5 years, and in all patients with T2DM starting at diagnosis (ADA, 2014b). The serum creatinine is used to estimate glomerular filtration rate (GFR) and stage the level of chronic kidney disease (CKD), if present.

To reduce the risk and slow the progression of DKD, blood glucose and blood pressure control should be optimized. Although low protein diets (below 0.6 to 0.8 g/kg) have been shown to lower albuminuria, they do not alter the course of GFR decline or improve glycemic or CVD risk measures, and therefore are not recommended (Evert et al, 2013).

Retinopathy

Diabetic retinopathy is estimated to be the most frequent cause of new cases of blindness among adults 20 to 74 years of age. Glaucoma, cataracts, and other disorders of the eye also occur earlier and more frequently with diabetes (ADA, 2018). Laser photocoagulation surgery can reduce the risk of further vision loss but usually does not restore lost vision—thus the importance for a screening program to detect diabetic retinopathy.

Neuropathy

Chronic high levels of blood glucose also are associated with nerve damage, and an estimated 50% of people with diabetes have mild to severe forms of nervous system damage (CDC, 2018). Intensive treatment of hyperglycemia reduces the risk and slows progression of

diabetic neuropathy but does not reverse neuronal loss. Peripheral neuropathy usually affects the nerves that control sensation in the feet and hands. Autonomic neuropathy affects nerve function controlling various organ systems. Cardiovascular effects include postural hypotension and decreased responsiveness to cardiac nerve impulses, leading to painless or silent ischemic heart disease. Sexual function may be affected, with impotence the most common manifestation.

Damage to nerves innervating the gastrointestinal tract can cause a variety of problems. Neuropathy can be manifested in the esophagus as nausea and esophagitis, in the stomach as unpredictable emptying, in the small bowel as loss of nutrients, and in the large bowel as diarrhea or constipation.

Gastroparesis is characterized by delayed gastric emptying in the absence of mechanical obstruction of the stomach. Common symptoms include feelings of fullness, bloating, nausea, vomiting, diarrhea, or constipation. One study found that the prevalence of gastroparesis in patients with diabetes was 64%, which is higher than reported in some previous studies (Alipour et al, 2017). Therefore gastroparesis should be suspected in individuals with erratic glucose control.

The first step in management of patients with neuropathy should be to aim for stable and optimal glycemic control. MNT involves minimizing abdominal stress. Small, frequent meals may be better tolerated than three full meals a day, and these meals should be low in fiber and fat. If solid foods are not well tolerated, liquid meals may have to be recommended. For patients using insulin, the timing of insulin administration should be adjusted to match the usually delayed nutrient absorption. Insulin injections may even be required after eating. Frequent blood glucose monitoring is important to determine appropriate insulin therapy.

A prokinetic agent such as metoclopramide is used most commonly to treat gastroparesis. Antiemetic agents may be helpful for the relief of symptoms. In very severe cases, generally with unintentional weight loss, a feeding tube is placed in the small intestine to bypass the stomach. Gastric electric stimulation with electrodes surgically implanted in the stomach may be used when medications fail to control nausea and vomiting.

HYPOGLYCEMIA OF NONDIABETIC ORIGIN

Hypoglycemia of nondiabetic origin has been defined as a clinical syndrome with diverse causes in which low levels of plasma glucose eventually lead to neuroglycopenia. Hypoglycemia means low (hypo-) blood glucose (glycemia). Normally the body is remarkably adept at maintaining fairly steady blood glucose levels—usually between 60 and 100 mg/dL (3.3 to 5.6 mmol/L), despite the intermittent ingestion of food. Maintaining normal levels of glucose is important because body cells, especially the brain and central nervous system, must have a steady and consistent supply of glucose to function properly. Under physiologic conditions the brain depends almost exclusively on glucose for its energy needs. This is true even with the presence of hunger.

Pathophysiology

In a small number of people, blood glucose levels drop too low. Symptoms are often felt when blood glucose is below 65 mg/dL (3.6 mmol/L). If the brain and nervous system are deprived of the glucose they need to function, symptoms such as sweating, shaking, weakness, hunger, headaches, and irritability can develop. Symptoms of hypoglycemia have been recognized at plasma glucose levels of about 60 mg/dL, and impaired brain function has occurred at levels of about 50 mg/dL. A hypoglycemia alert value greater than or equal to 70 mg/dL (3.9 mmol/L) can help determine therapeutic dose adjustment of glucose-lowering drugs and is often related to symptomatic hypoglycemia (ADA, 2018).

Hypoglycemia can be difficult to diagnose because these typical symptoms can be caused by many different health problems. For example, adrenaline (epinephrine) released as a result of anxiety and stress can trigger the symptoms similar to those of hypoglycemia. The only way to determine whether hypoglycemia is causing these symptoms is to measure blood glucose levels while an individual is experiencing the symptoms. Hypoglycemia can best be defined by the presence of three features known as **Whipple's triad**: (1) a low plasma or blood glucose level, (2) symptoms of hypoglycemia at the same time, and (3) resolution of the symptoms once the blood glucose returns to normal.

A fairly steady blood glucose level is maintained by the interaction of several mechanisms. After eating, carbohydrates are broken down into glucose and enter the bloodstream. As blood glucose levels rise, the pancreas responds by releasing the hormone insulin, which allows glucose to leave the bloodstream and enter various body cells, where it fuels the body's activities. Glucose is also taken up by the liver and stored as glycogen for later use.

When glucose concentrations from the last meal decline, the body goes from a fed to a fasting state. Insulin levels decrease, which keeps the blood glucose levels from falling too low. Stored glucose is released from the liver back into the bloodstream with the help of glucagon from the pancreas. Normally the body's ability to balance glucose, insulin, and glucagon (and other counterregulatory hormones) keeps glucose levels within the normal range. Glucagon provides the primary defense against hypoglycemia; without it, full recovery does not occur. Epinephrine is not necessary for counterregulation when glucagon is present. However in the absence of glucagon, epinephrine has an important role.

Types of Hypoglycemia

Two types of hypoglycemia can occur in people who do not have diabetes. If blood glucose levels fall below normal limits within 2 to 5 hours after eating, this is **postprandial (reactive) hypoglycemia**. It can be caused by an exaggerated or late insulin response caused by either insulin resistance or elevated GLP-1, alimentary hyperinsulinism, renal glycosuria, defects in glucagon response, or high insulin sensitivity. Additionally it can be caused by rare syndromes such as hereditary fructose intolerance, galactosemia, leucine sensitivity or a rare beta-cell pancreatic tumor (insulinoma), causing blood glucose levels to drop too low. Alimentary hyperinsulinism is common after gastric surgery, associated with rapid delivery of food to the small intestine, rapid absorption of glucose, and exaggerated insulin response. These patients respond best to multiple, frequent feedings.

The ingestion of alcohol after a prolonged fast or the ingestion of large amounts of alcohol and carbohydrates on an empty stomach ("gin-and-tonic" syndrome) also may cause hypoglycemia within 3 to 4 hours in some healthy persons.

Idiopathic reactive hypoglycemia is characterized by normal insulin secretion but increased insulin sensitivity and, to some extent, reduced response of glucagon to acute hypoglycemia symptoms. The increase in insulin sensitivity associated with a deficiency of glucagon secretion leads to hypoglycemia late postprandially. Idiopathic reactive hypoglycemia has been inappropriately overdiagnosed by physicians and patients, to the point that some physicians doubt its existence. Although rare, it does exist but can be documented only in persons with hypoglycemia that occurs spontaneously and in persons who meet the criteria of Whipple's triad.

Fasting hypoglycemia, or postabsorptive hypoglycemia, often is related to an underlying disease. This food-deprived hypoglycemia may occur in response to having gone without food for 8 hours or longer and can be caused by conditions that upset the body's ability to

balance blood glucose. These include eating disorders and other serious underlying medical conditions, including hormone deficiency states (e.g., hypopituitarism, adrenal insufficiency, catecholamine or glucagon deficiency), acquired liver disease, renal disease, certain drugs (e.g., alcohol, propranolol, salicylate), insulinoma (of which most are benign, but 6% to 10% can be malignant), and other nonpancreatic tumors. Taking high doses of aspirin also may lead to fasting hypoglycemia. Factitious hypoglycemia, or self-administration of insulin or sulfonyleurea in people who do not have diabetes, is a cause as well. Symptoms related to fasting hypoglycemia tend to be particularly severe and can include a loss of mental acuity, seizures, and unconsciousness. If the underlying problem can be resolved, hypoglycemia is no longer a problem.

Diagnostic Criteria

One of the criteria used to confirm the presence of hypoglycemia is a blood glucose level of less than 70 mg/dL (3.9 mmol/L); however, clinically significant hypoglycemia (level 2), is 54 mg/dL (3.0 mmol/L) (ADA, 2018). Previously the OGTT test was the standard test for this condition; however, this test is no longer used. Recording finger stick blood glucose measurements during spontaneous, symptomatic episodes at home is used to establish the diagnosis. An alternative method is to perform a glucose test in a medical office setting, in which case the patient is given a typical meal that has been documented in the past to lead to symptomatic episodes. Whipple's triad can be confirmed if symptoms occur. If blood glucose levels are low during the symptomatic period and if the symptoms disappear on eating, hypoglycemia is probably responsible. It is essential to make a correct diagnosis in patients with fasting hypoglycemia because the implications are serious.

Management of Hypoglycemia

The management of hypoglycemic disorders involves two distinct components: (1) relief of neuroglycopenic symptoms by restoring blood glucose concentrations to the normal range and (2) correction of the underlying cause. The immediate treatment is to eat foods or beverages containing carbohydrates. As the glucose from the breakdown of carbohydrates is absorbed into the bloodstream, it increases the level of glucose in the blood and relieves the symptoms. If an underlying problem is causing hypoglycemia, appropriate treatment of this disease or disorder is essential.

The goal of treatment is to adopt eating habits that will keep blood glucose levels as stable as possible (International Diabetes Center, 2013).

BOX 29.9 Guidelines for Preventing Hypoglycemic Symptoms in People Who Do Not Have Diabetes

1. Eat small meals, with snacks interspersed between meals and at bedtime. This means eating five to six small meals rather than two to three large meals to steady the release of glucose into the bloodstream.
2. Spread the intake of carbohydrate foods throughout the day. Most individuals can eat two to four servings of carbohydrate foods at each meal and one to two servings at each snack. If carbohydrates are removed from the diet completely, the body loses its ability to handle carbohydrates properly, so this is not recommended. Carbohydrate foods include starches, fruits and fruit juices, milk and yogurt, and foods containing sugar.
3. Avoid or limit foods high in sugar and carbohydrate, especially on an empty stomach. Examples of these foods are regular soft drinks, syrups, candy, fruit juices, regular fruited yogurts, pies, and cakes.
4. Avoid beverages and foods containing caffeine. Caffeine can cause the same symptoms as hypoglycemia and make the individual feel worse.
5. Limit or avoid alcoholic beverages. Drinking alcohol on an empty stomach and without food can lower blood glucose levels by interfering with the liver's ability to release stored glucose (gluconeogenesis). If an individual chooses to drink alcohol, it should be done in moderation (one or two drinks no more than twice a week), and food always should be eaten along with the alcoholic beverage.

Modified from International Diabetes Center: *Reactive and fasting hypoglycemia*, Minneapolis, 2013, International Diabetes Center.

To stay symptom-free, it is important for individuals to eat five to six small meals or snacks per day, as this helps to provide manageable amounts of glucose to the body. Recommended guidelines are listed in Box 29.9.

Patients with hypoglycemia also may benefit from learning carbohydrate counting and, to prevent hypoglycemia, eating three to four carbohydrate servings (15 g of carbohydrate per serving) at meals and one to two for snacks (see Appendix 18). Foods containing protein can be eaten at meals or with snacks. These foods would be expected to have minimum effect on blood glucose levels and can add extra food for satiety and calories. However, because protein and carbohydrate stimulate insulin release, a moderate intake may be advisable.

CLINICAL CASE STUDY

MP is a 65-year-old, nonsmoking Hispanic female who is being seen for management of type 2 diabetes. Her blood glucose levels are uncontrolled as evidenced by an A1C > 10, and she complains of increasing numbness in her feet and occasionally in her fingers, and frequent urination during the day and overnight. From interviewing her and reviewing her health record, you learn the following about her:

Education: did not complete high school, attended through middle school.

Occupation: not employed outside the home, babysits infant grandchild on a daily basis.

Household Members: lives with her husband and with one of her four adult children.

Ethnic Background: Latin American, born in Mexico, emigrated to the United States in 1980.

Religious Affiliation: Catholic.

Language: Native Spanish, speaks English—has difficulty reading English.

Patient History: Weighed more than 9 lb at birth.

MP was diagnosed with T2DM 10 or 15 years ago and her diabetes management history is as follows:

Type of Treatment: Nutrition therapy plus oral diabetes medication and long-acting insulin at bedtime (HS)

Medications: glargine 80 units at HS, metformin XR 1000 mg BID, enalapril 10 mg daily, simvastatin 40 mg daily, levothyroxine 75 mcg daily

Family History: Mother had type 2 diabetes, 12-year-old grandson recently diagnosed with prediabetes

Medical History: type 2 diabetes, hypertension, hyperlipidemia, hypothyroidism, episodic migraines (last occurrence 2017)

Physical examination shows the following:

Weight: 201 lbs.

Height: 5'2".

Temperature: 98.6°F

Blood Pressure: 143/88 mm Hg

Continued

CLINICAL CASE STUDY—cont'd

Heart Rate: 80 bpm
Laboratories: A1C 10

Nutrition Diagnostic Statement

- Altered blood glucose levels related to difficulty match insulin to carbohydrate intake as evidenced by excessive mealtime carbohydrate intake and elevated postprandial self-monitoring of blood glucose (SMBG) download data report.

Interventions

- For each of the two problem, etiology, and signs and symptoms (PES) statements, write a goal based on signs and symptoms.

- For the two goals, write two to three nutrition interventions based on the etiology that would be appropriate for MP.

NOTE: In a real face-to-face appointment between a registered dietitian nutritionist (RDN)/ Certified Diabetes Educator (CDE) and MP, they would collaboratively develop her goals together.

Evaluation and Monitoring

- When should the next nutrition counseling session be scheduled for MP?
- What would you assess at the follow-up visit based on the nutrition goals and interventions developed at the initial appointment?

Medical Nutrition Therapy for Thyroid, Adrenal, and Other Endocrine Disorders

Sheila Dean, DSc, RDN, LDN, CCN, IFMCP

KEY TERMS

5-deiodinase	Hashimoto's thyroiditis	thyroid-binding globulin (TBG)
Addison's disease	hyperthyroidism	thyroid peroxidase (TPO)
adrenal fatigue	hypothalamic-pituitary-thyroid axis	thyroid peroxidase antibodies (TPO Ab)
autoimmune thyroid disorders (AITDs)	(HPT axis)	thyroid-stimulating hormone (TSH)
calcitonin	hypothalamus	thyrotoxicosis
cortisol	hypothyroidism	thyrotropin-releasing hormone (TRH)
cretinism	pituitary gland	thyroxine (T ₄)
euthyroid sick syndrome	polycystic ovary syndrome (PCOS)	triiodothyronine (T ₃)
free T ₄	reverse T ₃ (rT ₃)	tyrosine
goitrin	Schmidt's syndrome	
Graves' disease	thyroglobulin antibodies (TGB Ab)	

Diabetes mellitus is the most common endocrine-related chronic disease (Centers for Disease Control and Prevention [CDC], 2018; National Institutes of Health [NIH] MedlinePlus, 2018). However, according to a comprehensive review of the prevalence and incidence of endocrine and metabolic disorders in the United States (2009), about 5% of the U.S. population age 12 and older has hypothyroidism, and more than half remain undiagnosed. Furthermore, individuals with diabetes tend to have a higher prevalence of thyroid disorders. According to National Health and Nutrition Examination Survey (NHANES) data, the largest community-based study of thyroid function in the United States, the prevalence of high serum thyroid-stimulating hormone (a marker for underfunctioning thyroid) was 2% in people aged 60 to 69 years, 6% in those aged 70 to 79 years, and 10% in those aged 80 years and older (Hollowell et al, 2002).

In an analysis that examined thyroid disease risk among multiple ethnicities in the U.S. military, the incident rate for thyroid disease, specifically Graves' disease (autoimmune hyperthyroid), was significantly higher among blacks and Asian/Pacific Islanders. The incidence of autoimmune hypothyroid, Hashimoto's thyroiditis, was highest in whites and lowest in blacks and Asian/Pacific Islanders (McLeod et al, 2014).

In a study that examined gender, race, and socioeconomic influence on diagnosis and treatment of thyroid disorders in Brazilians, frequency of hypothyroidism treatment was higher in women and highly educated participants and those with high net family incomes. Frequency of hyperthyroidism treatment was higher in older than in younger individuals. Sociodemographic factors strongly influenced the diagnosis and treatment of thyroid disorders, including the use of levothyroxine (Olmos et al, 2015).

Thyroid-related diseases often are poorly diagnosed, and much about their treatment requires greater clarification and study. For example, radiation exposure of the thyroid at a young age is a risk factor for the development of thyroid cancer, lasting for a lifetime after

exposure (Sinnott et al, 2010). Efforts to reduce exposure from medical x-ray examinations can protect the thyroid gland.

Genetic factors are implicated in endocrine autoimmune diseases. Recent genome-wide association studies (GWAS) have enabled identification of relevant immune response pathways; the same allele that predisposes someone to a certain autoimmune disease can be protective in another (Wiebolt et al, 2010). Thus endocrine GWAS are needed, especially for Graves' disease, Hashimoto's thyroiditis, and Addison's disease. Each of these disorders has stages beginning with genetic susceptibility, environmental triggers, and active autoimmunity, followed by metabolic derangements with overt symptoms of disease (Michels and Eisenbarth, 2010). Research is needed to clarify how nutrients interact with genetics, especially in these **autoimmune thyroid disorders (AITDs)**.

THYROID PHYSIOLOGY

The thyroid gland is a small, butterfly-shaped gland found just below the Adam's apple. Although it weighs less than an ounce, it produces hormones that influence essentially every organ, tissue, and cell in the body, thus having an enormous effect on health. The thyroid gland responds to **thyroid-stimulating hormone (TSH)**, a hormone secreted by the pituitary gland. When stimulated, the thyroid gland produces two main hormones: **thyroxine (T₄)**, a thyroid hormone named for its four molecules of iodine, and **triiodothyronine (T₃)**, a thyroid hormone named for its three molecules of iodine. T₃ is the most predominant and active form of thyroid hormone that the body can use. The thyroid gland regulates many processes in the body, including fat and carbohydrate metabolism, body temperature, and heart rate. The thyroid also produces **calcitonin**, a hormone that helps regulate the amount of blood calcium. **Reverse T₃ (rT₃)**, an isomer of

T_3 , is derived from T_4 through the action of deiodinase. Although the body cannot use rT_3 , it is not simply an inactive metabolite with no physiologic effect on the body. This will be discussed more later in the chapter. Common reasons for elevated rT_3 include inadequate iron levels, chronic inflammation, elevated cortisol, and liver abnormalities (Gomes-Lima and Burman, 2018).

The synthesis of these hormones requires **tyrosine**, a key amino acid involved in the production of thyroid hormone, and the trace mineral iodine. Within the cells of the thyroid gland, iodide is oxidized to iodine by hydrogen peroxide, a reaction termed the *organification* of iodide. Two additional molecules of iodine bind to the tyrosyl ring in a reaction that involves **thyroid peroxidase (TPO)**, an enzyme in the thyroid responsible for thyroid hormone production. Completed thyroid hormones are released into the circulation; however, metabolic effects of thyroid hormones result when the hormones ultimately occupy specific thyroid receptors. It is estimated that a cell needs five to seven times more T_4 to bind to the nuclear receptors to have a physiologic effect compared with the more biologically active T_3 .

The biosynthetic processes resulting in the creation of thyroid hormones within the thyroid gland are controlled by feedback mechanisms within the **hypothalamic-pituitary-thyroid axis (HPT axis)**. The HPT axis is part of the endocrine system responsible for the regulation of metabolism. As its name suggests, it depends on the **hypothalamus** (a tiny, cone-shaped structure located in the lower center of the brain that communicates between the nervous and endocrine systems), the **pituitary gland** (the master gland of the endocrine system located at the base of the brain), and the thyroid gland (Fig. 30.1).

The hypothalamus produces and secretes **thyrotropin-releasing hormone (TRH)**, which travels to the pituitary gland, stimulating it to release TSH, which signals the thyroid gland to upregulate its synthetic machinery. Although T_4 , T_3 , and rT_3 are generated within the thyroid gland, T_4 is quantitatively the major secretory product. All T_4 found in circulation is generated in the thyroid unless exogenously administered via thyroid replacement medication (see Table 30.2). Production

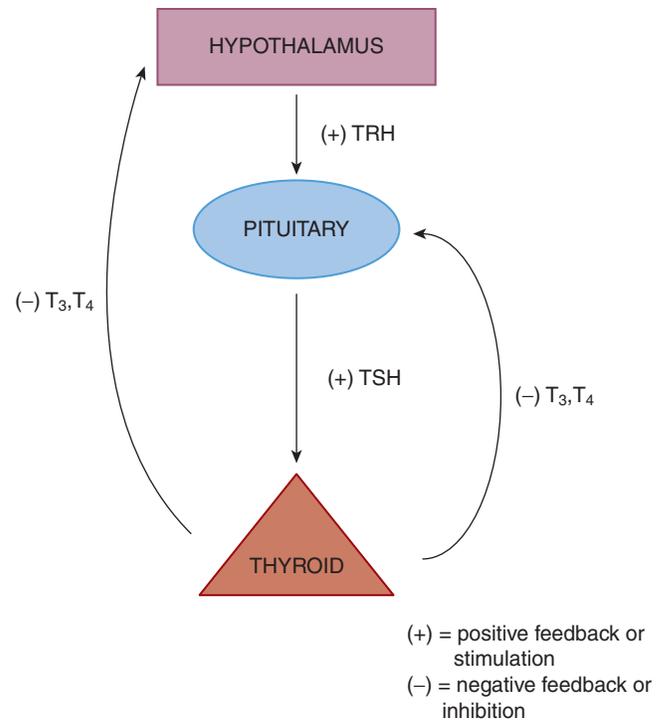

Fig. 30.1 The hypothalamus-pituitary-thyroid axis. *TRH*, Thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

of T_3 and rT_3 within the thyroid is relegated to very small quantities and is not considered significant compared with peripheral production in other body tissues (Fig. 30.2).

When T_4 is released from the thyroid, it is primarily in a bound form with **thyroid-binding globulin (TBG)**, a protein that transports thyroid hormones through the bloodstream, with lesser amounts bound

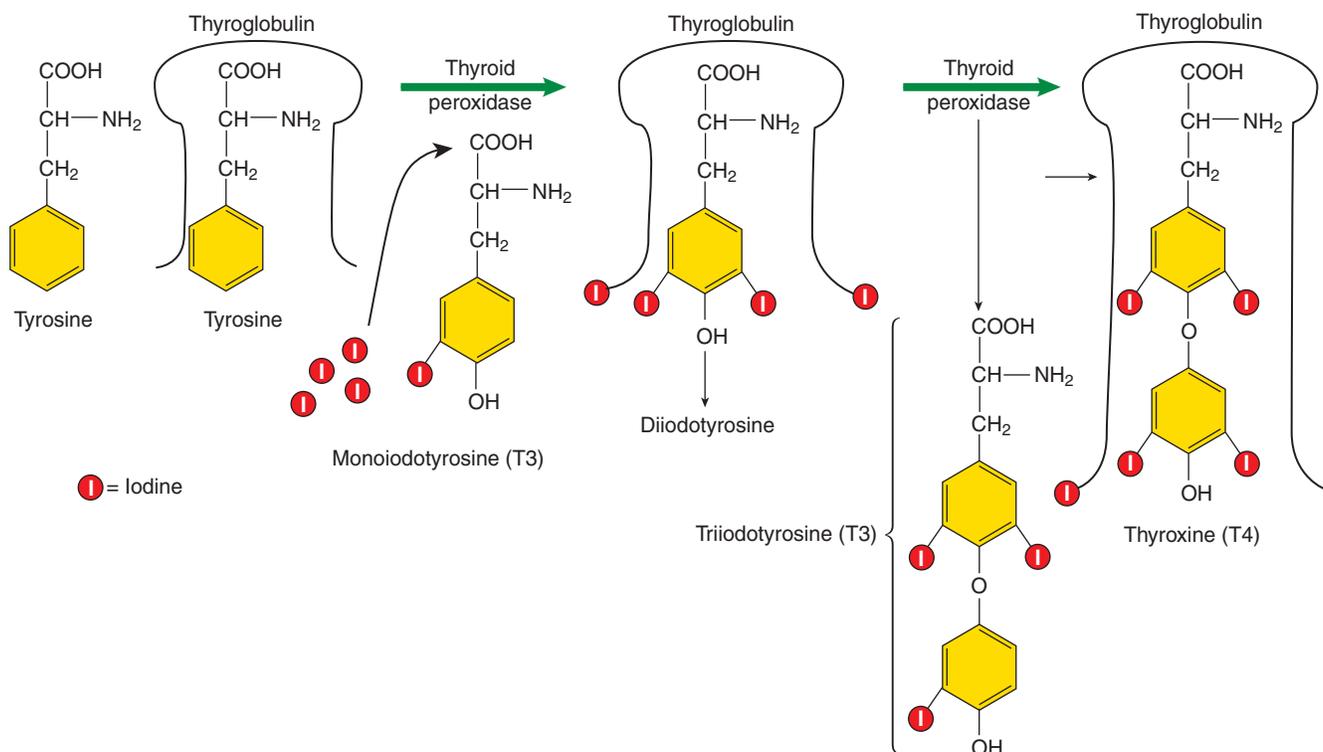

Fig. 30.2 Constructing thyroid hormones. (1) Accumulation of the raw materials tyrosine and iodide (I⁻), (2) fabrication or synthesis of the hormone, and (3) secretion of hormone into the blood either bound or as free T_4 .

to T_4 -binding prealbumin. It is estimated that only 0.03% to 0.05% of T_4 within the circulatory system is in a free or unbound form; this unbound T_4 is called **free T_4** . In peripheral tissues, approximately 70% of T_4 is converted to T_3 or rT_3 or eliminated. As mentioned, T_3 is considered to be the most metabolically active thyroid hormone. Although some T_3 is produced in the thyroid, approximately 80% to 85% is generated outside the thyroid gland, primarily by conversion via a deiodinase enzyme from T_4 to T_3 in the liver and kidneys. The pituitary and nervous system are also capable of converting T_4 to T_3 , and so are not reliant on T_3 produced in the liver or kidney. Within the liver and kidney, the enzyme responsible for production of T_3 is a selenium-dependent enzyme called **5-deiodinase**, an enzyme that removes one molecule of iodine from T_4 to form either T_3 or rT_3 (Fig. 30.3).

ASSESSMENT IN THYROID DISORDERS

Assessment begins with an evaluation of thyroid status based on laboratory data such as a full thyroid panel. In the absence of a full thyroid panel, a serum thyrotropin (also known as TSH) is the single best screening test for primary thyroid dysfunction for the vast majority of outpatient clinical situations (Garber et al, 2012). A TSH test does not screen for autoimmune disease. If autoimmune thyroid disease is suspected, additional tests must be done (described more below). Assessments also may include a diet history to evaluate micronutrients pertaining to thyroid health along with an evaluation of calorie and carbohydrate intake. In addition, an assessment of dietary intake of goitrogenic (thyroid-inhibiting) foods may be warranted.

Laboratory Norms: Functional versus Pathologic Ranges

A typical (statistical) reference range for TSH in many laboratories is approximately 0.2 to 5.5 mIU/L. Individuals with TSH values greater than 2 mIU/L have an increased risk of developing overt hypothyroidism during the next 20 years. Subclinical autoimmune thyroid disease is so common in the population that laboratory reference ranges derived from testing apparently healthy subjects easily could be misconstrued for those with disease. Importantly, several studies have detected an increase in thyroid antibody positivity with TSH concentrations outside the narrow range of 0.2 to 1.9 mIU/L (Fjaellagaard et al, 2015). This fact provides evidence that TSH in the upper reference range often is associated with abnormal pathologic findings (Hak et al, 2000; Khandelwal and Tandon, 2012; Saravanan et al, 2002), mitochondrial dysfunction, and morphologic skeletal muscle alterations including myalgia, muscle cramps, and weakness (Dunn et al, 2009). Additional evidence that thyroid function within the laboratory reference ranges can be associated with adverse outcomes is shown in Table 30.1. Conversely, decreased TSH levels combined with normal-to-high T_4 or T_3 levels may be suggestive of hyperthyroidism (see Thyroid Function Tests in Appendix 13).

Changes in 5-deiodination occur in a number of situations, such as stress, poor nutrition, illness, selenium deficiency, and certain drug therapies. Toxic metals such as cadmium, mercury, and lead have been associated with impaired hepatic 5-deiodination in animal models. (Soldin et al, 2008). Free radicals are also involved in inhibition of 5-deiodinase activity. In the course of chronic liver disease such as hepatic cirrhosis, alterations in hepatic deiodination resulting in

TABLE 30.1 Variation in Thyroid Function Within Reference Range and Adverse Outcomes

TSH >2 mIU/L*	Increased 20-year risk of hypothyroidism
TSH >2 mIU/L*	Increased frequency of thyroid autoantibodies
TSH >4 mIU/L*	Increased risk of heart disease
TSH 2-4 mIU/L†	Cholesterol values respond to thyroxine replacement
Free T ₄ <10.4 pmol/L†	Impaired psychomotor development of infant if occurs in first trimester of pregnancy

T₃, Thyroxine; TSH, thyroid-stimulating hormone.

*Typical reference ranges: TSH 0.2-5.5 mIU/L

†Typical reference ranges: free T₄ 9.8-25 pmol/L

Selenium deficiency
 Inadequate protein, excess carbohydrates
 High insulin
 Chronic illness
 Stress (cortisol)
 Cd, Hg, Pb, and other heavy metal toxins
 Compromised liver or kidney function

increased rT₃ and a simultaneous decrease in T₃ levels also have been observed (Box 30.1 and see Chapter 28).

HYPOTHYROIDISM

Of the detected cases of **hypothyroidism** (underactive thyroid) more than half are due to an autoimmune disorder called **Hashimoto's thyroiditis**, in which the immune system attacks and destroys thyroid gland tissue. A common clinical presentation of patients with functional changes of the endocrine system is altered thyroid function. Indeed *subclinical* hypothyroidism represents the first signs of thyroid hormone dysfunction for many individuals. Typical symptoms include low energy, cold hands and feet, fatigue, hypercholesterolemia, muscle pain, depression, and cognitive deficits (Box 30.2). Evaluation of thyroid hormone metabolism is needed before thyroid hormone replacement therapy.

BOX 30.2 Common Symptoms of Hypothyroidism and Hyperthyroidism

Hypothyroidism	Hyperthyroidism
Fatigue	Heat intolerance, sweating
Forgetfulness	Weight loss
Depression	Alterations in appetite
Heavy menses	Frequent bowel movements
Dry, coarse hair	Changes in vision
Mood swings	Fatigue and muscle weakness
Weight gain	Menstrual disturbance
Hoarse voice	Impaired fertility
Dry, coarse skin	Mental disturbances
Constipation	Sleep disturbances
	Tremors
	Thyroid enlargement

From Shomon M: *Thyroid Disease Symptoms—Hypothyroidism and Hyperthyroidism* (website): http://thyroid.about.com/cs/basics_starthere/a/symptoms.htm, 2008.

Women are five to eight times more likely than men to suffer from hypothyroidism. In addition, individuals who have celiac disease may be at risk (see *Clinical Insight: Was It Gluten That Caused Her Hypothyroidism?*)

CLINICAL INSIGHT**Gluten and Hypothyroidism**

A case report described a 23-year-old woman with a diagnosis of hypothyroidism caused by Hashimoto's thyroiditis and autoimmune Addison's disease who was found in evaluation to have elevated antiendomysial antibody levels (a marker of celiac disease [CD]). During a 3-month period on a gluten-free diet, the patient demonstrated remarkable clinical improvement in her gastrointestinal (GI)-related symptoms and, more importantly, in her thyroid function. She required progressively less thyroid and adrenal replacement therapy. After 6 months, her endomysial antibody level became negative, her antithyroid antibody titer decreased significantly, and thyroid medication was discontinued. This case report points out the potential important effect of a gluten-free diet on thyroid function, especially in the presence of CD.

A number of studies show the importance of gluten in the induction of endocrine autoantibodies and organ system dysfunction in adolescent celiac patients (Cassio et al, 2010; Meloni et al, 2009). Furthermore, the genetic risk for CD is largely related to human leukocyte antigen genotypes, which in turn is linked to autoimmune thyroid disease (Barker and Liu, 2008). According to the international medical bibliography, autoimmune Hashimoto's thyroiditis and CD are clearly associated (Freeman, 2016). This might be explained partly by the increased immunosensitivity of CD patients, as part of an autoimmune polyglandular syndrome (APS), by the deficiency of key elements such as selenium and iodine due to malabsorption (Stazi and Trinti, 2010) or due to antibodies that affect both target-tissues (Naiyer et al, 2008). Based on recommendations from a recent meta-analysis, all patients with autoimmune Hashimoto's thyroiditis should be screened for CD, given the increased prevalence of the coexistence of these two disorders (Roy et al, 2016). This study advocates that patients with Hashimoto's thyroiditis undergo celiac serologic tests (serum IgA and IgG gliadin antibodies [AGA-IgA, AGA-IgG], IgA transglutaminase antibodies [TGA], and serum IgA endomysium antibodies [EMA]), and that if any of the celiac serologic tests is positive, the patients must be investigated with gastroduodenoscopy and duodenal biopsy. It must be considered that positive thyroid and celiac tests might represent an epiphenomenon because serum autoantibodies generally do not reflect a clinical autoimmune disease (Liontiris and Mazokopakis, 2017). It has been reported that gluten-dependent diabetes and thyroidal-related antibodies were found in patients with CD but were eliminated after the implementation of a gluten-free diet (Duntas, 2009). A gluten-free diet may be warranted in cases of Hashimoto's thyroiditis, as the mounting evidence shows that the avoidance of gluten may reduce inflammation and auto-antibody titers. See Chapter 27 for additional information about CD.

Pathophysiology

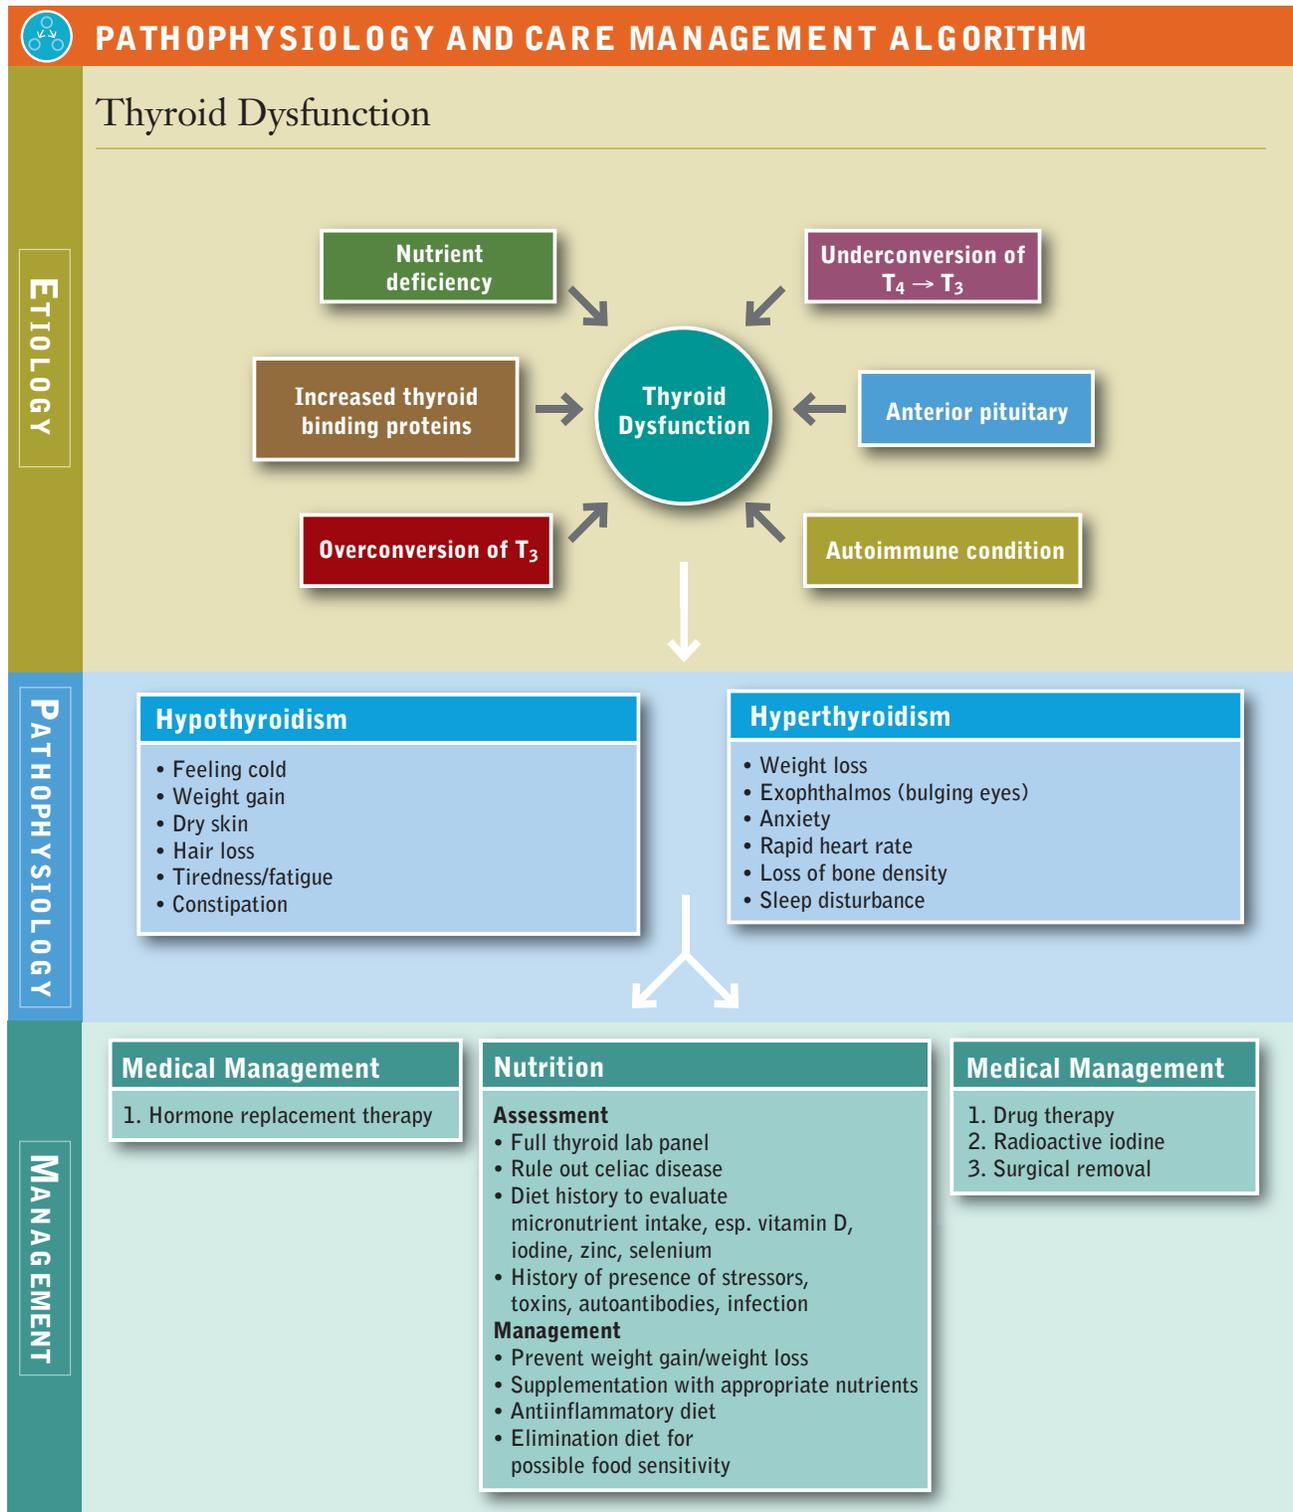

Hashimoto's thyroiditis is an autoimmune disorder in which the immune system attacks and destroys the thyroid gland. It is the most common form of hypothyroidism. The enlarged, chronically inflamed thyroid gland becomes nonfunctional, with reactive parts of the gland deteriorating after several years. Thyroid autoantibodies indicate the body's immune system is attacking itself and whether an autoimmune thyroid condition is present, be it hypothyroidism or hyperthyroidism, Epstein-Barr virus (EBV) has been implicated as a critical underlying factor in autoimmune thyroid disease. Janegova et al (2015) demonstrated a high prevalence of EBV infection in cases of Hashimoto's thyroiditis (80.7%) as well as in samples of Graves' disease (62.5%).

Specific antibody tests identify Hashimoto's thyroiditis. **Thyroid peroxidase antibodies (TPO Ab)** are immune cells that indicate the immune system is attacking TPO in the thyroid gland. The TPO Ab

test is the most important because TPO is the enzyme responsible for the production of thyroid hormones, and the most frequent target of attack in Hashimoto's. **Thyroglobulin antibodies (TGB Ab)** are immune cells that indicate the immune system is attacking thyroglobulin in the thyroid gland. Sometimes this test is necessary as well because it is the second most common target for Hashimoto's disease.

Schmid's syndrome refers to hypothyroidism with other endocrine disorders, including Addison's disease (adrenal insufficiency), hypoparathyroidism, and diabetes mellitus, all of which may be autoimmune in

nature. **Euthyroid sick syndrome** is hypothyroidism associated with a severe systemic illness that causes decreased peripheral conversion of T_4 to T_3 , an increased conversion of T_3 to the inactive rT_3 , and decreased binding of thyroid hormones. Conditions commonly associated with this syndrome include protein-calorie malnutrition, surgical trauma, myocardial infarction, chronic renal failure, diabetic ketoacidosis, anorexia nervosa, cirrhosis, thermal injury, and sepsis. Once the underlying cause is treated, the condition usually is resolved (see *Pathophysiology and Care Management Algorithm: Thyroid Dysfunction*).

Triggers

Adrenal dysfunction and oxidative stress. Low thyroid function is almost always secondary to some other condition, often adrenal dysfunction (Kaltsas et al, 2010) (see Adrenal Disorders later in this chapter).

Aging. Maintaining thyroid hormone function throughout the aging process appears to be an important hallmark of healthy aging. The incidence of hypothyroidism (underactive thyroid) increases with age. By age 60, 9% to 17% of men and women have an underactive thyroid. The absence of circulating thyroid autoantibodies in healthy centenarians is noted. Because unhealthy aging is associated with a progressively increasing prevalence of organ-specific and non-organ-specific autoantibodies, the absence of these antibodies may represent a significantly reduced risk for cardiovascular disease and other chronic age-related disorders.

Menopause. The relationship between thyroid hormone and the gonadal axis is well established; however, there are few studies on the relationship between thyroid function and menopause specifically. In addition, they do not necessarily clarify whether menopause has an effect on thyroid regardless of aging, despite the fact that hypothyroid symptoms and menopause symptoms (such as hot flashes, insomnia, irritability, and palpitations) are commonly confused. According to a report from the evaluation of the Study of Women's Health Across the Nation (SWAN), thyroid function does not appear to be directly involved in the pathogenesis of menopausal complications; however, menopause may modify the clinical expression of AITDs such as Hashimoto's thyroiditis (Del Ghianda et al, 2014).

Pregnancy. Thyroid dysfunction has been related to obstetric complications such as premature delivery, gestational hypertension, preeclampsia, and placental abruption. Nearly 1 out of 50 women in the United States is diagnosed with hypothyroidism during

pregnancy. Out of every 100 miscarriages, six are associated with thyroid hormone deficiency during pregnancy, up to 18% of women are diagnosed with postpartum thyroiditis, and approximately 25% of women develop permanent hypothyroidism (De Vivo et al, 2010; Yassa et al, 2010).

Global recommendations for iodine during pregnancy are 130-250 mcg/d depending on the country. In areas of severe iodine deficiency, maternal and fetal hypothyroxinemia can cause **cretinism** (condition of stunted physical growth and mental development). To prevent fetal damage, dietary iodine adequacy is essential during pregnancy (see Chapter 14 and Table 14.8) (Zimmermann, 2009).

Medical Management

When the thyroid is underactive (hypothyroidism) because of autoimmune disease (Hashimoto's disease), radioactive iodine treatment, congenital defects, or surgical removal (thyroidectomy), the conventional pharmacologic approach for treatment is prescription thyroid hormone replacement medication. Table 30.2 provides an overview of key forms of thyroid hormone replacement. With the further elucidation of the effects of genetics, new agents are likely to become available as adjunct therapy.

Medical Nutrition Therapy

Several nutrients are involved in thyroid health, particularly iodine and selenium. Because of the critical role of iodine in the synthesis of thyroid hormone, this trace mineral has received the most attention historically with respect to thyroid disorders. Other deficiencies of micronutrients such as iron, selenium, vitamin A, and possibly zinc may interact with iodine status and thyroid function (Hess, 2010; Köhrle, 2013).

Fasting or restrictive diets. Calorie and carbohydrate restriction may reduce substantially thyroid hormone activity. This

TABLE 30.2 Pharmacologic Treatments for Hypothyroidism

Medication Brand Name	Medication Generic Name	Use and Comments
Synthroid, Levoxyl	Levothyroxine—(synthetic T ₄)	Most commonly prescribed synthetic form of thyroid hormone replacement drug (thyroxine) that provides a steady dose of T ₄ for the body to convert to T ₃ . Available in a wide range of doses. Inactive ingredients include lactose and cornstarch.
Tirosint	Levothyroxine	A synthetic form of replacement hormone that includes only three inactive ingredients: gelatin, glycerin, and water. Is produced in a dedicated facility to eliminate the risk of cross-exposure.
Cytomel	Liothyronine—(synthetic T ₃)	Synthetic form of T ₃ , which can also be compounded. Sometimes prescribed in addition to T ₄ . Only effective for approximately 10 hours and must be taken twice daily.
Armour Thyroid	Desiccated natural thyroid	Prepared from dried or powdered porcine (pig) or mixed beef and pork thyroid gland for therapeutic use. Available by prescription and frequently used as an alternative to synthetic thyroid drugs. All brands contain a mixture of approximately 80% T ₄ and 20% T ₃ . Difficult to standardize. Compounded T ₃ medication is available as a time-released formula. Compounded medications are frequently not insurance covered but are less expensive than standard medications.
WP Thyroid, Nature-Throid	Desiccated natural thyroid	Provides the full range of thyroid hormones, including T ₄ , T ₃ , T ₂ , and T ₁ , which may be beneficial for those who have difficulty with T ₄ -T ₃ conversion. Available in 8-13 different strengths, ranging from low to high concentrations.
Thyrolar	Liotrix—(synthetic T ₄ -T ₃ combination)	Synthetic combination of T ₄ and T ₃ . Sometimes used in lieu of Armour Thyroid because of problem with standardization.

T₃, Triiodothyronine; T₄, thyroxine.

From Shomon M: *What is the best thyroid drug?* (website): <http://thyroid.about.com/cs/thyroiddrugs/a/bestdrug.htm>, 2014.

varies widely between individuals. Genetics, obesity, gender, and the macronutrient content of the hypocaloric diet influence the response. Nutritional status and energy expenditure influence thyroid function centrally at the level of TSH secretion, deiodination, and possibly elsewhere. Because an increase of rT_3 is found at the expense of T_3 during caloric restriction, it is possible that the hepatic pathways play a substantial role in metabolic control during energy balance. However, when caloric restriction is longer than 3 weeks, T_4 and rT_3 levels return to normal values (De Vries et al, 2015).

Fasting also exerts a powerful influence on the metabolism of thyroid hormones to save energy and limit catabolism. Mild elevations in endogenous cortisol levels may be partly responsible. Fasting decreases serum T_3 and T_4 concentrations, whereas intrahepatic thyroid hormone concentrations remain unchanged. However, ketones generated from calorie deprivation do not appear to suppress T_3 generation and hepatic 5-deiodinase activity. It appears that fasting-induced changes in liver thyroid hormone metabolism are not regulated via the hepatic autonomic input in a major way and more likely reflect a direct effect of humoral factors (factors that are transported by the circulatory system) on the hepatocyte. Overall during fasting, there is a down regulation of the HPT axis, which is assumed to represent an energy-saving mechanism, instrumental in times of food shortage (De Vries et al, 2015).

Goitrogens. Cyanogenic plant foods (cauliflower, broccoli, cabbage, Brussels sprouts, mustard seed, turnip, radish, bamboo shoot, and cassava) exert antithyroid activity through inhibition of the TPO enzyme. The hydrolysis of bioactive compounds called glucosinolates found in cruciferous vegetables may yield **goitrin**, a compound known to interfere with thyroid hormone synthesis. The hydrolysis of indole glucosinolates results in the release of thiocyanate ions, which can compete with iodine for uptake by the thyroid gland. Increased exposure to thiocyanate ions from cruciferous vegetable consumption, however, does not increase the risk of hypothyroidism unless accompanied by iodine deficiency. However, steaming, cooking, or fermenting may reduce the levels of goitrogens in goitrogenic foods (Jagminder et al, 2016).

Soybean, an important source of protein in many developing countries, also has goitrogenic properties when iodine intake is limited. The isoflavones, genistein and daidzein, inhibit the activity of TPO and can lower thyroid hormone synthesis. Furthermore, excessive intake of soybeans may interrupt the enterohepatic cycle of thyroid hormone metabolism. However, high intakes of soy isoflavones do not appear to increase the risk of hypothyroidism when iodine consumption is adequate.

Since the addition of iodine to soy-based formulas in the 1960s, there have been no further reports of hypothyroidism developing in soy formula-fed infants. Soybeans are by far the most concentrated source of isoflavones in the human diet. Small amounts are found in a number of legumes, grains, and vegetables. Average dietary isoflavone intakes in Asian countries, in particular in Japan and China, range from 11 to 47 mg/day because of intake of the traditional foods made from soybeans, including tofu, tempeh, miso, and matte, whereas intakes are considerably lower in Western countries (2 mg/day). Soy products (meat substitutes, soy milk, soy cheese, and soy yogurt), however, are gaining popularity in Western countries. Although research has not determined the exact effect of soy on the metabolic fate of thyroid hormones, excessive soy consumption is best approached cautiously in those with suspected impairment of thyroid metabolic pathways.

Iodine. As a trace element, iodine is present in the human body in amounts of 10 to 15 mg, and 70% to 80% of it is located in the thyroid gland. Ninety percent of it is organically bound to a protein produced in the thyroid gland called thyroglobulin (Tg). Iodide is actively absorbed in the thyroid gland to help produce the biochemically active thyroid hormones T_4 and T_3 (see Fig. 30.2). The thyroid gland must capture an estimated minimum of 60 mcg of iodide (the ionic form of iodine) daily to ensure an adequate supply for the production of thyroid hormone (Gropner and Smith, 2012). Inadequate intake of iodine impairs thyroid function and results in a spectrum of disorders. Randomized controlled intervention trials in iodine-deficient populations have shown that providing iron along with iodine results in greater improvements in thyroid function and volume than providing iodine alone (Hess, 2010). It is also vital to thyroid function, as it is a major cofactor and stimulator for the enzyme TPO.

In autoimmune Hashimoto's thyroiditis, supplementing with iodine may exacerbate the condition. Because iodine stimulates production of TPO, this in turn increases the levels of TPO Abs dramatically, indicating an autoimmune flare-up. Some people develop symptoms of an overactive thyroid, whereas others have no symptoms despite tests showing an elevated level of TPO Abs. Therefore one must be cautious regarding the use of high-dose iodine; however, a clinical evaluation and/or assessment (such as UI excretion laboratories) may help reveal whether iodine supplementation is warranted. Furthermore, although iodine deficiency is the most common cause of hypothyroidism for most of the world's population (Melse-Boonstra and Jaiswal, 2010), in the United States and other Westernized countries, Hashimoto's thyroiditis accounts for the majority of cases (Ebert, 2010).

Although the risk of iodine deficiency for populations living in iodine-deficient areas without adequate iodine fortification programs is well recognized, concerns have been raised that certain subpopulations may not consume adequate iodine in countries considered iodine sufficient. Vegetarian and nonvegetarian diets that exclude iodized salt, fish, and seaweed have been found to contain very little iodine.

Iron. Historically it has been thought that low thyroid function may contribute to anemia. Recent studies suggest that low thyroid function may be secondary to low iron status or anemia. The reason for this is because TPO is a glycosylated heme enzyme that is iron dependent. The insertion of heme iron into TPO is necessary for the enzyme to translocate to the apical cell surface of thyrocytes (or thyroid epithelial cells), thus assisting TPO to catalyze the two initial steps of thyroid hormone synthesis. A full assessment of iron status could likely help to identify the cause of many cases of thyroid malfunction. Treatment of anemic women with impaired thyroid function with iron improves thyroid-hormone concentrations, while T_4 (hormone replacement medication) and iron together are more effective in improving iron status (Hu and Rayman, 2017).

Selenium. Selenium, as selenocysteine, is a cofactor for 5-deiodinase. If selenium is deficient, the deiodinase activity is impaired, resulting in a decreased ability to deiodinate T_4 to T_3 . In animals, deficiencies of selenium are associated with impaired 5-deiodinase activity in the liver and kidney, as well as reduced T_3 levels. Evidence suggests a strong linear association between lower T_3/T_4 ratios and reduced selenium status, even among individuals considered to be euthyroid based on standard laboratory parameters. This association is particularly strong in older adults, possibly as the result of impaired peripheral conversion. An inverse relationship between T_3 and breast cancer is associated with decreased

selenium status, even when plasma T_4 and TSH concentrations may be similar. This combination of factors strongly suggests that low T_3 may be due to faulty conversion of T_4 to T_3 expected in selenium deficiency (De Sibio et al, 2014).

Selenium participates in the antioxidant network. It is a cofactor for glutathione peroxidase, an enzyme whose main biologic role is to protect the organism from oxidative damage. Several studies reported on the benefit of selenium treatment in Hashimoto's thyroiditis and Graves' disease. According to a systematic review and meta-analysis studies, selenium supplementation reduced serum TPO Ab levels in patients with chronic autoimmune thyroiditis (AIT) (Wichman et al, 2016).

Evidence also suggests that excessive intakes of selenium may exert a detrimental influence on thyroid hormone metabolism. Although individuals exposed to high dietary levels of selenium typically have normal levels of T_4 , T_3 , and TSH, a significant inverse correlation has been found between T_3 and selenium. Some researchers have hypothesized that the activity of 5-deiodinase may become depressed after a high dietary intake of selenium, suggesting a safe level of dietary selenium at or below 500 mcg daily. There is evidence from observational studies and randomized controlled trials that selenium/selenoproteins can reduce TPO-antibody titers, hypothyroidism, and postpartum thyroiditis (Hu and Rayman, 2017). In a 2016 study on selenium supplementation, authors conclude that selenium supplementation (83 mcg of selenomethionine per day orally for 4 months) could restore euthyroidism (healthy thyroid hormone balance) in one third of subclinical hypothyroidism patients with AIT (Pirola et al, 2016).

Magnesium. Magnesium is the fourth most abundant mineral in the body. It has been recognized as a cofactor for more than 300 enzymatic reactions, where it is crucial for adenosine triphosphate (ATP) metabolism and cellular energy production. Low serum magnesium is associated with several chronic diseases including thyroid disease. A cross-sectional study of over 1200 Chinese participants revealed that severely low serum magnesium was associated with increased risks of positive antithyroglobulin antibody and hypothyroidism. The risks of Hashimoto's thyroiditis diagnosed using ultrasonography in the lowest quartile group were higher than those in the adequate magnesium group (0.851 to 1.15mmol/L) ($p < 0.01$, odds ratios [ORs] = 2.748 to 3.236). The risks of total and subclinical-only hypothyroidism in the lowest quartile group were higher than those in the adequate magnesium group (0.851 to 1.15mmol/L) ($p < 0.01$, ORs = 4.482 to 4.971) (Wang et al, 2018).

Ideal intake for magnesium should be based on the DRI. Magnesium supplements are available as magnesium oxide, magnesium chloride, magnesium citrate, magnesium taurate, magnesium orotate, as well as other amino acid chelates. In the treatment of magnesium deficiency, organic bound magnesium salts, such as magnesium citrate, gluconate, orotate, or aspartate recommendations were made due to their high bioavailability (Kisters, 2013).

Vitamin D. Lower vitamin D status has been found in Hashimoto's thyroiditis patients than in controls, and inverse relationships of serum vitamin D with TPO/TGB Ab have been reported. However, other data and the lack of trial evidence suggest that low vitamin D status is more likely the result of autoimmune disease processes that include vitamin D receptor dysfunction (Hu and Rayman, 2017).

Oral vitamin D supplementation was found to reduce titers of thyroid antibodies in levothyroxine-treated women with postpartum thyroiditis and low vitamin D status. Vitamin D increased serum levels of 25-hydroxy vitamin D, as well as reduced titers of thyroid antibodies. This effect was more pronounced for TPO than

for TGB Ab and correlated with their baseline titers. Authors concluded that vitamin D preparations may reduce thyroid autoimmunity in levothyroxine-treated women with Hashimoto's thyroiditis and normal vitamin D status (Krysiak et al, 2017). Taking into consideration the low cost and the minimal side effects of vitamin D supplementation, screening for vitamin D deficiency and careful vitamin D supplementation with monthly monitoring calcium and 25-hydroxy vitamin D levels, when required, may be recommended for patients with Hashimoto's thyroiditis (Liontiris and Mazokopakis, 2017).

Management of Thyroid Disorders During Pregnancy

The American Thyroid Association recommendations on diagnosis and management of thyroid disease during pregnancy and the postpartum period were reported in a review article in 2017 with the following guidelines (Kalra et al, 2017).

Hypothyroidism and Pregnancy

Laboratory Assessment

1. TSH assessment should be based on population-based trimester specific reference ranges, calculated from data of healthy pregnant women without history of thyroid disease, with optimal iodine intake, and negative TPO Ab status.
2. If pregnancy specific population-based data is not available, upper reference limit (URL) of 4.0 mU/L may be used.
3. A level 0.5mU/L lower than nonpregnant URL can also be taken as URL for TSH in pregnancy.
4. Serum T_4 (thyroxin) is a highly reliable marker for thyroid function in last trimester of pregnancy.

Preconception Investigations

1. Test TSH in all women presenting with infertility.
2. Test TSH either before, or 1 to 2 weeks after, controlled ovarian hyper stimulation (COHS).
3. Nonpregnant women with mild TSH elevation following COHS should undergo repeat testing after 2 to 4 weeks.
4. Test TSH at time of diagnosis of pregnancy, in euthyroid, antibody positive women.

Iodine Intake

1. Ensure iodine intake of 250 mg/day, at least 3 months before conception.
2. Such intake is not required in women who are on treatment for either hypo- or hyper-thyroidism.
3. Avoid iodine intake > 500 mg/day.
4. Avoid iodine containing supplements in excess.

Additional Therapies

1. Selenium supplementation is not recommended for treatment of antibody positive pregnant women.
2. T_3 or desiccated thyroid is not recommended during pregnancy.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is a common endocrine disorder of unknown cause that affects an estimated 3% to 12% of women of reproductive age in Western societies (Moran et al, 2010; Velez and Motta, 2014). The condition is characterized by reproductive issues such as amenorrhea or other menstrual irregularities, anovulation, enlarged ovaries with multiple cysts, and infertility. More generalized symptoms include insulin resistance, acne, hirsutism (excessive or

TABLE 30.3 Nutrition Treatment for Polycystic Ovary Syndrome

Obesity	Institute weight management program of diet and exercise.
Insulin resistance	Restrict refined carbohydrates (low-glycemic index diet) and total calories. Increase high-fiber foods. Recommend small, frequent meals. Monitor carefully to ascertain benefit from high- versus low-carbohydrate diet. Consider supplementation with chromium picolinate.
Low serum 25 hydroxy vitamin D	Administer vitamin D ₃ (cholecalciferol).
Clomiphene-citrate resistant infertility	Use short-term NAC as adjunct.
Laboratory or clinical evidence of hypothyroidism	Institute thyroid hormone replacement. Use foods or supplements with selenium and iodine.

NAC, N-acetylcysteine.

abnormal distribution of hair growth), male-pattern baldness, weight gain, and sleep apnea (Table 30.3).

Pathophysiology

Biochemical and endocrine abnormalities in women with PCOS include a hyperandrogenic state in which there is a higher concentration of free androgens (dehydroepiandrosterone, testosterone, and androstenedione) and decreased hepatic production of sex hormone binding globulin (Sirmans and Pate, 2013). In addition to the elevated levels of androgens, hyperinsulinemia (which results from insulin resistance), impaired glucose tolerance, and hyperlipidemia are seen. Hyperandrogenism is responsible for many of the symptoms of PCOS, such as reproductive and menstrual abnormalities, hirsutism, and acne. Elevated androgen levels, in turn, appear to be due in part to hyperinsulinemia, which triggers the increase in androgen production. Thus interventions that improve insulin resistance and hyperinsulinemia may reverse some of the manifestations of PCOS.

The insulin resistance seen in 50% to 70% of women with PCOS is unique in that it occurs independent of body weight to some extent and is not always corrected by weight loss. It appears to result from insulin receptor phosphorylation abnormalities in an insulin-mediated signaling pathway (Sirmans and Pate, 2013). Conventional treatment of PCOS includes diet and exercise to promote weight loss. In women who have gained an excessive amount of weight, weight loss may improve insulin resistance, decrease androgen levels and hirsutism, and restore ovulation in some cases. Low-glycemic load diets historically have been recommended with evidence of their clinical effectiveness. The capacity of dietary carbohydrates to increase postprandial blood sugar response may be an important consideration for optimizing metabolic and clinical outcomes in PCOS. Furthermore, independent of weight loss, a low-glycemic load diet appears to result in greater improvements in health, including improved insulin sensitivity, improved menstrual regularity, better emotion scores (on a questionnaire designed to detect changes in quality of life), and decreased markers of inflammation compared with a conventional low-fat diet when matched closely for macronutrient and fiber content (Marsh et al, 2010).

Medical Management

Hypothyroidism occurs in some cases of PCOS. Laboratory tests for thyroid function are frequently normal in patients with clinical evidence of hypothyroidism, and treatment with thyroid hormone results in clinical improvement in many patients. Therefore an empirical trial of thyroid hormone should be considered for patients with PCOS who have clinical evidence of hypothyroidism.

Thyroid antibody status should be taken into account when considering treatment with thyroid hormone in women with PCOS. Metformin frequently is prescribed to improve insulin resistance, and treatment with this drug may lead to resumption of ovulation. Other therapies include the drugs clomiphene citrate (to induce ovulation) and spironolactone (an antiandrogen), as well as oral contraceptives (to treat menstrual irregularities and hirsutism).

Medical Nutrition Therapy

Nutritional interventions that may be beneficial for women with PCOS include dietary modifications designed to enhance insulin sensitivity. This includes recommending a low-glycemic load diet, consuming high-fiber foods, and preventing excess weight gain via calorie awareness and promotion of physical activity. Eating a diet that keeps blood sugar balanced, including combining low-glycemic carbohydrates with protein and eating smaller meals may also be of benefit. It is important to ensure optimal nutrient status for vitamin D and to screen for sub optimal thyroid function (see Table 30.3).

Complementary and Integrative Approaches

A critical review of the 12 randomized controlled trials (RCTs) highlights that oral administration of myo-inositol, alone or in combination with D-chiro-inositol, two stereoisomers of inositol (an intracellular messenger molecule), is capable of restoring insulin sensitivity and spontaneous ovulation and improving fertility in women with PCOS. These RCT studies support the hypothesis of a primary role of inositol phosphoglycans (IPGs) as second messengers of insulin signaling and demonstrate that myo-inositol supplementation beneficially affects the hormonal milieu of PCOS patients. Indeed, these trials provide evidence that myo-inositol reduces insulin levels, probably either by conversion to D-chiro-inositol (via the epimerase enzyme) or by serving as substrate for the formation of IPGs and D-chiro-inositol-containing IPGs, which would in turn amplify insulin signaling (Unfer et al, 2016).

N-Acetylcysteine (NAC) is an amino acid-derived supplement that may help improve insulin receptor activity, reduce testosterone, and increase spontaneous ovulation in PCOS. In a recent review of eight RCTs that compared metformin or placebo and NAC, women who took NAC were more likely to achieve pregnancy and to deliver a live baby, especially if resistant to the fertility drug clomiphene citrate. There was no benefit from NAC for improving menstrual regularity, acne, hirsutism, body mass index (BMI), fasting insulin, or fasting glucose. The typical dose of NAC was 1200 to 1800 mg/day (Thakker et al, 2015).

HYPERTHYROIDISM

Graves' disease is an autoimmune disease in which the thyroid is diffusely enlarged (goiter) and overactive, producing an excessive amount of thyroid hormones. It is the most common cause of **hyperthyroidism** (overactive thyroid) in the United States. Physical symptoms frequently include red, dry, swollen, puffy, and bulging eyes (exophthalmos), heat intolerance, difficulty sleeping, and anxiety (see Box 30.2). However,

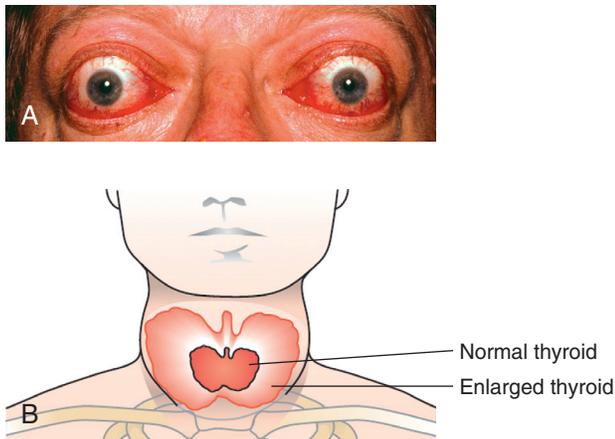

Fig. 30.4 A, Exophthalmos. (From SPL/Photo Researchers, Inc.) B, Thyroid enlargement. (From Buck C: 2011 ICD-9-CM, for Hospitals, vols 1-3, St Louis, 2011, WB Saunders.)

the most common sign of Graves' disease is goiter or thyroid enlargement (Fig. 30.4). The excessive thyroid hormones may cause a serious metabolic imbalance called **thyrotoxicosis**. The prevalence of maternal thyrotoxicosis is approximately 1 case per 1500 persons, with maternal Graves' disease being the most common cause (80% to 85%) (American Thyroid Association, 2019).

Pathophysiology

Commonly, patients have a family history involving a wide spectrum of autoimmune thyroid diseases, such as Graves' disease, Hashimoto's thyroiditis, or postpartum thyroiditis. In Graves' disease, the TRH receptor itself is the primary autoantigen and is responsible for the manifestation of hyperthyroidism. The thyroid gland is under continuous stimulation by circulating autoantibodies against the TRH receptor, and pituitary TSH secretion is suppressed because of the increased production of thyroid hormones. These thyroid-stimulating antibodies cause release of thyroid hormone and Tg, and they also stimulate iodine uptake, protein synthesis, and thyroid gland growth.

The Tg and TPO Abs appear to have little role in Graves' disease. However, as mentioned earlier, they are markers of Hashimoto's thyroiditis autoimmune disease against the thyroid. A TSH antibody—typically referred to as thyroid-stimulating immunoglobulin—test is used to identify hyperthyroidism, or Graves' disease.

Triggers

Graves' disease is an autoimmune disorder, influenced by a combination of environmental and genetic factors. Genetic factors contribute to approximately 20% to 30% of overall susceptibility. Other factors include infection, excessive iodide intake, stress, female gender, steroids, and toxins. Smoking has been implicated in the worsening of Graves' ophthalmopathy (eye disease) (Wiersinga, 2016). Graves' disease also has been associated with infectious agents such as *Yersinia enterocolitica* and *Borrelia burgdorferi*, as these bacteria have been shown to contain high-affinity binding sites for the hormone TSH (Hargreaves et al, 2013).

Genetics. Several autoimmune thyroid disease susceptibility genes have been identified and appear to be specific to either Graves' disease or Hashimoto's thyroiditis, whereas others confer susceptibility to both conditions. The genetic predisposition to thyroid autoimmunity may interact with environmental factors or events to precipitate the onset of Graves' disease. HLA-DRB1 and HLA-DQB1 appear to be associated with Graves' disease susceptibility.

Stress. Stress can be a factor for thyroid autoimmunity. Acute stress-induced immunosuppression may be followed by immune system hyperactivity, which could precipitate autoimmune thyroid disease. This may occur during the postpartum period, in which Graves' disease may occur 3 to 9 months after delivery. Estrogen may influence the immune system, particularly the beta-cells. Trauma to the thyroid also has been reported to be associated with Graves' disease. This may include surgery of the thyroid gland, percutaneous injection of ethanol, and infarction of a thyroid adenoma.

Medical Management

For patients with sustained forms of hyperthyroidism, such as Graves' disease or toxic nodular goiter, antithyroid medications can be used. The goal with this form of drug therapy is to prevent the thyroid from producing hormones (Table 30.4).

The effects of immunotherapy drugs are also being evaluated (Salvi, 2014) (see *Pathophysiology and Care Management Algorithm: Thyroid Dysfunction*).

MANAGING IMBALANCES OF THE HYPOTHALAMUS-PITUITARY-THYROID AXIS

The thyroid has a relationship to hypothalamic, pituitary, immune, adrenal, and cardiovascular functions that affect clinical, cellular, and molecular outcomes. A checklist of considerations is found in Box 30.3 and is discussed here.

TABLE 30.4 Treatments for Hyperthyroidism

Medication Brand Name	Medication Generic Name	Use and Comments
Tapazole	Methimazole (MMI)	Both drugs interfere with the thyroid gland's production of hormones. Both have side effects, which include rash, itching, joint pain, and fever.
Northyx	Propylthiouracil (PTU)	Liver inflammation or reduction in white blood cells may occur. Underlying hyperthyroidism can return when patient is no longer taking the medication.
Radioactive iodine		This is the most widely recommended permanent treatment of hyperthyroidism. Thyroid cells absorb radioactive iodine, which damages or kills them. If too many of the thyroid cells are damaged, remaining thyroid does not produce enough hormone, resulting in hypothyroidism, and supplemental thyroid hormone may be necessary.
Surgical Treatment		
<ul style="list-style-type: none"> • Partial or complete removal of the thyroid • Not as common as pharmacologic modes of treatment 		

BOX 30.3 Factors Promoting Thyroid Health in Adults

Consider

Protein: 0.8 g/kg/day
 Iodine (once autoimmune disease has been ruled out): 150 mcg/day
 Selenium (as L-selenomethionine): 75-200 mcg/day
 Zinc (as zinc citrate): 10 mg/day
 Vitamin D (as D₃ or cholecalciferol): 1000 IU/day
 Vitamin E (as D-alpha tocopherol succinate): 100 IU/day
 Vitamin C (as ascorbic acid): 100-500 mg/day
 Guggulsterones (from guggul extract): 100 mg/day
 Ashwaganda: 100 mg/day

Reduce or eliminate

Gluten (found in wheat, rye, oats, and barley)
 Processed soy
 Excessive uncooked goitrogenic foods
 Stress

Provide adequate precursors for the formation of T₄. Iodide is a limiting nutrient in many individuals for the production of T₄. Adequate levels of organic iodide, which can come from sea vegetables, iodized salt, and seafood, are important in T₄ production. Adequate dietary protein intake is important in establishing proper protein-calorie nutrition. Supplementation with tyrosine does not appear to have a beneficial effect on elevating thyroid hormones.

Reduce antithyroidal antibodies. A variety of food antigens could induce antibodies that cross-react with the thyroid gland. A food elimination diet using gluten-free grains and possible elimination of casein, the predominant milk protein, may be considered for hypothyroidism of unexplained origin. It also has been suggested that environmental toxins such as cadmium and lead may play a role in inducing AIT and thyroid dysfunction (Bajaj et al, 2016). Implementing nutritional support and providing adequate levels of vitamin D and selenium to support the immune system may be beneficial.

Improve the conversion of T₄ to T₃. Nutritional agents that help support proper deiodination by the type 1, 5-deiodinase enzyme include selenium (as L-selenomethionine) and zinc (as zinc glycinate or zinc citrate). Human studies repeatedly have demonstrated consequent reduced concentrations of thyroid hormones when a zinc deficiency is present (Blazewicz et al, 2010). In children with Down's syndrome, zinc sulfate may reduce thyroidal antibodies, improve thyroid function, and reduce the incidence of subclinical hypothyroidism (Mazurek and Wyka, 2016).

Zinc supplementation was also shown to ameliorate hazards of radiation on thyroid hormone indices (Al et al, 2016).

Enhance T₃ influence on mitochondrial function. A number of important nutritional relationships improve thyroid hormones' effects on the mitochondria, the organelles responsible for the majority of cellular energy production (Lanni et al, 2016). Selenium supplementation in animals can improve the production of T₃ and lower autoantibodies to thyroid hormones while improving energy production. Supplementation with selenomethionine results in improved deiodination of T₄, which may improve ATP formation by supporting improved mitochondrial activity. Food sources of selenium include the Brazil nut, snapper, cod, halibut, yellowfin tuna, salmon, sardines, shrimp, mushrooms, and barley.

Monitor use of botanical products. Based on animal studies, it appears that certain botanical preparations influence thyroid activity. The most significant products include *Commiphora mukul* (guggulsterones, from guggul extract) and *Withania somnifera* (ashwagandha). *C. mukul*

demonstrates strong thyroid stimulatory action. Its administration (1 mg/100 g body weight) increases iodine uptake by the thyroid, increases TPO activity, and decreases lipid peroxidation, suggesting that increased peripheral generation of T₃ might be mediated by this plant's antioxidant effects. *W. somnifera* (ashwagandha) root extract (1.4 g/kg) may increase T₃ and T₄ concentrations without changing 5-deiodinase activity (Sharma et al, 2018).

Avoid disruption of thyroid hormone metabolism from flavonoids. Flavonoids, natural and synthetic, have the potential to disrupt thyroid hormone metabolism. Synthetic flavonoid derivatives can decrease serum T₄ concentrations and inhibit the conversion of T₄ to T₃ and the metabolic clearance of rT₃ by the selenium-dependent 5-deiodinase. Naturally occurring flavonoids appear to have a similar inhibitory effect. Of the naturally occurring flavonoids, luteolin (most often found in leaves, but also seen in celery, thyme, dandelion, green pepper, thyme, perilla, chamomile tea, carrots, olive oil, peppermint, rosemary, and oregano) is the most active inhibitor of 5-deiodinase activity. Because isolated or concentrated flavonoids are increasingly used as therapeutic interventions, more research on the potential influence of these substances on thyroid hormone metabolism is desirable (Gonçalves et al, 2013). However, in patients with thyroid cancer who have reduced ability to uptake iodide, flavonoids such as rutin and apigenin (found in asparagus, figs, and green and unpeeled apples) are able to increase iodide uptake and may be useful and adjuvant in radioiodine therapy since this flavonoid increased thyroid uptake without adversely affecting thyroid function (Gonçalves et al, 2013; Gonçalves et al, 2017).

Use caution with supplements. Lipoic acid reduces the conversion of T₄ to T₃. Because it is usually not a therapeutic advantage to decrease peripheral activation of T₃ subsequent to T₄ therapy, use of lipoic acid supplements in hypothyroid patients receiving exogenous hormone therapy should be approached with caution. However, lipoic acid has been more recently shown to be a potential adjuvant therapy for advanced thyroid cancer because it could activate adenosine monophosphate activated protein kinase (AMPK) and inhibit transforming growth factor β-TGFβ pathway by reducing cancer cell migration and suppressing tumor growth (Jeon et al, 2016).

Maintain vitamin sufficiency. One nutrient that is critically important for establishing immune balance and preventing the production of autoantibodies is vitamin D. Vitamin D is considered a prohormone with antiproliferative, differentiating, and immunosuppressive activities. Vitamin D is an effective immune modulator and may suppress the development of autoimmune diseases, such as arthritis and multiple sclerosis (Baeke et al, 2010). Conversely, a vitamin D deficiency is associated with numerous autoimmune conditions, including Hashimoto's thyroiditis. More than 90% of people with autoimmune thyroid disease have a genetic defect affecting their ability to metabolize vitamin D (Feng et al, 2013; Kivity et al, 2011). Vitamin D also appears to work with other nutritional factors to help regulate immune sensitivity and may protect against development of autoantibodies. After exposure to heavy metals, decreases in a variety of hepatic antioxidant lipid peroxidation (the oxidative degradation of lipids) systems have been observed. Ascorbic acid has been shown to be effective in preventing lead-induced decreases in T₃ and hepatic 5-deiodination in an animal model (Ambali et al, 2011).

ADRENAL DISORDERS

Cushing's Syndrome

In Cushing's syndrome, too much cortisol remains in the bloodstream over a long period. The exogenous form occurs when individuals take steroids or other similar medications and ceases when the medication is stopped. Endogenous Cushing's syndrome is rare and occurs as the

result of a tumor on the adrenal or pituitary gland. Weight gain, insulin resistance, high blood sugar, excessive thirst, easy bruising, depression, muscle loss, and weakness are common symptoms. Because cortisol causes bone loss over time, a diet rich in calcium and vitamin D may help prevent osteoporosis. Reducing sodium, optimal hydration, and caloric awareness can also assist with weight management and the prevention of fluid retention.

Addison's Disease

Primary adrenal insufficiency, also known as **Addison's disease**, is rare. In this condition, insufficient steroid hormones are produced in spite of adequate levels of the hormone adrenocorticotropic hormone (ACTH). People with Addison's disease lose the ability to appropriately regulate blood sugar and will have low levels of cortisol, aldosterone, epinephrine, and norepinephrine. This leads to loss of appetite, fatigue, low blood pressure, nausea and vomiting, and, for some, darkening of skin on the face and neck. Patients with Addison's disease have an increased need for salt and water and also need to eat regular balanced meals (with low-glycemic carbohydrate and protein) to regulate blood sugar.

Adrenal Insufficiency/Adrenal Fatigue

Adrenal fatigue has been identified as a collection of signs and symptoms caused by the decreased ability of the adrenal glands to respond adequately to stress. A variety of terms are found in the scientific literature that address adrenal fatigue, including subclinical adrenal insufficiency, adrenal stress, adrenal exhaustion, adrenal burn-out, and adrenal imbalance (Allen Jr, 2013). The adrenals are the two triangular-shaped glands located at the top of each kidney and are responsible primarily for governing the body's adaptations to stress of any kind. Under the influence of stress, the adrenals will respond with increased hormone production, which can cause elevated blood sugar and blood pressure. Over time, the adrenal can become decompensated, where the hormone output may be diminished. This is often referred to as adrenal fatigue. This can occur whether the source of stress—physical, emotional, or psychological—is chronic and continues to persist causing a cumulative effect, or is a very intense single event stressor. In other words, the adrenal glands are unable to keep pace with the demands of perpetual fight-or-flight arousal, resulting in subclinical adrenal dysfunction. The most common symptoms of adrenal fatigue include, but are not limited to, excessive fatigue and exhaustion, hair loss, hypoglycemia, hormone imbalance, poor digestion, low immune function, slow recovery from illness, inability to concentrate, and inability to cope with stressors.

Chronic adrenal stress causes the following (Sun et al, 2016; Tsigos and Chrousos, 2002):

- Affects communication between the brain and hormone-secreting glands. The hypothalamus and pituitary gland direct hormone production, including that of the thyroid. When the hypothalamus and pituitary weaken because of chronic adrenal stress, they are not able to communicate well with the thyroid gland.
- Increases thyroid-binding protein activity, so that thyroid hormones cannot get into cells to do their job.
- Hampers the conversion of T_4 to active forms of T_3 , which can lead to fatigue.
- Interferes with the biotransformation (detoxification) pathways through which thyroid hormones exit the body, leading to thyroid hormone imbalance.
- Causes cells to lose sensitivity to thyroid hormones.
- Weakens the immune barriers of the digestive tract, lungs, and brain; promotes poor immune regulation.

The impact of high stress on intestinal microflora has been examined as well. A significant decrease in the number of *Bifidobacteria* and *Lactobacilli* was reported. Conversely, an increase in the number of *Escherichia coli* and enterobacteria were also reported, suggesting that the increased chronic stress disrupts intestinal microflora ecology. The authors propose is that stress induces increased permeability of the gut, allowing bacteria and bacterial antigens to cross the epithelial barrier and activate a mucosal immune response, which in turn alters the composition of the microbiome and leads to enhanced hypothalamic-pituitary-adrenal (HPA) activation (Dinan and Cryan, 2012).

These are some of the ways adrenal stress directly affect thyroid function (Herman et al, 2016). Chronic adrenal stress affects other systems of the body, which in turn decreases thyroid function. For example, the adrenal hormone **cortisol** plays a large role in thyroid health. Cortisol is a life-sustaining hormone essential to the maintenance of homeostasis. It often is called the “stress hormone” because it influences, regulates, or modulates many of the changes that occur in the body in response to stress, including, but not limited, to the following:

- Antiinflammatory actions
- Blood glucose levels
- Blood pressure
- Central nervous system activation
- Fat, protein, and carbohydrate metabolism to maintain blood glucose
- Heart and blood vessel tone and contraction
- Immune responses

Cortisol levels follow a circadian rhythm and normally fluctuate throughout the day and night, peaking at about 8 a.m and reaching a low at about 4 p.m (Allen Jr, 2013). It is very important that bodily functions and cortisol levels return to normal after a stressful event. Adrenal fatigue appears to occur when the amount of stress or combined stresses overextends the capacity of the body to compensate for and recover from that stress. When this happens repeatedly, it exhausts the adrenal and thyroid glands, as well as the hypothalamus and the pituitary gland. Over time this exhaustion leads to functional hypothyroidism. In addition, constant cortisol production increases risk for obesity and weakens the gastrointestinal (GI) tract, making one more susceptible to inflammation, dysbiosis (poor gut health), and infection (Foster, 2017; van der Valk et al, 2018).

The following include common integrative interventions in the treatment of adrenal fatigue (Allolio et al, 2007; Charmandari, 2014):

- B-complex vitamins to provide cofactors for adrenal hormone production
- Exercise in moderation
- Low-glycemic load, nutrient-dense diet
- Antianxiolytic/sedative botanicals (i.e. chamomile and lavender) (Head and Kelly, 2009).
- Probiotics
- Optimizing sleep habits
- Relaxation and stress management

Overt stressors such as childhood emotional abuse and posttraumatic stress disorder (PTSD) may result in cortisol hyperactivity, thus leading to pituitary and adrenal hyperreactivity and adrenal fatigue and decompensation (Rasmusson et al, 2001). Increased cortisol signaling, however, has been shown to be neurocognitively beneficial in depressed women with a history of maltreatment (Abercrombie et al, 2018).

CLINICAL CASE STUDY

Frank is a 72-year-old black man from Jamaica who moved to the United States 2 years ago. He has been diagnosed with hypothyroidism this past year. He comes to your clinic taking Synthroid, garlic, and chamomile. His diet history indicates daily intake of chicken, rice, celery, green pepper, mango, and papaya. He states that he has been very tired lately, has little energy, and has constipation. His hormone levels on his last medical report were thyroxine (T_4): 1.7 ng/dL, triiodothyronine (T_3): 75 ng/dL, and thyroid-stimulating hormone (TSH): 6 U/mL, indicative that his hypothyroidism is still not well controlled.

Nutrition Diagnostic Statement

- Food-medication interaction related to mixing Synthroid with foods and herbs that aggravate thyroid dysfunction as evidenced by fatigue, constipation, high TSH, and low serum T_3 and T_4 .

Nutrition Care Questions

1. What other information do you need for a more thorough assessment?
2. Taking into consideration his Jamaican heritage, advice would you offer Frank about his diet?
3. What foods and supplements conflict with Synthroid?
4. Because he is a recent immigrant, what potential stressors may he be experiencing?

Medical Nutrition Therapy for Anemia

Michelle Loy, MPH, MS, RDN

KEY TERMS

anemia	intrinsic factor (IF)	polycythemia
aplastic anemia	iron deficiency anemia	protoporphyrin
ceruloplasmin	koilonychia	reticulocytosis
ferritin	macrocytic anemia	restless legs syndrome (RLS)
ferroprotein	meat-fish-poultry (MFP) factor	serum
glossitis	megaloblastic anemia	sickle cell disease (SCD)
hematocrit	microcytic anemia	sideroblastic (pyridoxine-responsive) anemia
heme iron	nonheme iron	soluble serum transferrin receptors (STFRs)
hemoglobin	normochromic	sports anemia
hemolytic anemia	nutritional anemias	thalassemia
hepcidin	pagophagia	total iron-binding capacity (TIBC)
hereditary hemochromatosis	pernicious anemia	transferrin
holotranscobalamin II (holo TCII)	pica	transferrin receptor
hypochromic	plasma	transferrin saturation

Anemia is the predominant hematologic disorder in the United States and is associated with medical consequences that influence morbidity and mortality. Anemia affects 5.6% of the nation's population with the prevalence being highest among women of reproductive age, adults 60 years or older, blacks, and Hispanics (Le, 2016). Anemia is also a serious global health burden affecting 2 billion people worldwide with the highest rates occurring in South Asia and central and west sub-Saharan Africa (Kassebaum, 2016). Globally, young children, women, and older adults are at highest risk of developing anemia. To best address this serious health problem, nutrition professionals need a solid understanding of the relevant terminology along with the etiology, pathophysiology, and medical and nutritional management of the most common types of anemia.

Hemoglobin is a conjugated protein containing four heme groups and globin; it is the oxygen-carrying pigment of the erythrocytes. The **hematocrit** is the volume percentage of erythrocytes in the blood. **Plasma** is the liquid portion of whole blood containing coagulation factors; **serum** is the liquid portion of whole blood without coagulation factors.

Anemia is a deficiency in the size or number of red blood cells (RBCs) or the amount of hemoglobin they contain. This deficiency limits the exchange of oxygen and carbon dioxide between the blood and the tissue cells. Anemia classification is based on cell size—macrocytic (large), normocytic (normal), and microcytic (small)—and on hemoglobin content: **hypochromic** (pale color from deficiency of hemoglobin) and **normochromic** (normal color) (Table 31.1).

Macrocytic anemia presents with larger-than-normal RBCs, plus increased mean corpuscular volume (MCV) and mean corpuscular

hemoglobin concentration (MCHC). **Microcytic anemia** is characterized by smaller-than-normal erythrocytes and less circulating hemoglobin, as in iron deficiency anemia and thalassemia.

Most anemias are caused by a lack of nutrients required for normal erythrocyte synthesis, principally iron, vitamin B₁₂, and folate. These anemias that result from an inadequate intake of iron, protein, certain vitamins, copper, and other heavy metals are called **nutritional anemias**. Other anemias result from conditions such as hemorrhage, genetic abnormalities, chronic disease states, or drug toxicity and have varying degrees of nutritional consequence.

IRON-RELATED BLOOD DISORDERS

Iron status can range from overload to deficiency and anemia. Routine measurement of iron status is necessary because approximately 6% of Americans have a negative iron balance, approximately 10% have a gene for positive balance and increased storage of iron, and approximately 1% have iron overload. Anemia also affects some groups more than others. Non-Hispanic blacks and Hispanics have the highest prevalence of anemia followed by non-Hispanic whites. As shown in Fig. 31.1, stages of iron status range from iron overload to iron deficiency anemia and are summarized as follows (Herbert, 1992):

- Stage I and stage II negative iron balance (i.e., iron depletion). In these stages iron stores are low and there is no dysfunction. In stage I negative iron balance, reduced iron absorption produces moderately depleted iron stores. Stage II negative iron balance is characterized by severely depleted iron stores.
- Stage III and stage IV negative iron balance (i.e., iron deficiency). Iron deficiency is characterized by inadequate body

TABLE 31.1 Morphologic Classification of Anemia

Morphologic Type of Anemia	Underlying Abnormality	Clinical Syndromes	Treatment
Macrocytic (MCV > 94; MCHC > 31)			
Megaloblastic	Vitamin B ₁₂ deficiency	Pernicious anemia	Vitamin B ₁₂
	Folate deficiency	Nutritional megaloblastic anemias, malabsorption syndromes	Folic acid
	Inherited disorders of DNA synthesis	Orotic aciduria Sickle cell disease	Treatment based on the nature of the disorder
	Drug-induced disorders of DNA synthesis	Side effects of chemotherapeutic agents, anticonvulsants, oral contraceptives	Discontinue offending drug and administer folic acid
Nonmegaloblastic	Accelerated erythropoiesis	Hemolytic anemia	Treatment of underlying disease
Hypochromic Microcytic (MCV < 80; MCHC < 31)			
	Iron deficiency	Chronic loss of blood, inadequate diet, impaired absorption, increased demands	Ferrous sulfate or ferrous bis glycinate and correction of underlying cause
	Disorders of globin synthesis	Thalassemia Hemoglobin E Hemoglobin C	Nonspecific Mild – does not require treatment; Severe – frequent blood transfusions to provide healthy RBCs with normal Hgb
	Disorders of porphyrin and heme synthesis	Pyridoxine-responsive anemia	Pyridoxine
	Other disorders of iron metabolism	Copper deficiency	Copper
Normochromic Normocytic (MCV 82-92; MCHC > 30)			
	Recent blood loss	Various	Transfusion, iron, correction of underlying condition
	Overexpansion of plasma volume	Edema of pregnancy	Restore homeostasis
	Hemolytic diseases	Overhydration	Treatment based on the nature of the disorder
	Hypoplastic bone marrow	Aplastic anemia Pure RBC aplasia	Transfusion Androgens
	Infiltrated bone marrow	Leukemia, multiple myeloma, myelofibrosis	Chemotherapy
	Endocrine abnormality	Hypothyroidism, adrenal insufficiency	Treatment of underlying disease
	Chronic disease		Treatment of underlying disease
	Renal disease	Renal disease	Treatment of underlying disease
	Liver disease	Cirrhosis	Treatment of underlying disease

DNA, Deoxyribonucleic acid; MCHC, mean corpuscular hemoglobin concentration: concentration of hemoglobin expressed in grams per deciliter (g/dL); MCV, mean corpuscular volume: volume of one red blood cell expressed in femtoliters (fl); RBC, red blood cell.

Modified from Wintrobe MM et al: *Clinical hematology*, ed 8, Philadelphia, 1981, Lea & Febiger.

iron, possibly causing dysfunction and disease. In stage III negative iron balance, dysfunction is not accompanied by anemia; anemia develops in stage IV negative iron balance.

- c. Stage I and stage II positive iron balance. Stage I positive balance usually lasts for several years with no dysfunction. Supplements of iron and/or vitamin C promote progression to dysfunction or disease, whereas iron removal prevents progression to disease. Iron overload disease develops in persons with stage II positive balance after years of iron overload have caused progressive damage to tissues and organs.

Iron status has a variety of indicators. Serum **ferritin** is an iron apoferritin complex, one of the chief storage forms of iron. Serum ferritin levels are in equilibrium with body iron stores. Very early (stage I) positive iron balance may best be recognized by measuring **total iron-binding capacity (TIBC)**, the capacity of transferrin to take on or become saturated with iron. Conversely, measurement of serum or plasma ferritin levels may best reveal early (stages I or II) negative iron balance, although serum TIBC may be as good an indicator (see Chapter 5). **Transferrin saturation** is the measure of the amount of iron bound to transferrin and is a gauge of iron supply to the tissues; the percent saturation = serum iron/TIBC × 100.

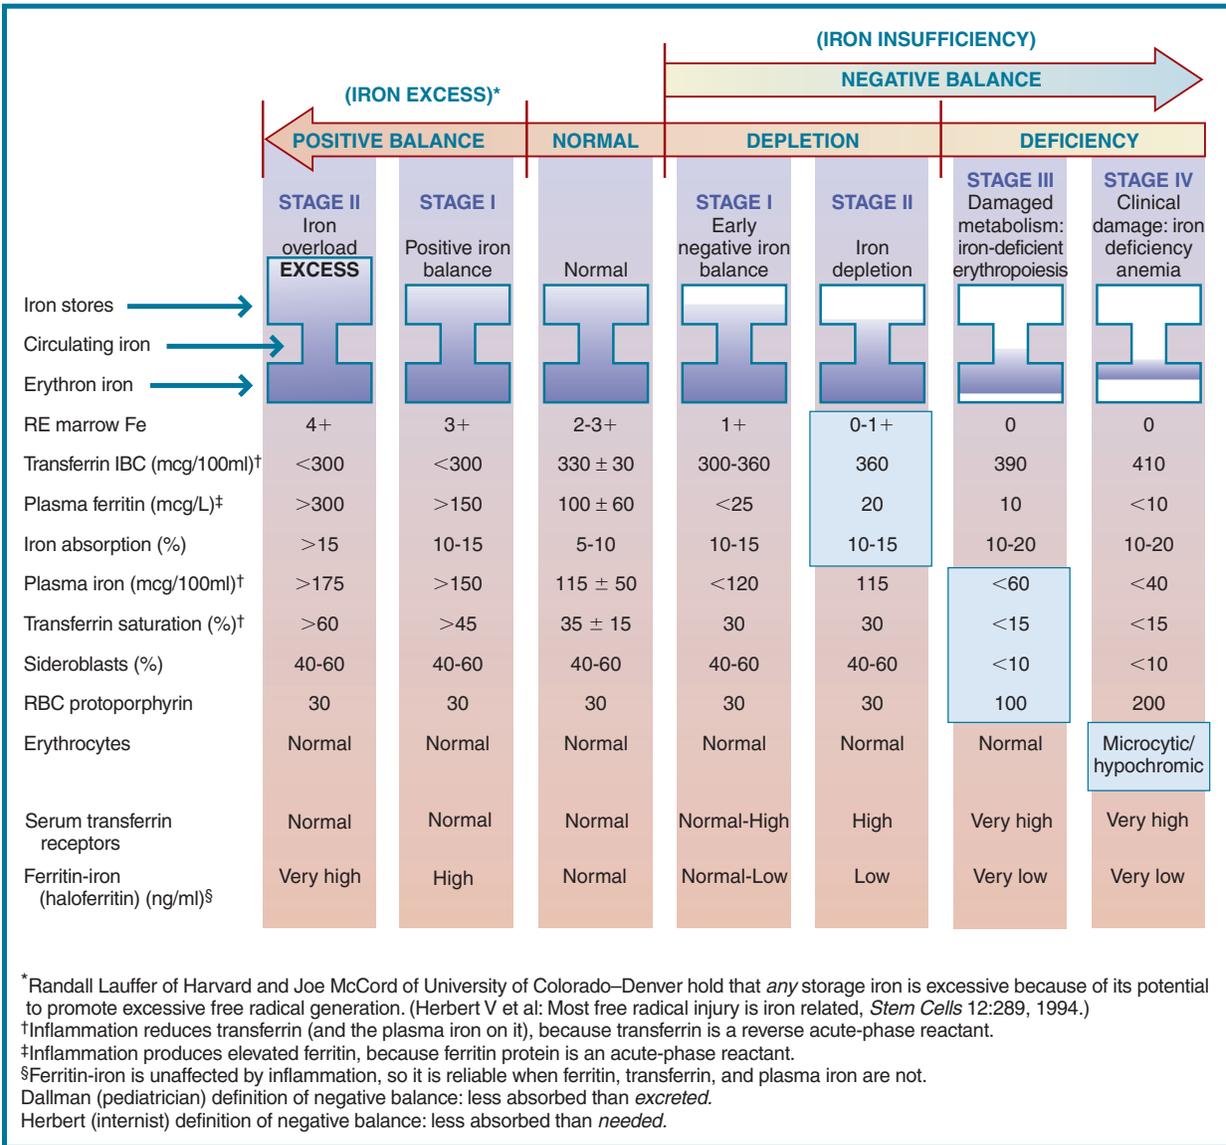

Fig. 31.1 Sequential stages of iron status. IBC, Iron-binding capacity; RBC, red blood cell; RE, reticuloendothelial cells. (Copyright Victor Herbert, 1995.)

Iron Deficiency Anemia

Pathophysiology

Iron deficiency anemia is characterized by the production of microcytic erythrocytes and a diminished level of circulating hemoglobin. This microcytic anemia is the last stage of iron deficiency, and it represents the end point of a long period of iron deprivation. There are many causes of iron deficiency anemia as discussed in **Box 31.1**.

A common cause of iron deficiency is blood loss, either chronic or acute, including heavy menstrual bleeding in women. It can also be caused by malabsorption, medications, and inadequate intake. Because anemia is the last manifestation of chronic, long-term iron deficiency, the symptoms reflect a malfunction of a variety of body systems. Inadequate muscle function is reflected in decreased work performance and exercise tolerance. Neurologic involvement is manifested by behavioral changes such as fatigue, anorexia, and **pica** (consumption of nonfood items), especially **pagophagia** (ice eating). Abnormal cognitive development in children may indicate iron deficiency before it has developed into overt anemia (**Jáuregui-Lobera, 2014**).

BOX 31.1 Causes of Iron Deficiency Anemia

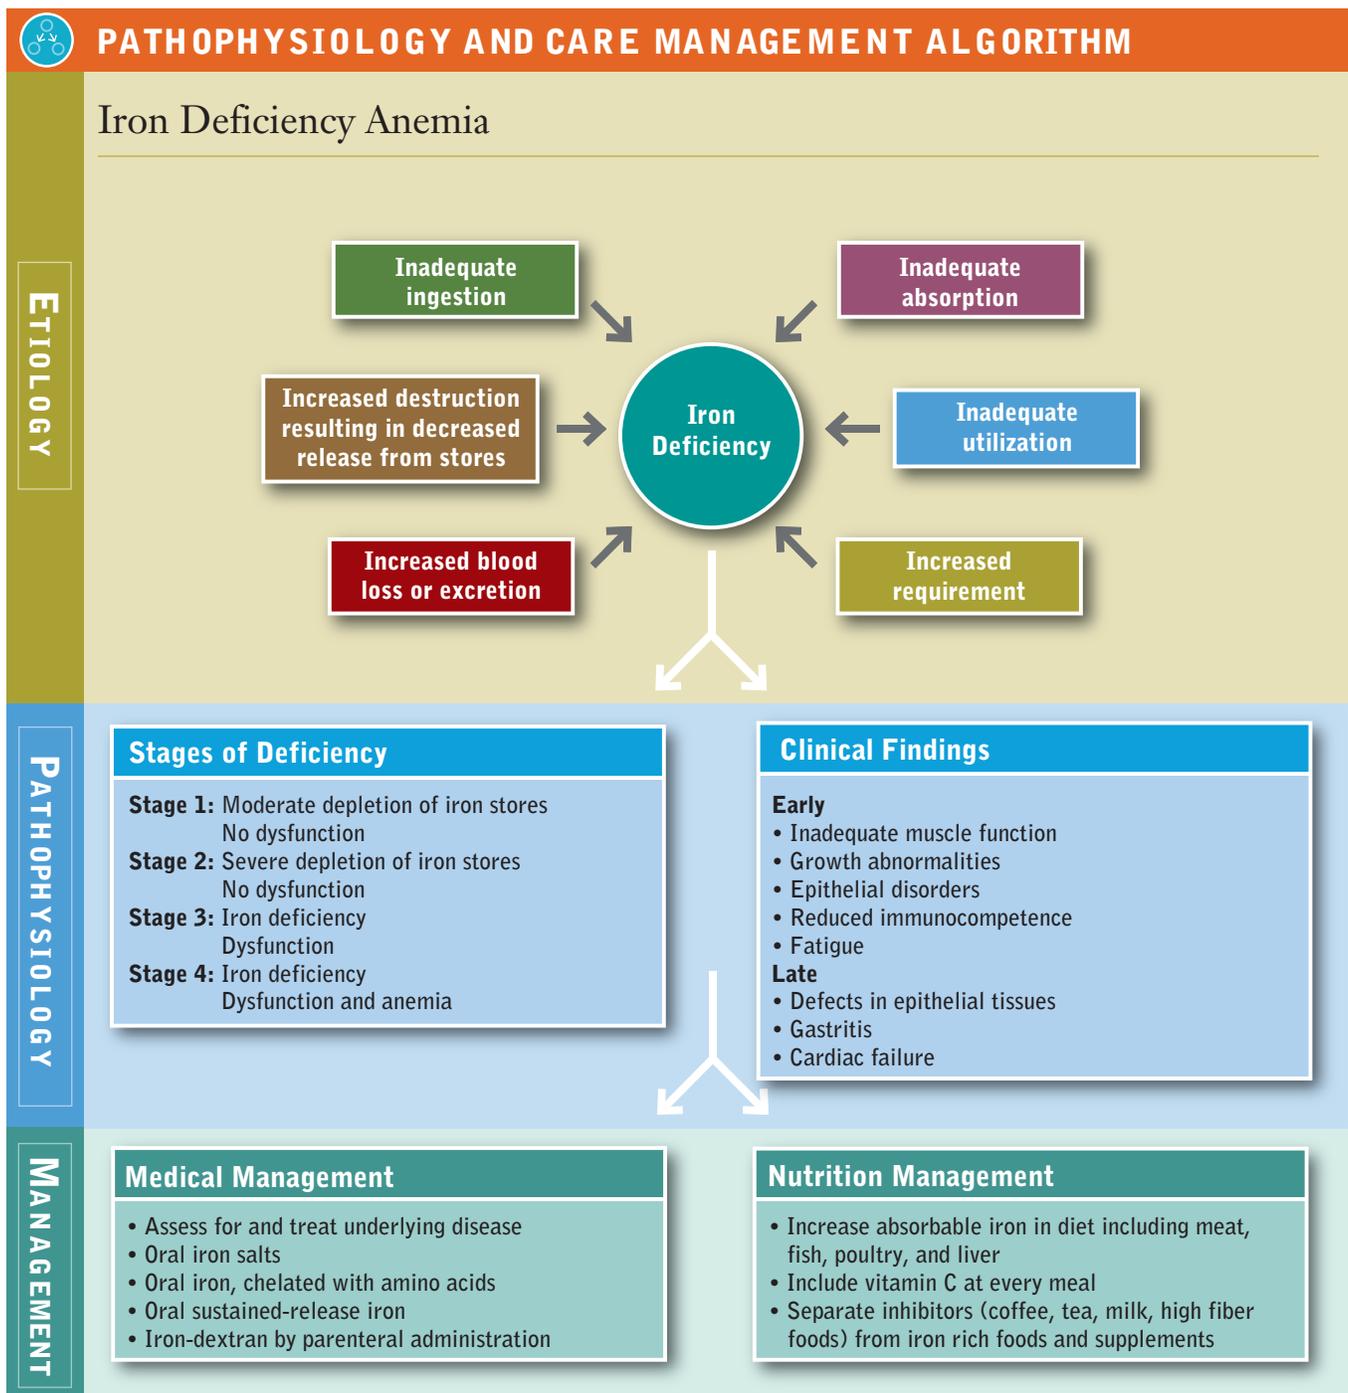

Inadequate Ingestion	Poor diet without supplementation of iron
Inadequate Absorption	Diarrhea, achlorhydria, intestinal disease such as celiac disease, atrophic gastritis, partial or total gastrectomy, or drug interference
Inadequate Utilization	Chronic gastrointestinal disturbances
Increased Requirement	Increase of blood volume, which occurs during infancy, adolescence, pregnancy, and lactation and which is not being matched with intake
Increased Excretion	Excessive menstrual blood (in females); hemorrhage from injury; or chronic blood loss from a bleeding ulcer, bleeding hemorrhoids, esophageal varices, regional enteritis, celiac disease, Crohn's disease, ulcerative colitis, parasitic or malignant disease
Increased Destruction	Caused by a chronic inflammation or other chronic disorder leading to destruction of RBC's

Growth abnormalities, epithelial disorders, and a reduction in gastric acidity are also common. A possible sign of early iron deficiency is reduced immunocompetence, particularly defects in cell-mediated immunity and the phagocytic activity of neutrophils, which may lead to frequent infections. **Restless legs syndrome (RLS)** with leg pain or discomfort may result from a lack of iron in the brain; this alters dopamine production and movement (Connor et al, 2017).

As iron deficiency anemia becomes more severe, defects arise in the structure and function of the epithelial tissues, especially of the tongue, nails, mouth, and stomach. The skin may appear pale in people with lighter complexions, and the inside of the lower eyelid may be light pink instead of red regardless of skin tone. Mouth changes

include atrophy of the lingual papillae, burning, redness, and in severe cases, **glossitis**, a completely smooth, waxy, and glistening appearance of the tongue. Angular stomatitis and a form of dysphagia may occur. Gastritis occurs frequently and may result in achlorhydria (low stomach acid). Fingernails can become thin and flat, and eventually **koilonychia** (spoon-shaped nails) may be noted (Fig. 31.2).

Progressive, untreated anemia results in cardiovascular and respiratory changes that can eventually lead to cardiac failure. Some social and emotional behavioral symptoms respond to iron therapy before the anemia is cured, suggesting they may be the result of tissue depletion of iron-containing enzymes rather than a decreased level of hemoglobin (see *Pathophysiology and Care Management Algorithm: Iron Deficiency Anemia*).

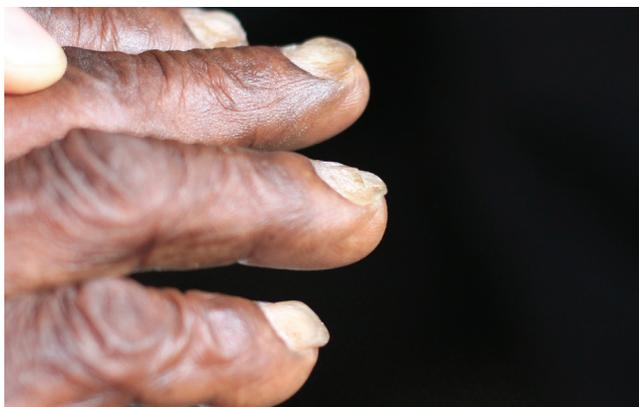

Fig. 31.2 Fingernails with cup-like depressions (koilonychia) are a sign of iron deficiency in adults. (From Heitz C. Koilonychia. In: Flickr [website]. <https://www.flickr.com/photos/coreyheitzmd/15023020192>. April 14, 2014.)

Assessment

A definitive diagnosis of iron deficiency anemia requires more than one method of iron evaluation; serum ferritin, iron, and transferrin are the most useful. The evaluation also should include an assessment of cell size and shape (morphology). By itself, hemoglobin concentration is unsuitable as a diagnostic tool in cases of suspected iron deficiency anemia for three reasons: (1) it is affected only late in the disease, (2) it cannot distinguish iron deficiency from other anemias, and (3) hemoglobin values may be within the normal range despite iron deficiency.

After absorption, iron is transported by plasma **transferrin**—a beta-1 globulin (protein) that binds iron derived from the gastrointestinal tract, iron storage sites, or hemoglobin breakdown—to the bone marrow (hemoglobin synthesis), endothelial cells (storage), or placenta (fetal needs). Transferrin molecules are generated on the surface of RBCs in response to the need for iron. With iron deficiency, so many **transferrin receptors** are on the cell surface unbound to iron that some of them break off and float in the serum. Their presence is an

early sign of developing iron deficiency; a higher quantity of **soluble serum transferrin receptors (STFRs)** means greater deficiency of iron. Progressive stages of iron deficiency can be evaluated by measurements, as shown in **Table 31.2**.

Protoporphyrin is the iron-containing portion of the respiratory pigments that combines with protein to form hemoglobin or myoglobin. The zinc protoporphyrin (ZnPP)/heme ratio is measured to assess iron deficiency. However, both this ZnPP/heme ratio and hemoglobin levels are affected by chronic infection and other factors that can produce a condition that mimics iron deficiency anemia when, in fact, iron is adequate.

At higher altitudes, where there is a lower availability of oxygen, hematocrit and hemoglobin levels increase to adapt (Ryan et al, 2014). This must be considered when assessing anemia. High altitude is 4900 to 11,500 feet; very high altitude is 11,500 to 18,000 feet; extreme altitude is above 18,000 feet.

Medical Management

Treatment of iron deficiency anemia should focus primarily on the underlying cause, although this is often difficult to determine. The goal is repletion of iron stores.

Oral supplementation. The chief treatment for iron deficiency anemia involves oral administration of inorganic iron in the ferrous form. Although the body uses ferric and ferrous iron, the reduced ferrous is easier on the gut and better absorbed. At a dose of 30 mg, absorption of ferrous iron is three times greater than if the same amount were given in the ferric form.

Iron is best absorbed when the stomach is empty. However, under these conditions it tends to cause gastric irritation, which is a direct result of the high quantity of free ferrous iron in the stomach. Gastrointestinal side effects can include nausea, epigastric discomfort and distention, heartburn, diarrhea, or constipation. If these side effects occur, the patient is told to take the iron with meals instead of on an empty stomach; however, this sharply reduces the absorbability of the iron. Chelated forms of iron (combined with amino acids or Krebs cycle intermediaries) are more bioavailable than nonchelated iron. Chelated iron is less affected by inhibitors of iron absorption,

TABLE 31.2 Biochemical Evaluation of Iron Deficiency

Measure	Reference Range	Deficiency
Serum or plasma ferritin	Newborn 25-200 ng/mL; 25-200 mcg/dL Neonate – 5 mos 50-200 ng/mL; 50-200 mcg/dL 6 mos-15 yr 7-142 ng/mL; 7-142 mcg/dL F 15 yr + 10-150 ng/mL; 10-150 mcg/dL M 15 yr + 12-300 ng/mL; 12-300 mcg/dL	The most sensitive indicator of iron deficiency. Low levels of ferritin are also seen in severe protein depletion. Females – < 10 mcg/dL Males – < 12 mcg/dL
Serum or plasma iron	F 40-150 mcg/dL; 7.2-26.9 mmol/L M 50-160 mcg/dL; 8.9-28.7 mmol/L	A good measure of quantity of iron bound to transferrin. Females – < 40 mcg/dL Males – < 50 mcg/dL
Total iron-binding capacity (TIBC)	250-460 mcg/dL; 45-82 mmol/L	TIBC primarily reflects liver function and is an indirect measurement of transferrin. Increases with iron-deficiency anemia.
Transferrin saturation	F 15%-50% M 20%-50%	Measures the iron supply to the tissues. Calculated by dividing serum iron by the TIBC multiplied by 100. Levels less than 16% are considered inadequate for erythropoiesis.
Soluble serum transferrin receptor (STFR)	F 1.9-4.4 mg/L M 2.2-5 mg/L	STFR reflects the rate of red blood cell (RBC) production in bone marrow. Ordered to differentiate between iron deficiency anemia and anemia of chronic disease. More sensitive than serum ferritin because it is elevated with iron deficiency, is within normal limits (WNL) in chronic disease or inflammation, and is low with iron overload.

TABLE 31.3 Forms of Iron Supplements

Iron Supplement	Advantages	Disadvantages
Ferrous sulfate	Most commonly studied Least expensive	Most constipating
Ferrous gluconate	Generally well tolerated with few gastrointes- tinal side effects	
Carbonyl iron (slow iron)	Generally well tolerated with few gastrointes- tinal side effects	Slow rate of solu- bilization, which slows the rate of absorption
Chelated iron (ferrous fumarate, succi- nate, aspartate, and bis glycinate)	Better absorbed Fewer side effects Least constipating	More expensive

including phytate, oxalate, phosphate, and calcium. Chelated iron, particularly ferrous bis glycinate, causes less gastrointestinal disturbances than elemental iron and it can be given in a lower dose (Ferrari et al, 2012; Milman et al, 2013). Micronutrient powders (MNP) containing iron may be useful methods of home food fortification for children under age 2 (De-Regil et al, 2013). The MNPs can be added to semisolid foods without affecting the sensory appeal of the foods. Various forms of iron supplements are discussed in Table 31.3.

Health professionals usually prescribe oral iron three times daily for 3–6 months to treat iron deficiency. Depending on the severity of the anemia and the patient's tolerance, the daily dose of elemental iron recommended is 50 to 100 mg three times daily for adults and 2–6 mg/kg of body weight divided into three doses per day for children (Short and Domagalski, 2013; Wang, 2016). Vitamin C given with the iron greatly increases iron absorption, but at higher doses it may also increase gastric irritation by intensifying oxidative stress in the gastrointestinal tract. Taking it with a high vitamin C food such as orange juice may be better tolerated.

Absorption of 10 to 20 mg of iron per day permits RBC production to increase to approximately three times the normal rate and, in the absence of blood loss, hemoglobin concentration to rise at a rate of 0.2 g/dL daily. Increased **reticulocytosis** (an increase in the number of young RBCs) is seen within 2 to 3 days after iron administration, but affected persons may report subjective improvements in mood and appetite sooner. The hemoglobin level will begin to increase by day 4. Iron therapy should be continued for 4–6 months, even after restoration of normal hemoglobin levels, to allow for repletion of body iron reserves. Coordination of care with a physician is essential with therapeutic iron supplementation.

Parenteral iron administration. If iron supplementation fails to correct the anemia, (1) the patient may not be taking the supplemental iron as prescribed due to gastric distress, (2) bleeding may be continuing at a rate faster than the erythroid marrow can replace blood cells, or (3) the supplemental iron is not being absorbed, possibly as a result of malabsorption secondary to steatorrhea, celiac disease, or hemodialysis. Parenteral administration is also used for patients who are receiving erythropoietin, a hormone that stimulates blood cell production. It is most often given as iron dextran but can also be given as iron sucrose or ferric gluconate. Although replenishment of iron stores by this route is faster, it is more expensive and intravenous therapy carries additional risk.

Medical Nutrition Therapy

Nutrition assessments and interventions should consider the amount of absorbable dietary iron consumed. A good source of iron contains a substantial amount of iron in relation to its calorie content and

contributes at least 10% of the recommended dietary allowance (RDA) for iron. Liver; kidney; beef; dried fruits; dried peas and beans; nuts; dark green leafy vegetables; and fortified whole-grain breads, muffins, cereals, and nutrition bars are among the foods that rank highest in iron content (see Appendix 42). It is estimated that 1.8 mg of iron must be absorbed daily to meet the needs of 80% to 90% of adult women and adolescent boys and girls.

Form of iron. **Heme iron** (approximately 15% of which is absorbable) is the organic form in meat, fish, and poultry, and is known as the **meat-fish-poultry (MFP) factor**. It is much better absorbed than nonheme iron. **Nonheme iron** can also be found in MFP, as well as in legumes, grains, vegetables, herbs and fruits, but it is not part of the heme molecule. The absorption rate of nonheme iron varies between 3% and 8% depending on the presence of dietary enhancing factors, specifically vitamin C and meat, fish, and poultry. Vitamin C not only is a powerful reducing agent, but also binds iron to form a readily absorbed complex. The mechanism by which the MFP factor potentiates the absorption of nonheme iron in other foodstuffs is unknown.

Inhibitors. Iron absorption can be inhibited to varying degrees by factors in foods that bind iron, including carbonates, oxalates, phosphates, and phytates (whole grain breads and cereals and legumes [beans]). Factors in vegetable fiber may inhibit nonheme iron absorption. If taken with meals, tea and coffee can reduce iron absorption by 50% through the formation of insoluble iron compounds with tannin. Iron in egg yolk is poorly absorbed because of the presence of phosvitin.

Bioavailability of dietary iron. Because typical Western diets generally contain 6 mg/1000 kcal of iron, the bioavailability of iron in the diet is more important in correcting or preventing iron deficiency than the total amount of dietary iron consumed. The rate of absorption depends on the iron status of the individual, as reflected in the level of iron stores. The lower the iron stores, the greater the rate of iron absorption. Individuals with iron deficiency anemia absorb approximately 20% to 30% of dietary iron compared with the 5% to 10% absorbed by those without iron deficiency.

IRON OVERLOAD

Excess iron is stored as ferritin and hemosiderin in the macrophages of the liver, spleen, and bone marrow. The body has a limited capacity to excrete iron and is efficient at recycling it. Approximately 1 mg of iron is excreted daily through the gastrointestinal tract, urinary tract, and skin. When red blood cells are no longer functional (after about 120 days), they are re-absorbed by the spleen. Iron from these cells can be recycled by the body. To maintain a normal iron balance, the daily obligatory loss must be replaced by the absorption of heme and nonheme food iron. Persons with iron overload excrete increased amounts of iron, especially in the feces, to compensate partially for the increased absorption and higher stores.

Excessive iron intake usually stems from accidental incorporation of iron into the diet from environmental sources. In the United States iron-containing supplements remain a common source of excessive iron ingestion, especially among children (Chang and Rangan, 2011). In other parts of the world, excessive iron intake may result from consumption of beverages or foods prepared in iron-containing cooking vessels (National Library of Medicine, 2019).

Uncommon disorders associated with iron overload include hemochromatosis, thalassemias, sideroblastic anemia, chronic hemolytic anemia, ineffective erythropoiesis, transfusional iron overload (secondary to multiple blood transfusions), porphyria cutanea tarda, aplastic anemia, and alcoholic cirrhosis. **Aplastic anemia** is a normochromic-normocytic anemia accompanied by a deficiency of all the formed elements in the blood; it can be caused by exposure to toxic

chemicals, ionizing radiation, and medications, although the cause is often unknown.

Brain iron increases with age and is abnormally elevated in neurodegenerative diseases, including Alzheimer's disease and Parkinson's disease (Ward et al, 2014). Several gene variants affect iron metabolism and may contribute to early onset of these conditions.

Hemochromatosis

Hereditary hemochromatosis is a general term for a group of rare genetic disorders that are characterized by the accumulation of iron in body organs, typically the liver, pancreas, and heart. Over time this accumulation is associated with organ damage, organ failure, and sometimes premature death. The most common form of hemochromatosis goes by several names including hereditary iron overload (HFE-related) hemochromatosis, type I or classic hemochromatosis, or hereditary hemochromatosis. The disease generally does not become apparent until 20 to 40 years of age. Men are usually diagnosed earlier than women because they have no physiologic mechanisms for losing iron such as menstruation, pregnancy, or lactation. Symptoms include fatigue, joint pain, and enlarged liver and spleen. The exact prevalence of this disorder is unknown, but it is thought to be the most common autosomal recessive disorder in Caucasian populations. In individuals of Northern European descent, it is estimated to have an incidence of 1 in 227 people. People with this condition absorb three times more iron from their food than those without hemochromatosis. Those who have two affected genes (homozygous) will likely die of iron overload unless they donate blood frequently. Otherwise, the excessive iron absorption continues unabated.

The Hemochromatosis and Iron Overload Screening Study (HEIRS) notes that non-Hispanic whites have the highest prevalence of the C282Y mutation of the hereditary iron (HFE) gene and thus hemochromatosis, followed by Native Americans, Hispanics, African Americans, Pacific Islanders, and Asians (Adams, 2015). Asians and Pacific Islanders have the highest levels of iron in their blood of all racial and ethnic groups, but they have the lowest prevalence of the gene mutation found with the typical form of hemochromatosis. Results from the HEIRS study suggest that increased iron values in non-Caucasian populations may be associated with non-HFE hemochromatosis and secondary iron overload.

Pathophysiology

Hepcidin is a peptide synthesized in the liver that functions as the principal regulator of systemic iron homeostasis. It regulates iron transport from iron-exporting tissues into plasma. Hepcidin deficiency underlies most known forms of hereditary hemochromatosis. Hepcidin inhibits the cellular efflux of iron by binding to and inducing the degradation of **ferroprotein**, the sole iron exporter in iron-transporting cells. Hepcidin controls plasma iron concentration and tissue distribution of iron by inhibiting intestinal iron absorption, iron recycling by macrophages, and iron mobilization from hepatic stores (Ganz, 2011).

Hepcidin synthesis is increased by iron loading and decreased by anemia and hypoxia. Its synthesis is also greatly increased during inflammation, trapping iron in macrophages, decreasing plasma iron concentrations, and causing iron-restricted erythropoiesis that is characteristic of anemia of chronic disease. There is evidence that the mutation of the HFE gene leading to hemochromatosis is also associated with increased levels of gastrin in the stomach, leading to increased levels of gastric acid and thus increased absorption of iron (Ganz, 2011). In hemochromatosis iron absorption is enhanced, resulting in a gradual, progressive accumulation of iron. Most affected persons do not know they have it.

A progressive, positive iron balance may result in a variety of serious problems, including hepatomegaly, skin pigmentation, arthritis, heart disease, hypogonadism, diabetes mellitus, and cancer. Individuals with abnormally high iron levels are more likely to develop cancer of the colon. Iron is a prooxidant that can be used for tumor cell growth and proliferation. There also seems to be increased risk for age-related macular degeneration, Alzheimer's disease, and Parkinson's disease because of the oxidative damage associated with iron overload (Belaidi and Bush, 2016; Fleming and Ponka, 2012).

Assessment

If an iron overload is suspected, serum ferritin level (storage iron) and percent of transferrin saturation ($[\text{serum iron}/\text{TIBC}] \times 100$) should be performed (Bacon et al, 2011). Iron overload may be present if the transferrin saturation is greater than or equal to 45% and if the serum ferritin level is elevated. If transferrin saturation and ferritin levels are elevated, HFE mutation analysis is recommended.

Medical Management

The patient with iron overload may simultaneously be anemic as a result of damage to the bone marrow, an inflammatory disorder, cancer, internal bleeding, or chronic infection. Iron supplements should not be taken until the cause is known.

For patients with significant iron overload, weekly phlebotomy for 2 to 3 years may be required to eliminate all excess iron (Bacon et al, 2011). Treatment for noninherited forms of secondary iron overload also may involve iron depletion with intravenous deferoxamine or oral deferasirox, chelating agents that are excreted by the kidneys, or with calcium disodium ethylenediaminetetraacetic acid (EDTA). Morbidity and mortality are reduced if excess body iron is removed by phlebotomy therapy before hepatic cirrhosis or diabetes develops.

Medical Nutrition Therapy

Individuals with iron overload should reduce meat, fish and poultry and consume more of a plant based or vegetarian diet. Reduced vitamin C is recommended as well as avoidance of vitamin C supplements, as this can increase absorption of iron.

Affected persons should avoid foods that are fortified with iron (i.e., breakfast cereals, energy or sports bars, and meal-replacement drinks or shakes). They should also avoid iron supplements or multiple vitamin and mineral supplements that contain iron. The RDA for iron should not be exceeded, and for some, lower intakes are recommended (see RDA tables at the beginning of the book).

MEGALOBlastic ANEMIAS

Megaloblastic anemia reflects a disturbed synthesis of DNA, which results in morphologic and functional changes in erythrocytes, leukocytes, and platelets and their precursors in the blood and bone marrow. This anemia is characterized by the presence of large, immature, abnormal, RBC progenitors in the bone marrow; 95% of cases are attributable to folate or vitamin B₁₂ deficiency. Two disorders of cobalamin metabolism arise from mutations of the methionine synthase and methionine synthase reductase genes; these disorders feature megaloblastic anemia and neurologic manifestations (see Chapter 6).

Both vitamins are essential to the synthesis of nucleoproteins. Hematologic changes are the same for both; however, the folic acid deficiency is the first to appear. Normal body folate stores are depleted within 2 to 4 months in individuals consuming folate-deficient diets. By contrast, vitamin B₁₂ stores are depleted only after several years of a vitamin B₁₂-deficient diet. In persons with vitamin B₁₂ deficiency, folic acid supplementation can mask B₁₂ deficiency (Fig. 31.3).

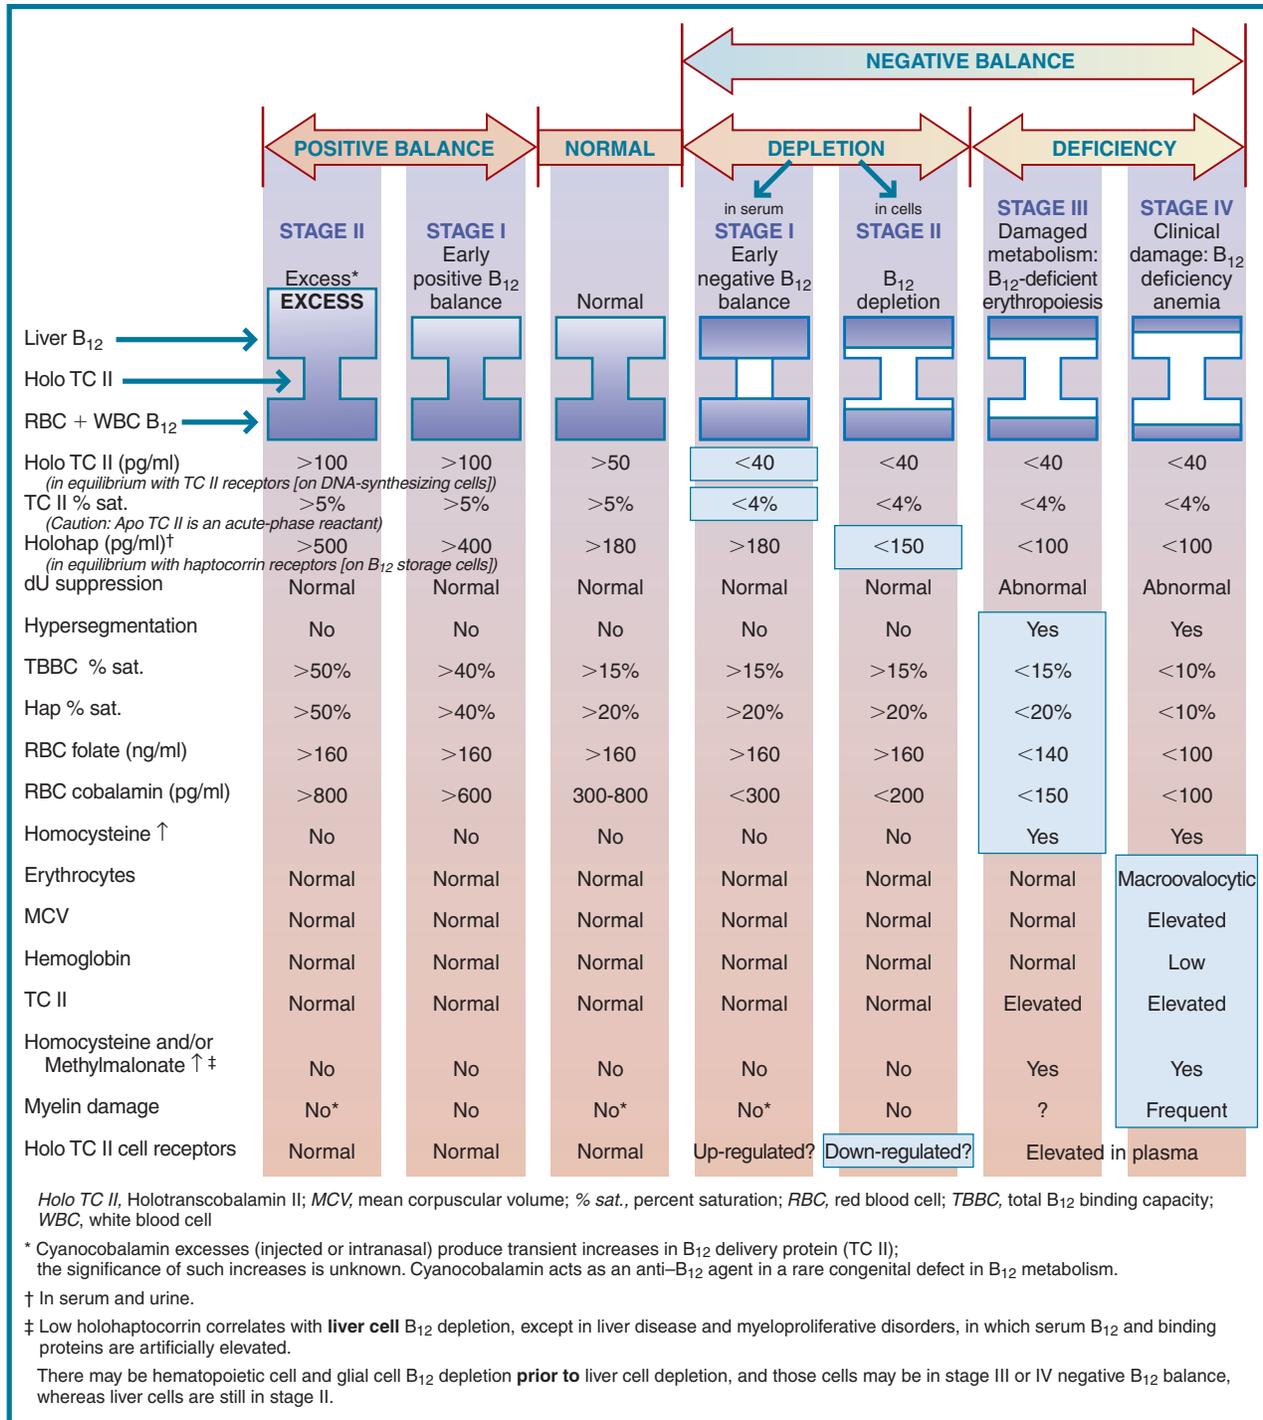

Fig. 31.3 Sequential stages of vitamin B₁₂ status. (From Herbert V: Staging vitamin B₁₂. In Ziegler EE, Filer LJ, editors: *Present knowledge in nutrition*, ed 7, Washington, DC, 1996, International Life Sciences Institute Press.)

In correcting the anemia, the vitamin B₁₂ deficiency may remain undetected, leading to the irreversible neuropsychiatric damage that is corrected only with B₁₂ supplementation (see Chapter 41).

Folate-Deficiency Anemia

Etiology

Folate is a naturally occurring B vitamin found in foods in the tetrahydrofolate (THF) form. Folic acid is the synthetic version of the vitamin

found in the fully oxidized monoglutamate form, which may be found in fortified foods and supplements. Folate-deficiency anemia is associated with prolonged inadequate diets, inadequate absorption, inadequate use of folic acid caused by genetic aberrations, and increased requirements resulting from pregnancy or growth. Folate-deficiency anemia can affect pregnant women and occurs in infants born to mothers with folate deficiency. Folate deficiency in early pregnancy can result in an infant born with a neural tube defect (see Chapter 14). Other causes are intestinal disorders resulting in malabsorption (celiac

BOX 31.2 Causes of Folate Deficiency

Inadequate Ingestion	Poor diet (lack of or overcooked fruits and vegetables), vitamin B ₁₂ or vitamin C deficiency, chronic alcoholism
Inadequate Absorption	Celiac disease, tropical sprue, drug interactions, congenital defects
Inadequate Utilization	Antagonists, anticonvulsants, enzyme deficiency, vitamin B ₁₂ and vitamin C deficiency, chronic alcoholism, excess glycine and methionine
Increased Requirement	Extra tissue demand, infancy, increased hematopoiesis, increased metabolic activity, Lesch-Nyhan syndrome, drugs
Increased Excretion	Vitamin B ₁₂ deficiency, liver disease, kidney dialysis, chronic exfoliative dermatitis
Increased Destruction	Dietary oxidants

Modified from Herbert V, Das KC: Folic acid and vitamin B₁₂. In Shils ME et al, editors: *Modern nutrition in health and disease*, ed 8, vol 1, Philadelphia, 1994, Lea & Febiger.

disease, tropical sprue, and inflammatory bowel disease), use of certain drugs (anticonvulsants, barbiturates, cycloserine, sulfasalazine, cholestyramine, and metformin), amino acid excess (glycine and methionine), and alcohol.

Because alcohol interferes with the folate enterohepatic cycle, most people with alcoholism have a negative folate balance or a folate deficiency. Alcoholics constitute the only group that generally has all six causes of folate deficiency simultaneously: inadequate ingestion, absorption, and use, and increased excretion, requirement, and destruction of folate (see Chapter 28). **Box 31.2** describes the causes of folate deficiency.

Folate absorption takes place in the small intestine. Enzyme conjugases (e.g., pteroylpolyglutamate hydrolase, the folate conjugase), found in the brush border of the small intestine, hydrolyze the polyglutamates to monoglutamates and reduce them to dihydrofolate and tetrahydrofolic acid (THFA) in the small intestinal epithelial cells (enterocytes). From the enterocytes these forms are transported to the circulation, where they are bound to protein and transported as methyl THFA into the cells of the body.

In the absence of vitamin B₁₂, 5-methyl THFA, the major circulating and storage form of folic acid, is metabolically inactive. To be activated the 5-methyl group is removed, and THFA is cycled back into the folate pool, where it functions as the main 1-carbon-unit acceptor in mammalian biochemical reactions. THFA may then be converted to the coenzyme form of folate required to convert deoxyuridylylate to thymidylate, which is necessary for DNA synthesis.

MTHFR allele. A genetic defect found in 25% of Hispanics, 10% of Caucasians and Asians, and 1% of African Americans is the methylenetetrahydrofolate reductase (MTHFR) deficiency (National Institutes of Health, Office of Dietary Supplements, 2018) (see Chapter 6). The allele is problematic in pregnancy and may contribute to miscarriages, anencephaly, or neural defects (see Chapter 14). Because MTHFR irreversibly reduces 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, its deficiency may result in developmental delay, motor and gait dysfunction, seizures, neurologic impairment, extremely high levels of homocysteine, clotting disorders, and other conditions.

Methylfolate trap. Vitamin B₁₂ deficiency can result in a folate deficiency by causing folate entrapment in the metabolically useless form of 5-methyl THFA (**Fig. 31.4**). The lack of vitamin B₁₂ to remove the 5-methyl unit means that metabolically inactive methyl THFA is

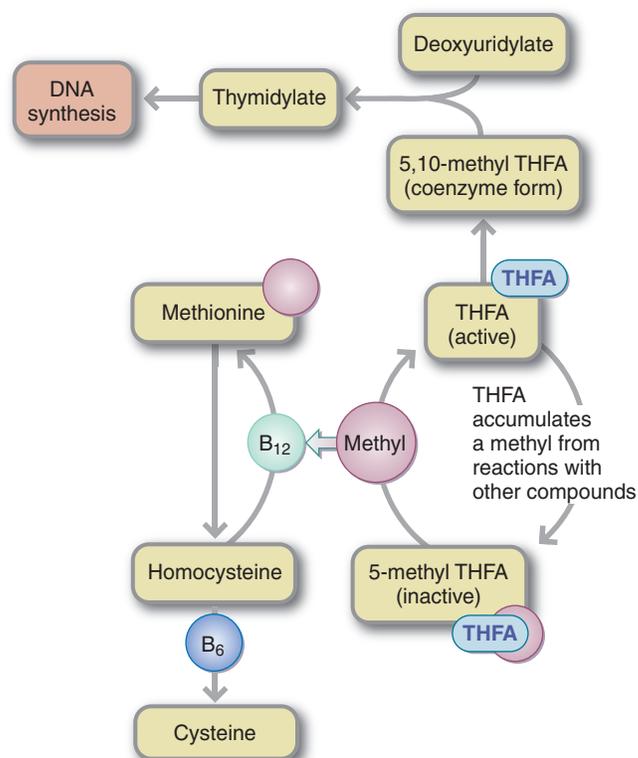

Fig. 31.4 Methylfolate trap. A deficiency of vitamin B₁₂ can result in a deficiency of folic acid because folate is trapped in the form of 5-methyltetrahydrofolate (5-methyl THFA), which cannot be converted to THFA and methyl groups donated by the vitamin B₁₂-dependent pathway. DNA, Deoxyribonucleic acid; THFA, tetrahydrofolic acid.

trapped. It cannot release its 1-carbon methyl group to become THFA, the basic 1-carbon carrier that picks up 1-carbon units from one molecule and delivers them to another. Hence a functional folate deficiency results.

Pathophysiology

Folate deficiency develops in four stages: two that involve depletion, followed by two marked by deficiency (**Fig. 31.5**):

Stage 1: Characterized by early negative folate balance (serum depletion to less than 3 ng/mL)

Stage 2: Characterized by negative folate balance (cell depletion), with a decrease in erythrocyte folate levels to less than 160 ng/mL

Stage 3: Characterized by damaged folate metabolism, with folate-deficient erythropoiesis. This stage is characterized by slowed DNA synthesis, manifested by an abnormal diagnostic deoxyuridine (dU) suppression test correctable in vitro by folates, granulocyte nuclear hypersegmentation, and macroovalocytic red cells.

Stage 4: Characterized by clinical folate-deficiency anemia, with an elevated MCV and anemia.

Because of their interrelated roles in the synthesis of thymidylate in DNA formation, a deficiency of either vitamin B₁₂ or folate results in a megaloblastic anemia. The immature nuclei do not mature properly in the deficient state; and large (macrocytic), immature (megaloblastic) RBCs are the result. The common clinical signs of folate deficiency include fatigue, dyspnea, sore tongue, diarrhea, irritability, forgetfulness, anorexia, glossitis, and weight loss.

Normal body folate stores are depleted within 2 to 4 months on a folate-deficient diet, resulting in a macrocytic, megaloblastic anemia

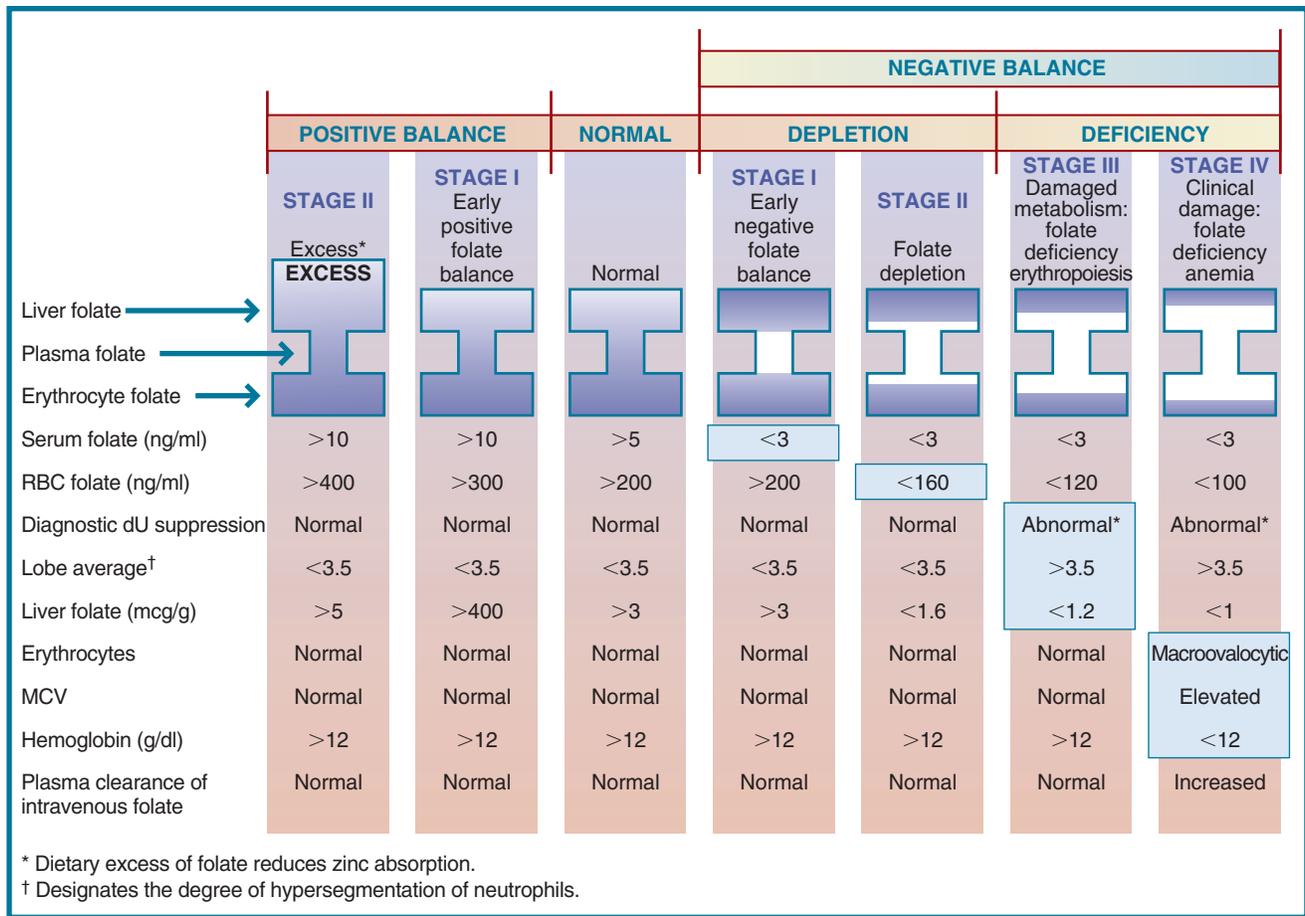

Fig. 31.5 Sequential stages of folate status. *dU*, Deoxyuridine; *MCV*, mean corpuscular volume; *RBC*, red blood cell. (From Herbert V: Folic acid. In Shils ME et al, editors: *Modern nutrition in health and disease*, ed 9, Philadelphia 1998, Lea & Febiger.)

with a decreased number of erythrocytes, leukocytes, and platelets. Folate-deficiency anemia is manifested by very low serum folate (<3 ng/mL) and RBC folate levels of less than 140 to 160 ng/mL. Whereas a low serum folate level merely diagnoses a negative balance at the time the blood is drawn, a red cell folate (RCF) level measures actual body folate stores, and thus is the superior measurement for determining folate nutriture. To differentiate folate deficiency from vitamin B₁₂ deficiency, levels of serum folate, RCF, serum vitamin B₁₂, and vitamin B₁₂ bound to transcobalamin II (TCII) can be measured simultaneously using a radioassay kit. Also diagnostic for folate deficiency is an elevated level of formiminoglutamic acid in the urine, as well as the dU suppression test in bone marrow cells or peripheral blood lymphocytes (see Chapter 5 and Appendix 12).

Medical Management

Before treatment is initiated, it is important to diagnose the cause of the megaloblastosis correctly. Administration of folate corrects megaloblastosis from either folate or vitamin B₁₂ deficiency, but it can mask the neurologic damage of vitamin B₁₂ deficiency, allowing the nerve damage to progress to the point of irreversibility.

A dosage of 1 mg of folate taken orally every day for 2 to 3 weeks replenishes folate stores. Maintaining repleted stores requires an absolute minimum oral intake of 50 to 100 micrograms of folate from food and or dietary supplements daily. When folate deficiency is complicated by alcoholism, genetic aberrations, or other conditions that suppress hematopoiesis, increase folate requirements, or reduce folate absorption, therapy should remain at 500 to 1000 micrograms daily.

Symptomatic improvement, as evidenced by increased alertness, and appetite, may be apparent within 24 to 48 hours, long before hematologic values revert to normal, a gradual process that takes approximately a month.

Medical Nutrition Therapy

After the anemia is corrected, the patient should be educated to eat multiple servings of folate-rich fresh fruit or dark green vegetables or to drink a glass of vegetable or fruit and vegetable juice daily (see Appendix 31 for a list of folate-containing foods). Fresh, uncooked fruits and vegetables are good sources of folate because folate can easily be destroyed by heat. In 1998 the Food and Drug Administration required that grains be fortified with folic acid. The RDAs for folate are summarized on the inside cover of this text. The RDA for adults is 400 mcg daily. The Dietary Guidelines for Americans recommend that women of childbearing age who may become pregnant and those in their first trimester of pregnancy consume adequate synthetic folic acid (400 mcg/day and 600 mcg/day, respectively) from fortified foods and supplements in addition to consuming a variety of foods containing folate (see Chapter 14 and Appendix 31).

Vitamin B₁₂ Deficiency and Pernicious Anemias

Intrinsic factor (IF) is a glycoprotein secreted by parietal cells of the gastric mucosa in the gastric juice that is necessary for the absorption of dietary vitamin B₁₂. Ingested vitamin B₁₂ is freed from protein by gastric acid and gastric and intestinal enzymes. The free vitamin B₁₂ attaches to salivary R-binder, which has a higher affinity for the

vitamin than does IF. An acid pH (2.3) is needed, such as that found in the healthy stomach.

Etiology

The release of pancreatic trypsin into the proximal small intestine destroys R-binder and releases vitamin B₁₂ from its complex with R-protein. With an alkaline pH (6.8) in the intestine, IF binds the vitamin B₁₂. The vitamin B₁₂-IF complex is then carried to the ileum. In the ileum, with the presence of ionic calcium (Ca²⁺) and a pH (>6), the complex attaches to the surface vitamin B₁₂-IF receptors on the ileal cell brush border. Here, the vitamin B₁₂ is released and attaches to **holotranscobalamin II (holo TCII)**. Holo TCII is vitamin B₁₂ attached to the beta-globulin, the major circulating vitamin B₁₂ delivery protein. Like IF, holo TCII plays an active role in binding and transporting vitamin B₁₂. The TCII-vitamin B₁₂ complex then enters the portal venous blood.

Other binding proteins in the blood include haptocorrin, also known as transcobalamin I (TCI) and transcobalamin III (TCIII). These are alpha-globulins, larger macromolecular-weight glycoproteins that make up the R-binder component of the blood. Unlike IF, the R-proteins are capable of binding not only vitamin B₁₂ but also many of its biologically inactive analogs. Although approximately 75% of the vitamin B₁₂ in human serum is bound to haptocorrin and roughly 25% is bound to TCII, only TCII is important in delivering vitamin B₁₂ to all the cells that need it. After transport through the bloodstream, TCII is recognized by receptors on cell surfaces. Patients with haptocorrin abnormalities have no symptoms of vitamin B₁₂ deficiency. Those lacking TCII rapidly develop megaloblastic anemia. Vitamin B₁₂ is excreted in urine.

Pathophysiology

Pernicious anemia is a megaloblastic, macrocytic anemia caused by a deficiency of vitamin B₁₂, most commonly from a lack of IF. Rarely, vitamin B₁₂ deficiency anemia occurs in strict vegetarians whose diet contains no vitamin B₁₂ except for traces found in plants contaminated by microorganisms capable of synthesizing vitamin B₁₂. Other causes include autoimmune disorders that destroy gastric parietal cells; antibody to IF; bariatric or intestinal surgery; bacterial overgrowth in the small intestine; malabsorption in the small intestine due to celiac disease, Crohn's disease, HIV, tropical sprue, and cancers involving the small intestine; drugs (paraaminosalicylic acid, colchicine, neomycin, metformin, antiretrovirals); and long-term ingestion of alcohol or calcium-chelating agents (Box 31.3).

Aging is associated with B₁₂ deficiency for various reasons as discussed in Chapter 19. Approximately 1% to 2% of the U.S. population over the age of 51 years has clinical B₁₂ deficiency, and it is thought that 10% to 20% have subclinical deficiency (Carmel, 2011). The incidence of B₁₂ deficiency in older individuals may be related to medications commonly used in this population such as H₂ antagonists (see Appendix 13) and metformin used to treat type-2 diabetes (Herbert 2019).

Stages of Deficiency

As a result of normal enterohepatic circulation (i.e., excretion of vitamin B₁₂ and analogs in bile and resorption of vitamin B₁₂ in the ileum), it may take up to a year or two for strict vegetarians who are not receiving vitamin B₁₂ supplementation to develop a vitamin B₁₂ deficiency. Serum B₁₂, homocysteine, and methylmalonic acid levels are not as effective as predictors of B₁₂-responsive neurologic disorders; patients with unexplained leukoencephalopathy should be treated proactively because even long-standing deficits may be reversible (Graber et al, 2010).

Stage 1: Early negative vitamin B₁₂ balance begins when vitamin B₁₂ intake is low or absorption is poor, depleting the primary delivery protein, TCII. A low TCII (<40 pg/mL) may be the earliest detectable

BOX 31.3 Causes of Vitamin B₁₂ Deficiency

Inadequate ingestion	Poor diet resulting from a vegan diet and lack of supplementation, chronic alcoholism, poverty
Inadequate absorption	Gastric disorders, small intestinal disorders, competition for absorption sites, pancreatic disease, HIV, or AIDS, gastritis, gastric surgery
Inadequate use	Vitamin B ₁₂ antagonists, congenital or acquired enzyme deficiency, abnormal binding proteins
Increased requirement	Hyperthyroidism, increased hematopoiesis
Increased excretion	Inadequate vitamin B ₁₂ binding protein, liver disease, renal disease
Increased destruction	Pharmacologic doses of ascorbic acid when it functions as a prooxidant
Medication induced	Drugs that suppress gastric acid and metformin have been associated with B ₁₂ deficiency

AIDS, Acquired immune deficiency syndrome; *HIV*, human immunodeficiency virus.

sign of a vitamin B₁₂ deficiency (Nexo and Hoffmann-Lucke, 2011). This is a vitamin B₁₂ predeficiency stage.

Stage 2: Vitamin B₁₂ depletion shows a low B₁₂ on TCII and a gradual lowering of B₁₂ in haptocorrin (holohap <50 pg/mL), the storage protein.

Stage 3: Damaged metabolism and vitamin B₁₂-deficient erythropoiesis includes an abnormal dU suppression, hypersegmentation, a decreased TIBC and holohap percent saturation, a low RCF level (<140 ng/mL), and subtle neuropsychiatric damage (impaired short-term and recent memory).

Stage 4: Clinical damage occurs, including vitamin B₁₂ deficiency anemia; it includes all preceding parameters, along with macrocytic erythrocytes, elevated MCV, elevated TCII levels, increased homocysteine and methylmalonic acid levels, and myelin damage. Leukoencephalopathy and autonomic dysfunction occur with very low serum B₁₂ levels (<200 pg/mL); psychiatric changes, neuropathy, and dementia also may occur (Graber et al, 2010) (see Fig. 31.3).

Clinical Findings

Pernicious anemia affects not only the blood but also the gastrointestinal tract and the peripheral and central nervous systems. This distinguishes it from folate-deficiency anemia. The overt symptoms, which are caused by inadequate myelination of the nerves, include paresthesia (especially numbness and tingling in the hands and feet), diminution of the senses of vibration and position, poor muscular coordination, poor memory, and hallucinations. If the deficiency is prolonged, the nervous system damage may be irreversible, even with initiation of vitamin B₁₂ treatment.

Helicobacter pylori causes peptic ulcer disease and chronic gastritis (see Chapter 26). Both conditions are associated with hypochlorhydria, reduced production of IF by epithelial cells in the stomach, vitamin B₁₂ malabsorption, and pernicious anemia. There is also a correlation between autoimmune gastritis and pernicious anemia. More than 90% of patients with pernicious anemia have parietal cell antibodies (PCAs), and 50% to 70% have elevated IF antibodies. Serum vitamin B₁₂ levels of the *H. pylori*-infected patients are significantly lower than that of uninfected patients.

A study on *H. pylori* infection and autoimmune type atrophic gastritis examined serum markers for gastric atrophy (pepsinogen I, pepsinogen I/II, and gastrin) and autoimmunity. Positive serum autoimmune markers (IF antibodies and PCA) suggest that *H. pylori* contributes to autoimmune gastritis and pernicious anemia (Veijola et al, 2010).

Vitamin B₁₂ deficiency is an important modifiable risk factor for osteoporosis in men and women. Adults with low vitamin B₁₂ levels have a lower average bone mineral density and greater risk for osteoporosis (Karpouzou et al, 2017).

Reduced vitamin B₁₂ status and elevated homocysteine concentrations are common. These alterations are problematic among vegans (Elmadfa and Singer, 2009). B₁₂-folate-homocysteine interactions aggravate heart disease and may lead to adverse pregnancy outcomes (Ganguly and Alam, 2015; Shahbazian et al, 2016) (see Chapters 14 and 32).

Assessment

Vitamin B₁₂ stores are depleted after several years without vitamin B₁₂ intake. A low holo TCII value (<40 pg/mL) is a sign of early B₁₂ deficiency.

Other laboratory tests that may be helpful in diagnosing a vitamin B₁₂ deficiency and determining its cause include measurements of serum B₁₂, IF antibody (IFAB), PCA, serum homocysteine and serum methylmalonic acid (MMA) levels (see Chapter 5 and Appendix 12). The IFAB and PCA tests can determine whether the deficiency is caused by a lack of IF.

Medical Management

Treatment usually consists of an intramuscular or subcutaneous injection of 100 mcg or more of vitamin B₁₂ once per week. After an initial response is elicited, the frequency of administration is reduced until remission can be maintained indefinitely with monthly injections of 100 mcg. Very large oral doses of vitamin B₁₂ (1000 mcg daily) are also effective, even in the absence of IF, because approximately 1% of vitamin B₁₂ is absorbed by diffusion. Initial doses should be increased when vitamin B₁₂ deficiency is complicated by debilitating illness such as infection, hepatic disease, uremia, coma, severe disorientation, or marked neurologic damage. A response to treatment is evidenced by improved appetite, alertness, and cooperation, followed by improved hematologic results, as manifested by marked reticulocytosis within hours of an injection.

Medical Nutrition Therapy

A high-protein diet (1.5 g/kg of body weight) is desirable for blood cell regeneration. Because green leafy vegetables contain iron and folate, the diet should contain increased amounts of these foods. Meats (especially beef and pork), eggs, milk, and milk products are particularly rich in vitamin B₁₂ (see Appendix 31).

For those individuals prescribed metformin for treatment of diabetes, 10% to 30% have reduced vitamin B₁₂ absorption. Metformin negatively affects the calcium-dependent membrane and the B₁₂-IF complex by decreasing the absorbability by the ileal cell surface receptors. Increased intake of calcium may reverse the vitamin B₁₂ malabsorption. However a recent study found that supplementation with a multivitamin supplement was protective against B₁₂ deficiency.

The Institute of Medicine recommends that people older than age 50 consume vitamin B₁₂ in its crystalline form (i.e., in fortified cereals or supplements) to overcome the effects of atrophic gastritis. The RDAs for B₁₂ are summarized in the front of the book. The RDA for adult men and women is 2.4 mcg daily.

OTHER NUTRITIONAL ANEMIAS

Anemia of Protein-Energy Malnutrition

Protein is essential for the proper production of hemoglobin and RBCs. Because of the reduction in cell mass and thus oxygen

requirements in protein-energy malnutrition (PEM), fewer RBCs are required to oxygenate the tissue. Because blood volume remains the same, this reduced number of RBCs with a low hemoglobin level (hypochromic, normocytic anemia), which can mimic an iron deficiency anemia, is actually a physiologic (nonharmful) rather than harmful anemia. In acute PEM, the loss of active tissue mass may be greater than the reduction in the number of RBCs, leading to **polycythemia** (an increase in RBCs where they make up a larger proportion of the blood volume). The body responds to this RBC production, which is not a reflection of protein and amino acid deficiency but of an oversupply of RBCs. Iron released from normal RBC destruction is not reused in RBC production but is stored so that iron stores are often adequate. Iron deficiency anemia can reappear with rehabilitation when RBC mass expands rapidly.

The anemia of PEM may be complicated by deficiencies of iron and other nutrients and by associated infections, parasitic infestation, and malabsorption. A diet lacking in protein is usually deficient in iron, folic acid, and, less frequently, vitamin B₁₂. The nutrition counselor plays an important role in assessing recent and typical dietary intake of these nutrients.

Copper Deficiency Anemia

Copper and other heavy metals are essential for the proper formation of hemoglobin. **Ceruloplasmin**, a copper-containing protein, is required for normal mobilization of iron from its storage sites to the plasma. In a copper-deficient state, iron cannot be released; this leads to low serum iron and hemoglobin levels, even in the presence of normal iron stores. Other consequences of copper deficiency suggest that copper proteins are needed for use of iron by the developing erythrocyte and for optimal functions of the erythrocyte membrane. The amounts of copper needed for normal hemoglobin synthesis are so minute that they are usually amply supplied by an adequate diet; however, copper deficiency may occur in infants who are fed cow's milk or a copper-deficient infant formula. It also may be seen in children or adults who have a malabsorption syndrome or who are receiving long-term total parenteral nutrition that does not supply copper.

Sideroblastic (B₆-Responsive) Anemia

Sideroblastic (pyridoxine-responsive) anemia is characterized by a derangement in the final pathway of heme synthesis, leading to a buildup of immature RBCs. It has four primary characteristics: (1) microcytic and hypochromic RBCs; (2) high serum and tissue iron levels (causing increased transferrin saturation); (3) the presence of an inherited defect in the formation of δ -aminolevulinic acid synthetase, an enzyme involved in heme synthesis (pyridoxal-5-phosphate is necessary in this reaction); and (4) a buildup of iron-containing immature RBCs (sideroblasts, for which the anemia is named). The iron that cannot be used for heme synthesis is stored in the mitochondria of immature RBCs. These iron-laden mitochondria do not function normally, and the development and production of RBCs become ineffective. The symptoms are those of anemia and iron overload. Even though the anemia responds to the administration of pharmacologic doses of pyridoxine and thus is referred to as pyridoxine-responsive anemia, the neurologic and cutaneous manifestations of vitamin B₆ deficiency are not observed. This distinguishes it from anemia caused by a dietary vitamin B₆ deficiency.

Treatment consists of a therapeutic trial dose of 50 to 200 mg daily of pyridoxine or pyridoxal phosphate (PLP or pyridoxal-5-phosphate) which is 30 to 150 times the RDA. If the anemia responds to one or the other, pyridoxine therapy is continued for life. However, if the anemia is only partially corrected, a normal hematocrit value is never regained. Patients respond to this treatment to varying degrees, and some may only achieve near-normal hemoglobin levels.

Acquired sideroblastic anemias such as those attributable to drug therapy (isoniazid, chloramphenicol), copper deficiency, hypothermia, and alcoholism are not responsive to B₆ administration.

Vitamin E–Responsive Hemolytic Anemia

Hemolytic anemia occurs when defects in RBC membranes lead to oxidative damage and eventually to cell lysis. This anemia is caused by shortened survival of mature RBCs. Vitamin E, an antioxidant, is involved in protecting the membrane against oxidative damage, and one of the few signs noted in vitamin E deficiency is early hemolysis of RBCs.

NONNUTRITIONAL ANEMIAS

Anemia of Pregnancy

A physiologic anemia is the anemia of pregnancy, which is related to increased blood volume and usually resolves with the end of the pregnancy. However, demands for iron during pregnancy also are increased so that inadequate iron intake may also play a role in whether it develops (see Chapter 14 for further discussion).

Anemia of Chronic Disease

Anemia of chronic disease occurs from inflammation, infection, autoimmune disorders, chronic kidney and liver disease and malignancy because there is decreased RBC production, usually as a result of disordered iron metabolism. Ferritin levels are normal or increased, but serum iron levels and TIBC are low (see Chapter 5). It is important that this form of anemia, which is mild and normocytic, not be mistaken for iron deficiency anemia; iron supplements should not be given. Standard therapy involves treating the underlying disorder, which usually improves or corrects this anemia (Nemeth and Ganz, 2014). Erythrocyte transfusion and erythropoiesis-stimulating agents (ESAs) may be required in rare but severe cases.

Sickle Cell Disease

Pathophysiology

Sickle cell disease (SCD) describes a group of inherited blood disorders of RBCs. It is typically associated with African ancestry but affects millions of people worldwide including Central and South American, Mediterranean, and South Asian populations (Centers for Disease Control and Prevention [CDC], 2018). Those affected inherit two abnormal hemoglobin genes called hemoglobin S, one from each parent. This results in impaired hemoglobin synthesis, which produces sickle-shaped RBCs that get caught in capillaries and do not carry oxygen well (Fig. 31.6). The sickle-shaped RBCs die earlier than typical RBCs, usually in 10 to 20 days. The bone marrow cannot make new cells fast enough to replace them, which can result in anemia and enlargement of the spleen. The disease is usually diagnosed at birth and affects 100,000 in the United States, although 1 to 3 million Americans have the sickle cell trait, characterized by having only one copy of the sickle cell gene. (Centers for Disease Control and Prevention [CDC], 2018).

In addition to anemia, SCD is characterized by episodes of pain resulting from the occlusion of small blood vessels by the abnormally shaped erythrocytes. The occlusions frequently occur in the abdomen, causing acute, severe abdominal pain. The hemolytic anemia and vasoocclusive disease can result in impaired liver function, jaundice, gallstones, and deteriorating renal function. The constant hemolysis of erythrocytes increases iron stores in the liver; however, iron deficiency anemia and SCD can coexist. Iron overload is less common and is usually a problem only in those who have received multiple blood transfusions.

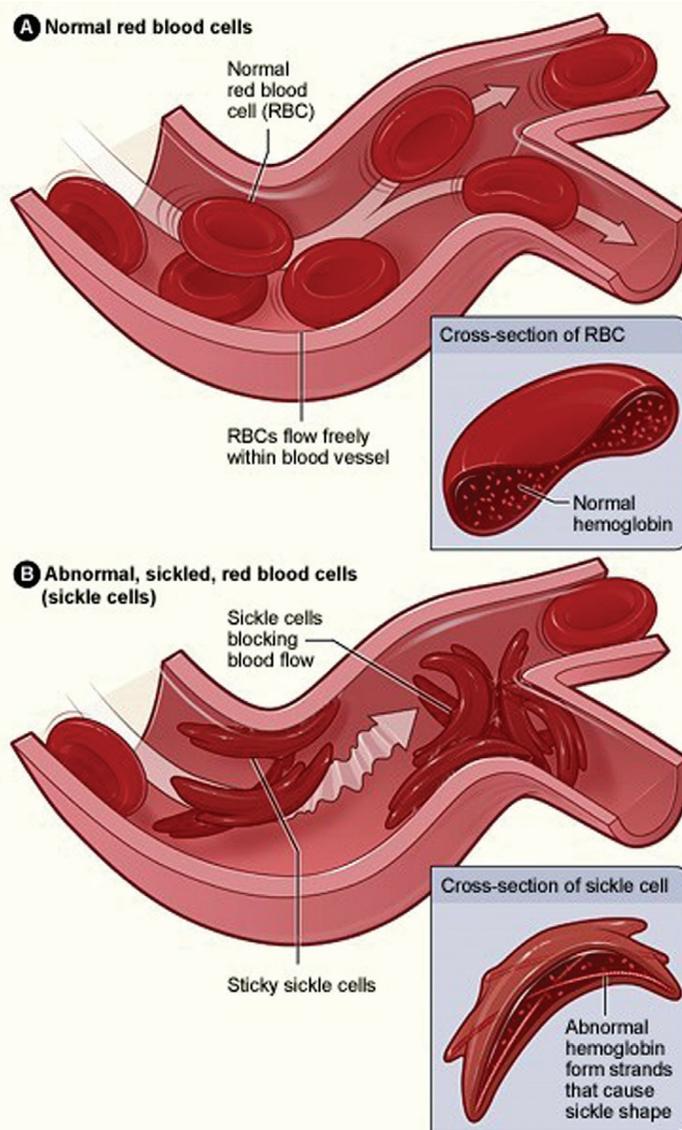

Fig. 31.6 **A**, Normal red blood cells and **B**, Abnormal, sickled red blood cells. (From National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI): *Sickle cell disease* (website). <https://www.nhlbi.nih.gov/health-topics/sickle-cell-disease>, 2018.)

Typically serum homocysteine levels are elevated, which may be due to low concentrations of vitamin B₆. Children with SCD were found to have these lower vitamin B₆ levels despite B₆ intakes comparable to those of unaffected children.

Medical Management

A new set of guidelines for managing SCD recommends using monthly blood transfusions and the drug hydroxyurea (Yawn et al, 2014). Consistent blood transfusions stop the body from producing sickle cells and attempts to normalize RBC count. Hydroxyurea increases the production of healthy fetal hemoglobin, reducing hospitalizations. Because hydroxyurea also lowers the number of white blood cells, patients must be monitored regularly with blood tests.

Other treatment for SCD focuses on relieving pain during a crisis, keeping the body oxygenated (using oxygen therapy if needed), and possibly administering an exchange transfusion. It is important that SCD not be mistaken for iron deficiency anemia, which can be treated

with iron supplements, because iron stores in the patient with SCD secondary to transfusions are frequently excessive.

Zinc can increase the oxygen affinity of normal and sickle-shaped erythrocytes. Thus zinc supplements may be beneficial in managing SCD, especially because decreased plasma zinc is common in children with the SS genotype SCD and is associated with decreased linear and skeletal growth, muscle mass, and sexual maturation. Zinc supplementation also may prevent the deficit in growth that appears in these children (Hyacinth et al, 2010) Because zinc competes with copper for binding sites on proteins, the use of high doses of zinc may cause copper deficiency, so supplementation with at least the RDA of copper is recommended.

Medical Nutrition Therapy

Children with SCD and their families should receive instruction about how they can develop a well-balanced food plan providing enough calories and protein for growth and development. Their dietary intake may be low because of the abdominal pain characteristic of the disease. They also have increased metabolic rates, leading to a need for a higher caloric intake. This hypermetabolism probably is due to a constant inflammation and oxidative stress (Hyacinth et al, 2010; Yawn et al, 2014). Therefore their diets must be high enough in calories to meet these needs and must provide foods high in folate and the trace minerals zinc and copper (see Appendix 47 for sources of zinc).

In addition, these children may be low in vitamins A, C, D, and E; folate; calcium; and fiber. The diet should be high in folate (400 to 600 mcg daily) because the increased production of erythrocytes needed to replace the cells being continuously destroyed also increases folate requirements (see Appendix 31).

When assessing the nutrition status of patients with SCD, clinicians must pay attention to the questions related to the use of vitamin and mineral supplements, the consumption of alcohol (which increases iron absorption), and sources of protein (animal sources being high in zinc and iron) in the diet. A multivitamin and mineral supplement containing 50% to 150% of the RDA for folate, zinc, and copper (not iron) is recommended.

Dietary fluid and sodium intake influence the risk for vasoocclusive events in SCD; increasing fluid intake and limiting high-sodium foods should be discussed (Fowler et al, 2010) (see Chapter 32). Intake of 2 to 3 quarts of water daily is recommended. Finally, it is important to remember that patients with SCD may require higher than RDA amounts of protein.

If it is necessary for the diet to be low in absorbable iron, the diet should emphasize vegetable proteins. Iron-rich foods, such as liver, iron-fortified formula, iron-fortified cereals, and iron-fortified energy bars and iron-fortified sport drinks, should be excluded. Substances such as alcohol and vitamin C supplements, both of which enhance iron absorption, should be avoided. Rarely, iron deficiency may be present in some patients with SCD; iron deficiency should be confirmed and the diet adjusted appropriately.

Hypochromic Microcytic Transient Anemia (Sports Anemia)

Increased RBC destruction, along with decreased hemoglobin, serum iron, and ferritin concentrations, may occur at the initiation and early stages of a vigorous training program. **Sports anemia** is associated with a reduction in hemoglobin in the early stages of aerobic training due to hemodilution. The adaptations are considered advantageous and do not impair physical performance (see Chapter 22 for further discussion).

Athletes who have hemoglobin concentrations below those needed for optimal oxygen delivery may benefit from consuming nutrient and iron-rich foods; ensuring that their diets contain adequate protein; and

avoiding tea, coffee, antacids, H₂-blockers, and tetracycline, all of which inhibit iron absorption. No athlete should take iron supplements unless true iron deficiency is diagnosed based on a complete blood cell count with differential, serum ferritin level, serum iron level, TIBC, and percent saturation of iron-binding capacity. Athletes who are female, vegetarian, involved in endurance sports, or entering a growth spurt are at risk for iron deficiency anemia and therefore should undergo periodic monitoring (see Chapter 22).

Thalassemias

Thalassemias (alpha and beta) are inherited anemias characterized by microcytic, hypochromic, and short-lived RBCs resulting from defective hemoglobin synthesis, which primarily affect persons from the Mediterranean, Southern Asia, Africa, and the Middle East (National Heart, Lung, and Blood Institute, 2014). Severity of the disorder ranges from asymptomatic or mild anemia to more severe symptoms requiring routine blood transfusions. The ineffective erythropoiesis leads to an increase in plasma volume, progressive splenomegaly, and bone marrow expansion with the result of facial deformities, osteomalacia, and bone changes. Ultimately there is increased iron absorption and progressive iron deposition in tissues, resulting in oxidative damage. The accumulation of iron causes dysfunction of the heart, liver, and endocrine glands. Because patients with the more severe form require transfusions to stay alive, they also must have regular chelation therapy to prevent the damaging buildup of iron that can occur. Impaired growth in children accompanying thalassemia major can be partially corrected by increasing caloric intake.

Medical Nutrition Therapy

The diet should emphasize foods high in folate, vitamins A and C, and trace minerals, including zinc, copper, and selenium (Cunningham, 2016). Additionally, adequate intake of calcium and vitamin D is needed to support bone health. Patients not receiving blood transfusions should consume a moderately low-iron diet that limits iron-fortified foods and high red meat intakes. Multivitamin and mineral supplements that contain amounts of iron and vitamin C above the RDA should be also avoided. Patients receiving transfusions with chelation therapy do not need to follow a low-iron diet.

CLINICAL CASE STUDY

Marisa, a 27-year-old Hispanic female, reports increased symptoms of restless legs syndrome, fatigue, and heavy menses for the past year. A physical examination reveals inflammation and tenderness around her knee and ankle joints.

Her typical daily intake includes:

B: Coffee with milk, eggs and a white flour tortilla

L: Vegetable soup with chicken and water

S: sweet roll and another cup of coffee with milk.

D: Cheese enchiladas with red sauce and sour cream, pinto beans and hot tea.

Medications: None

Height: 5'5"

Weight: 164 lbs lb

Laboratory Values:

	Client	Normal Range	
WBC	8.3	3.8-10.5	K/uL
RBC	4.86	3.8-5.20	M/uL
HGB	10.8 L	12.0-16.0	g/dL
HCT	32.7 L	34.5-45.0	%
MCV	74.1 L	80.0-100.0	fl
MCH	24.3 L	27.0-34.0	pg

CLINICAL CASE STUDY—cont'd

	Client	Normal Range	
MCHC	30.4 L	32.0-36.0	gm/dL
IRON	28 L	40-160	ug/dL
UIBC	429 H	110-370	ug/dL
TIBC	508 H	220-430	ug/dL
% Saturation, Iron	12 L	14-50	%
Transferrin	435 H	200-400	mg/dL
Ferritin	12 L	15-150	ng/mL
C-Reactive Protein	0.96 H	0.00-0.40	mg/dL
Vitamin D	14.6 L	30.0-100.0	ng/mL

Nutrition Diagnostic Statements

- Increased nutrient needs (iron) related to heavy menses and suboptimal intake of dietary iron as evidenced by multiple low iron status labs including hematocrit (HCT), hemoglobin (HGB), and ferritin.
- Altered nutrition-related laboratory value related to predicted pro-inflammatory diet pattern as evidenced by low intake of omega-3 fatty acids and bioactive compounds, elevated C-reactive protein (CRP), and painful joints.

Nutrition Care Questions

1. Evaluate her laboratory test results. What type of anemia does she likely have? Are there any other concerning labs?
2. Assess Marisa's diet. Does it appear she is taking in adequate iron? What are her dietary inhibitors?
3. Considering her Mexican heritage, what nutrition recommendations would you have for Marisa?
4. What vitamin/mineral supplements, if any, should be part of her treatment plan?

Cardiovascular disease (CVD) is a group of interrelated diseases that includes atherosclerosis, hypertension, ischemic heart disease, peripheral vascular disease, and heart failure (HF). These diseases are interrelated and often coexist. An estimated 84,000,000 adult Americans (one in three) have one or more types of CVD (Box 32.1).

CVD remains the number one killer of men and women in the United States; one of every three deaths is attributed to CVD. CVD is the cause of more deaths than cancer, chronic lower respiratory diseases, and accidents combined. Every 25 seconds, an American suffers a coronary event and about every minute someone will die of one. On average, someone in the United States suffers a stroke every 40 seconds (American Heart Association [AHA], 2015). The lifetime risk for CVD in American men is two in three and for women is one in two (AHA, 2015). Worldwide, 18 million deaths per year are attributed to CVD (Yusuf et al, 2014).

Atherosclerotic cardiovascular disease (ASCVD) involves the narrowing of small blood vessels that oxygenate the heart muscle by the build-up of **plaque** (the lesion in the blood vessels). The plaque, known as atherosclerosis, can rupture, causing a blood clot to form that blocks the artery or travels somewhere else in the body, causing blockage at that site. The result can be a **myocardial infarction (MI)**,

which is also called a heart attack or in the brain it is called an ischemic **stroke**, which is also known as a **cerebrovascular accident (CVA)**. Heart disease and stroke cause the most deaths in both sexes of all ethnic groups, increasing with age. Until the age of 65 years, black men have the highest rates of ASCVD deaths; thereafter, white men have the highest rates. Black women have higher rates than white women at all ages. Among whites older than age 18, 12.1% have CVD. In the same age group, 10.2% of blacks have heart disease, and in Hispanics the incidence is 8.1%. The incidence in adult Native Americans is 12.1%, in Native Hawaiians or other Pacific Islanders it is 19.7%, and in Asians it is 5.2% (AHA, 2015). This chapter discusses the incidence, pathophysiologic findings, prevention, and treatment of each of the CVDs.

ATHEROSCLEROSIS AND CORONARY HEART DISEASE

Anatomy and Physiology

Blood vessels are composed of three layers. The outer layer is mainly connective tissue that gives structure to the vessels. The middle layer is smooth muscle that contracts and dilates to control blood flow and

BOX 32.1 Types and Incidence of Cardiovascular Disease in the United States

Hypertension: 75,000,000
 Coronary heart disease: 25,155,000
 Myocardial infarction: 790,000
 Heart failure: 6,500,000
 Stroke: 7,950,000

Because of comorbidities, it is not possible to add these numbers together to reach a total (American Heart Association [AHA], 2010; <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5408160/>; https://www.cdc.gov/heartdisease/heart_attack.htm).

blood pressure. The inner lining is a thin layer of **endothelial cells** (the endothelium) that in a healthy state is smooth and responsive. The endothelium functions as a protective barrier between tissues and circulating blood. It facilitates bidirectional passage of macromolecules and blood gases to and from tissues and blood. Endothelial cells sense changes in blood flow and respond with the release of bioactive substances that maintain vascular homeostasis. One such substance is

nitric oxide (NO). NO is a soluble gas continually synthesized from the amino acid L-arginine in endothelial cells. NO has a wide range of biologic properties that maintain vascular homeostasis. It appears to be involved in protection from injurious substances and plays a key role in vasodilation (Tousoulis et al, 2012). Decreased NO is a factor in the endothelial cell dysfunction that disrupts vascular balance and can result in vasoconstriction, platelet activation, leukocyte adherence, and vascular inflammation.

Pathophysiology

ASCVD involves the accumulation of plaque within the walls of the arteries. It starts with injury to the endothelial cells with an associated inflammatory response involving phagocytes and monocytes. Once in the tissue, monocytes evolve into a specialized type of macrophage called a **foam cell** that ingests oxidized cholesterol and becomes **fatty streaks** in these vessels. Intracellular microcalcification occurs, forming deposits within the vascular smooth muscle cells of the surrounding muscular layer (Fig. 32.1).

A protective fibrin layer or **atheroma** forms between the fatty deposits and the artery lining. Atheromas produce enzymes that cause the artery to enlarge over time, thus compensating for the narrowing

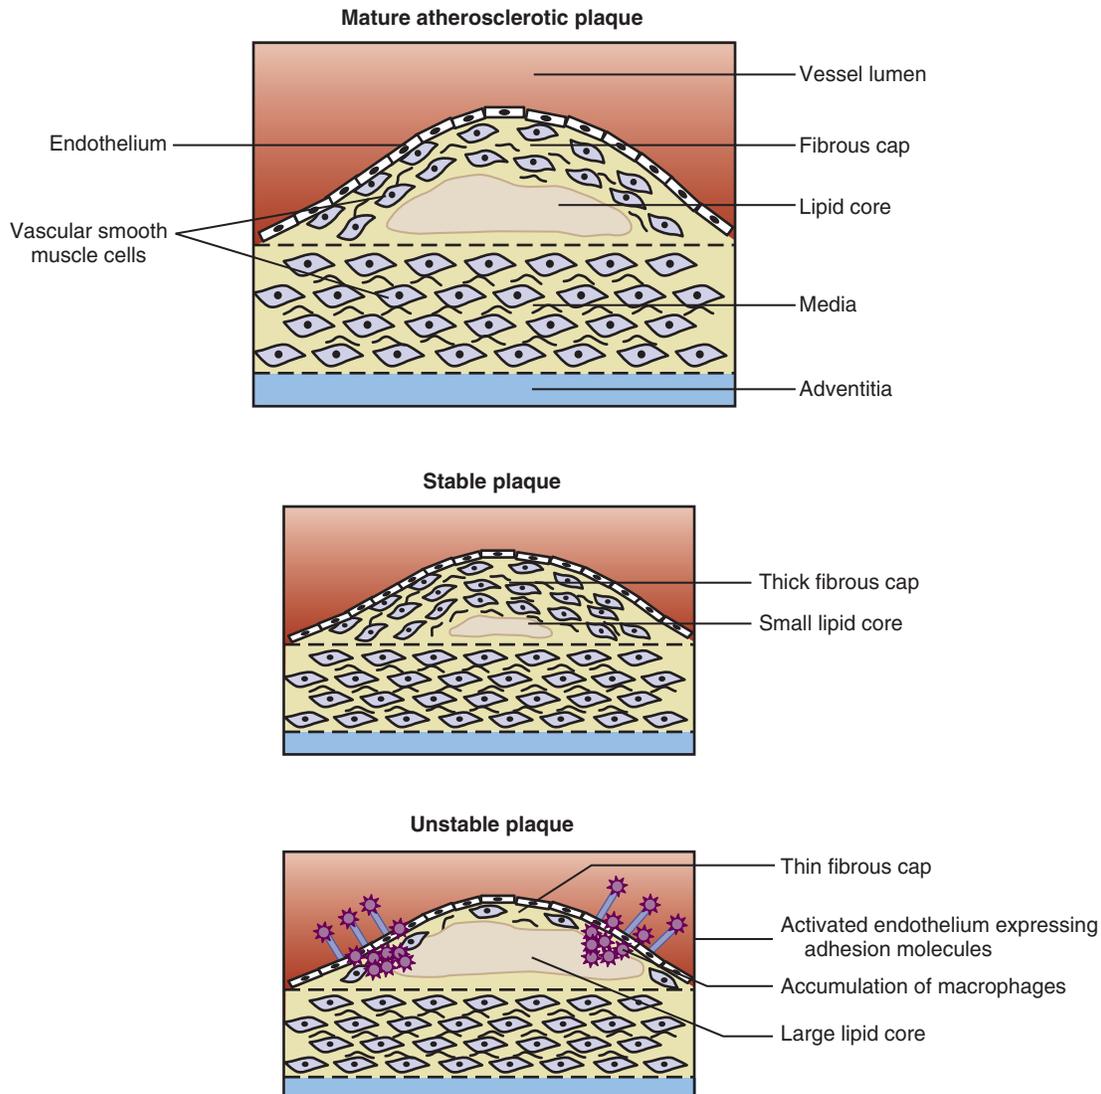

Fig. 32.1 The structure of mature, stable, and unstable plaque. (From Rudd JHF et al: Imaging of atherosclerosis—can we predict plaque rupture? *Trends Cardiovasc Med* 15:17, 2005.)

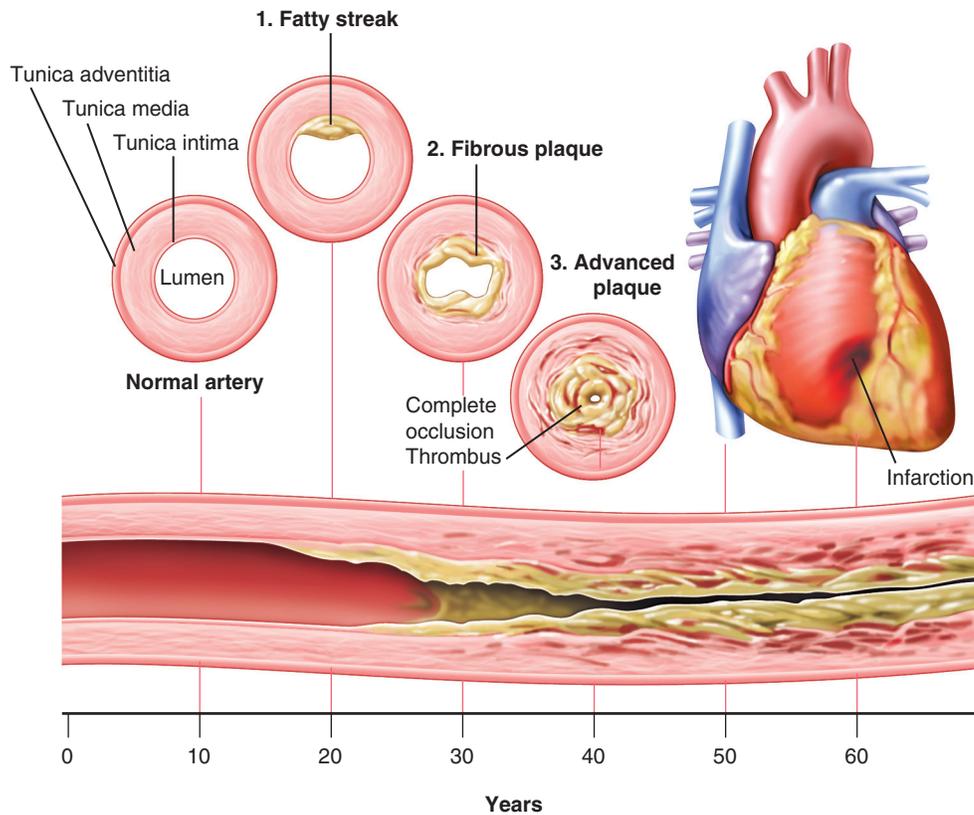

Fig. 32.2 Natural progression of atherosclerosis. (From Harkreader H: *Fundamentals of nursing: caring and clinical judgment*, Philadelphia, 2007, Saunders.)

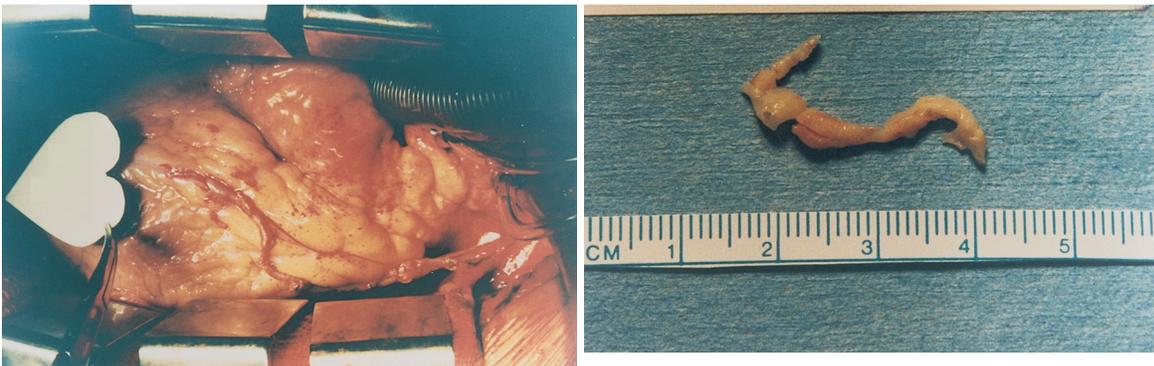

Fig. 32.3 Plaque that can be surgically removed from the coronary artery. (Photographs courtesy Ronald D. Gregory and John Riley, MD.)

caused by the plaque. This “remodeling” of the shape and size of the blood vessel may result in an aneurysm. Atheromas can rupture or break off, forming a **thrombus** (blood clot), where they attract blood platelets and activate the clotting system in the body. This response can result in a blockage and restricted blood flow.

Only high-risk or vulnerable plaque forms thrombi. Vulnerable plaques are lesions with a thin fibrous cap, few smooth muscle cells, many macrophages (inflammatory cells), and a large lipid core (Fig. 32.2). Arterial changes begin in infancy and progress asymptotically throughout adulthood (Fig. 32.3).

The clinical outcome of impaired arterial function arising from atherosclerosis depends on the location of the impairment. In the

coronary arteries atherosclerosis can cause **angina** (chest pain), MI, and sudden death; in the cerebral arteries it causes strokes and **transient ischemic attacks (TIAs)**; and in the peripheral circulation it causes intermittent claudication, limb **ischemia** (inadequate blood supply), and gangrene (Fig. 32.4). Thus atherosclerosis is the underlying cause of many forms of CVD.

Dyslipidemia refers to a blood lipid profile that increases the risk of developing atherosclerosis. Three important biochemical measurements in ASCVD include lipoproteins, total cholesterol, and triglycerides. Cholesterol is delivered into cell walls by **low-density lipoprotein (LDL)**, especially smaller particles. To attract and stimulate the macrophages, the cholesterol must be released from the LDL

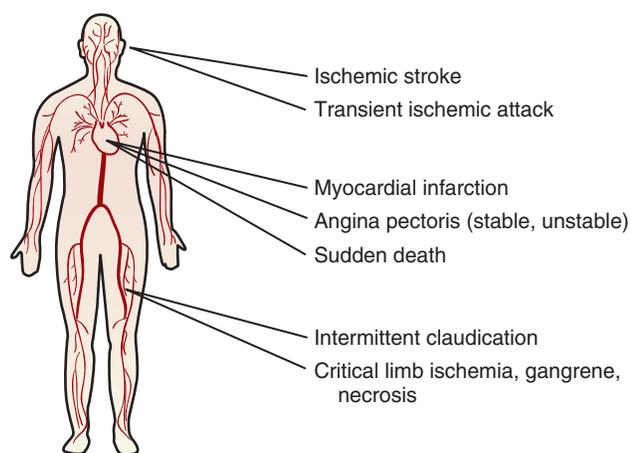

Fig. 32.4 Major clinical manifestations of atherothrombotic disease. (From Viles-Gonzalez JF, et al: Atherothrombosis: a widespread disease with unpredictable and life-threatening consequences, *Eur Heart J* 25:1197, 2004.)

particles and oxidized, a key step in the ongoing inflammatory process. Additionally, macrophages must move excess cholesterol quickly into **high-density lipoprotein (HDL)** particles to avoid becoming foam cells and dying. The typical dyslipidemic condition is one in which LDL levels are elevated (hyperlipidemia) and HDL levels are low.

Lipoproteins

Lipids are not water soluble, so they are carried in the blood bound to protein. These complex particles, called **lipoproteins** that are manufactured in the liver, vary in composition, size, and density. Lipoproteins measured in clinical practice—chylomicrons, **very-low-density lipoprotein (VLDL)**, **low-density lipoproteins (LDL)**, and **high-density lipoproteins (HDL)**—consist of varying amounts of triglyceride, cholesterol, phospholipid, and protein. Each class of lipoprotein actually represents a continuum of particles. The ratio of protein to fat determines the density; thus particles with higher levels of protein are the most dense (e.g., HDLs have more protein than LDLs). The physiologic role of lipoprotein includes transporting lipid to cells for energy, storage, or use as substrate for synthesis of other compounds such as prostaglandins, thromboxanes, and leukotrienes.

The largest particles, **chylomicrons**, transport dietary fat and cholesterol from the small intestine to the liver and periphery. Once in the bloodstream, the triglycerides within the chylomicrons are hydrolyzed by lipoprotein lipase (LPL), located on the endothelial cell surface in muscle and adipose tissue. **Apolipoproteins** carry lipids in the blood and also control the metabolism of the lipoprotein molecule. Apo C-II, one of the apolipoproteins, is a cofactor for LPL. When approximately 90% of the triglyceride is hydrolyzed, the particle is released back into the blood as a remnant. The liver metabolizes these chylomicron remnants, but some deliver cholesterol to the arterial wall and thus are considered atherogenic. Consumption of high-fat meals produces more chylomicrons and remnants. Plasma studies are done when fasting; chylomicrons are normally absent.

VLDL particles are synthesized in the liver to transport endogenous triglyceride and cholesterol. Triglyceride accounts for 60% of the VLDL particle. The large, buoyant VLDL particle is believed to be nonatherogenic. Vegetarian and low-fat diets increase the formation of large VLDL particles. Smaller VLDL particles (i.e., remnants) are formed from triglyceride hydrolysis by LPL. Normally these remnants, called **intermediate-density lipoproteins (IDLs)**, are atherogenic and

are taken up by receptors on the liver or converted to LDLs. Some of the smaller LDL particles stay in the blood, are oxidized, and are then taken into the arterial wall. Clinically, a total triglyceride level is a measurement of the triglycerides carried on the VLDL and the IDL remnants.

LDL is the primary cholesterol carrier in blood, formed by the breakdown of VLDL. High LDL cholesterol is associated specifically with atherosclerosis (Stone et al, 2014). A recent change in recommendations from American College of Cardiology (ACC)/American Heart Association (AHA) was to drop the actual serum LDL ASCVD prevention target. LDL levels are used for dosing medication but are otherwise only considered part of a bigger picture of risk and should not be assessed in isolation. After LDL formation, 60% is taken up by LDL receptors on the liver, adrenals, and other tissues. The remainder is metabolized via nonreceptor pathways. The number and activity of these LDL receptors are major determinants of the LDL level in the blood. Apolipoprotein B is the structural protein for all of the atherogenic lipoproteins (VLDL, IDL, LDL) and modulates the transport of lipids from the gut and liver to the tissues. The two forms, apo B and apoB-100, are synthesized in the liver. ApoB-100 constitutes 95% of the apolipoproteins in LDL. ApoB-48 is synthesized in the intestines and is the structural component of chylomicrons.

HDL particles contain more protein than any of the other lipoproteins, which accounts for their metabolic role as a reservoir of the apolipoproteins that direct lipid metabolism. Apo A-I, the main apolipoprotein in HDL, is an antiinflammatory, antioxidant protein that also helps to remove cholesterol from the arterial wall to the liver for excretion or repackaging. This process prevents the build-up and oxidation of cholesterol in the arteries. Evaluation of apo A-I or the ratio of apo B to apo A-I has been proposed to assess risk and determine treatment (Navab et al, 2011). The lower the ratio, the lower the ASCVD risk. Both apo C and apo E on HDL are transferred to chylomicrons. Apo E helps receptors metabolize chylomicron remnants and also inhibits appetite. Therefore high HDL levels are associated with low levels of chylomicrons; VLDL remnants; and small, dense LDLs. Epidemiologic studies have shown an inverse correlation between HDL levels and risk of cardiovascular events. And generally a high HDL level is considered heart-protective. However there is recent evidence that very high levels of HDL cholesterol (greater than 97) are actually a risk factor (Madsen et al, 2017).

Total Cholesterol

A total cholesterol measurement captures cholesterol contained in all lipoprotein fractions: 60% to 70% is carried on LDL, 20% to 30% on HDL, and 10% to 15% on VLDL.

Triglycerides

The triglyceride-rich lipoproteins include chylomicrons, VLDLs, and any remnants or intermediary products formed in metabolism. Of these triglyceride-rich lipoproteins, chylomicrons and VLDL remnants are known to be atherogenic because they activate platelets, the coagulation cascade, and clot formation. All contain the apo B lipoprotein. Fasting triglyceride levels are classified as normal (<150 mg/dL), borderline high (150 to 199 mg/dL), high (200 to 499 mg/dL), and very high (>500 mg/dL) (Stone et al, 2014).

Patients with familial dyslipidemias have high triglyceride levels (**hypertriglyceridemia**). Triglycerides in the very high range place the patient at risk for pancreatitis. Triglyceride measurements are now considered along with glucose intolerance, hypertension, low HDL cholesterol, and high LDL cholesterol as part of the **metabolic syndrome**.

GENETIC HYPERLIPIDEMIAS

The study and identification of the genes responsible for the familial forms of hyperlipidemia have provided insight into the roles of enzymes, apolipoproteins, and receptors on cells involved in lipid metabolism. Several forms of hyperlipidemia have strong genetic components and are described here.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is a genetic disorder characterized by elevated LDL cholesterol and premature CVD, with a prevalence of approximately one in 200 to 500 for heterozygotes in North America and Europe (Brautbar, 2015).

In FH elevated cholesterol is already present at birth and results in early atherosclerotic disease. The optimal age range for screening is between 2 and 10 years. Currently, it is considered unreasonable to start a restricted diet before age 2, and there are no safety data on the use of statins before age 8 to 10 (Nordestgaard et al, 2013). Men with FH seem to develop CVD before women. Hypertension, smoking, diabetes, and high triglycerides and low HDL cholesterol are all well-established additional risk factors in FH.

The Familial Hypercholesterolemia Foundation recently convened a panel of international experts to “assess the utility of genetic testing.” The rationale was (1) facilitation of definitive diagnosis; (2) pathogenic variants indicate higher cardiovascular risk, which indicates the potential need for more aggressive lipid lowering; (3) increase in initiation of and adherence to therapy; and (4) cascade testing of at-risk relatives. Their Expert Consensus Panel recommendations were to make FH genetic testing a standard of care for patients with definite or probable FH, as well as for their at-risk relatives. They recommended testing for the genes encoding the low-density lipoprotein receptor (LDLR), apolipoprotein B, and proprotein convertase subtilisin/kexin 9 (PCSK9) (Sturm et al, 2018). Treatment with statin drugs improves arterial function and structure (Masoura et al, 2011). Ultrasound of the Achilles tendon for **xanthomas** (cholesterol deposits from LDL) correctly identifies the majority of FH patients (Harada, 2017).

Polygenic Familial Hypercholesterolemia

Polygenic FH is the result of multiple gene defects. The *APOE-4* allele is common in this form. The diagnosis is based on two or more family members having LDL cholesterol levels above the 90th percentile without any tendon xanthomas. Usually these patients have lower LDL cholesterol levels than patients with the nonpolygenic form, but they remain at high risk for premature disease. The treatment is lifestyle change in conjunction with cholesterol-lowering drugs.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) is the most prevalent primary dyslipidemia, but its precise definition is controversial. FCHL is characterized by fluctuations in serum lipid concentrations and may present as mixed hyperlipidemia, isolated hypercholesterolemia, hypertriglyceridemia, or as a normal serum lipid profile in combination with abnormally elevated levels of apolipoprotein B. (Bello-Chavolla et al, 2018). Several lipoprotein patterns may be seen in patients with FCHL. These patients can have (1) elevated LDL levels with normal triglyceride levels (type IIa), (2) elevated LDL levels with elevated triglyceride levels (type IIb), or (3) elevated VLDL levels (type IV). Often these patients have the small, dense LDL associated with ASCVD. Consequently all forms of FCHL cause premature disease; approximately 15% of patients who have an MI before the age of 60 have FCHL. The defect in FCHL is hepatic overproduction of apo B-100 (VLDL) or a defect in the gene that produces hepatic lipase, the

liver enzyme involved in triglyceride removal from the bloodstream. Patients with FCHL usually have other risk factors such as obesity, hypertension, diabetes, or metabolic syndrome. If lifestyle measures are ineffective, treatment includes medication. Patients with elevated triglyceride levels also need to avoid alcohol.

Familial Dysbetalipoproteinemia

Familial dysbetalipoproteinemia (type III hyperlipoproteinemia) is relatively uncommon. Catabolism of VLDL and chylomicron remnants is delayed because *APOE-2* replaces *APOE-3* and *APOE-4*. For dysbetalipoproteinemia to be seen, other risk factors such as older age, hypothyroidism, obesity, diabetes, or other dyslipidemias such as FCHL must be present. Total cholesterol levels range from 300 to 600 mg/dL, and triglyceride levels range from 400 to 800 mg/dL. This condition creates increased risk of premature ASCVD and peripheral vascular disease. Diagnosis is based on determining the isoforms of *APOE*. Treatment involves weight reduction, control of hyperglycemia and diabetes, and dietary restriction of saturated fat and cholesterol. If the dietary regimen is not effective, drug therapy is recommended.

Medical Diagnosis

Noninvasive tests such as electrocardiograms, treadmill stress tests, thallium scans, and echocardiography are used initially to establish a cardiovascular diagnosis. A more definitive, invasive test is **angiography (cardiac catheterization)**, in which a dye is injected into the arteries, and radiographic images of the heart are obtained. Most narrowing and blockages from atherosclerosis are readily apparent on angiograms; however, neither smaller lesions nor lesions that have undergone remodeling are visible.

Magnetic resonance imaging (MRI) scans show the smaller lesions and can be used to follow atherosclerosis progression or regression after treatments. To predict MI or stroke, measuring the intimal thickness of the carotid artery may be used. Intracoronary thermography helps to determine the presence of vulnerable plaque.

Finally, the calcium in atherosclerotic lesions can be assessed. Electron beam computed tomography (ECT) measures calcium in the coronary arteries; persons with a positive scan are far more likely to have a future coronary event than those with a negative scan.

Approximately two thirds of cases of acute coronary syndromes (unstable angina and acute MI) happen in arteries that are minimally or mildly obstructed. This illustrates the role of thrombosis in clinical events. In the ischemia of an infarction, the myocardium or other tissue is deprived of oxygen and nourishment. Whether the heart is able to continue beating depends on the extent of the musculature involved, the presence of collateral circulation, and the oxygen requirement.

Prevention and Management of Risk Factors

The identification of risk factors for ASCVD and stroke has been a landmark achievement. The primary prevention of these disorders involves the assessment and management of the risk factors in the asymptomatic person. Persons with multiple risk factors are the target population, especially those with modifiable factors (Box 32.2).

Risk factor reduction has been shown to reduce CVD in persons of all ages. Many coronary events could be prevented with adoption of a healthy lifestyle (eating a heart-healthy diet, exercising regularly, managing weight, and not using tobacco) and adherence to lipid and hypertension drug therapy (Stone et al, 2014). The Framingham Heart Study, conducted over several decades, has provided a plethora of useful information to researchers (see *Focus On*: Framingham Heart Study).

BOX 32.2 Cardiovascular Disease Risk Factors**Major Risk Factors**

Hypertension
 Age (older than 45 years for men, 55 years for women)
 Diabetes mellitus
 Estimated glomerular filtration rate <60 mL/min
 Microalbuminuria
 Family history of premature cardiovascular disease (men <55 years of age, or women <65 years of age)

Modifiable Cardiovascular Risk Factors

Lipoprotein profile
 Low-density lipoprotein (LDL) cholesterol, elevated
 Total triglycerides, elevated
 Elevated trimethylamine N-oxide (TMAO)
 High-density lipoprotein (HDL) cholesterol, low
 Inflammatory markers

Fibrinogen
 C-reactive protein

Lifestyle Risk Factors

Tobacco use, particularly cigarettes
 Physical inactivity
 Poor diet
 Stress
 Insufficient sleep
 Excessive alcohol consumption

Related Conditions

Hypertension
 Obesity (body mass index >30)
 Metabolic syndrome (including reduced HDL, elevated triglycerides, abdominal obesity)

Modified from National Institutes of Health, National Heart, Lung, and Blood Institute, National High Blood Pressure Education Program: The seventh report of the Joint National Committee on prevention, detection, evaluation, and treatment of high blood pressure, NIH Publication No. 04-5230, August 2004.

FOCUS ON**Framingham Heart Study**

The Framingham Heart Study (FHS) has conducted seminal research defining cardiovascular disease (CVD) risk factors and fundamentally shaping public health guidelines for CVD prevention over the past five decades. The success of the original cohort, initiated in 1948, paved the way for further epidemiologic research in preventive cardiology.

Since 1948 various leading investigators (Dr. Joseph Mountain, Dr. Thomas Dawber, Dr. William Kannel, and Dr. William Castelli) have been studying the population of Framingham, Massachusetts, to determine the prevalence and incidence of CVD and factors related to its development. This is the largest epidemiologic study of CVD in the world. Initial study participants ($n = 5209$) were healthy adults between 30 and 62 years of age. Because of the predominance of white individuals of European descent in the three original generations of FHS participants, the FHS enrolled the OMNI1 and OMNI2 cohorts in 1994 and 2003, respectively, aimed to reflect the current greater racial and ethnic diversity of the town of Framingham.

The study continues today, looking at the children and grandchildren of the original cohort. Through this cohort study, the concept of risk factors and thus prevention was born. Modifiable risk factors not only predict disease in healthy adults but also contribute to the disease process in those who have atherosclerotic disease. The seven major risk factors identified by the FHS are age, sex, blood pressure, total and high-density lipoprotein cholesterol, smoking, glucose intolerance, and left-ventricular hypertrophy (Opie et al, 2006). All FHS cohorts have been examined approximately every 2 to 4 years since the initiation of the study.

In addition to the contributions toward understanding CVD risk factors, the FHS has also been instrumental in establishing the epidemiology of specific CVD subtypes. The FHS demonstrated much of the characteristics and prognosis surrounding myocardial infarction (MI), including its frequent presentation as sudden cardiac death, and the high mortality associated with first MI, particularly in women. Heart failure has been and is a growing epidemic. The FHS was one of the first to describe the incidence, prevalence, and grim natural history of heart failure and also identified hypertension, valvular heart disease, and coronary disease as key etiologies for heart failure (Tsao and Vasan, 2015).

Milestones of the Framingham Heart Study

- 1960 Cigarette smoking found to increase the risk of heart disease.
 - 1961 Cholesterol level, blood pressure, and electrocardiogram abnormalities found to increase the risk of heart disease.
 - 1967 Physical activity found to reduce the risk of heart disease, and obesity found to increase the risk of heart disease.
 - 1970 High blood pressure found to increase the risk of stroke.
 - 1976 Menopause found to increase the risk of heart disease.
 - 1978 Psychosocial factors found to affect heart disease.
 - 1988 High levels of high-density lipoprotein cholesterol found to reduce risk of death.
 - 1994 Enlarged left ventricle (one of two lower chambers of the heart) found to increase the risk of stroke.
 - 1994 OMNI1 included changing racial and ethnic diversity.
 - 1996 Progression from hypertension to heart failure described.
 - 2003 OMNI2 included changing racial and ethnic diversity.
 - 2006 Genetic Research Study begins to identify genes underlying CVDs in 9000 participants from three generations.
 - 2008 Discovery and publication of four risk factors that raise probability of developing precursor of heart failure; new 30-year risk estimates developed for serious cardiac events.
 - 2009 Researchers find parental dementia may be linked to poor memory in middle-aged adults.
 - 2011 Blood lipids and the incidence of atrial fibrillation: The multiethnic study of atherosclerosis and the FHS.
- In 1971 the offspring study was begun to measure the influence of heredity and environment on the offspring of the original cohort. The younger group appears to be more health conscious because they have lower rates of smoking, lower blood pressures, and lower cholesterol levels than their parents at the same age. The Generation III Cohort Study of the grandchildren is presently underway.

Data from Framingham Heart Study: *A timeline of milestones from the Framingham heart study* (website). <http://www.framingham.com/heart/timeline.htm>, 2015.

In the medical model, primary prevention of ASCVD and stroke involves altering similar risk factors toward a healthy patient profile. For ischemic stroke, atherosclerosis is the underlying disease. Therefore optimal lipid levels, as determined by the National Cholesterol Education Program (NCEP) for hypercholesterolemia, are also the target levels to prevent stroke.

Although the National Heart, Lung, and Blood Institute created the NCEP, the AHA has endorsed it. The AHA suggests that primary prevention of CVD should begin in children older than age 2 (Gidding et al, 2009). Dietary recommendations for children are a bit more liberal than those for adults. Activity is emphasized in maintaining ideal body weight. Early screening for dyslipidemia is recommended for children with a family history of hypercholesterolemia or ASCVD.

For adults, a total cholesterol level of 170 mg/dL or less is now considered optimal, including an HDL of at least 50 mg/dL. The new 2013 guidelines no longer rely strictly on cholesterol levels for advising patients or dosing medications. Instead the patient's overall health is evaluated for treatment decisions. The guidelines advise assessing factors such as age, gender, race, whether a patient smokes, blood pressure and whether it is being treated, whether a person has diabetes, and blood cholesterol levels in determining risk. They also suggest that health care providers should consider other factors, including family history. Only after that very personalized assessment is a decision made on what treatment would work best. The ASCVD Risk Calculator developed by the ACC/AHA expert panel is available at the ACC.org website.

Inflammatory Markers

Fifty percent of heart attacks occur in individuals with normal serum cholesterol, which has led to research on other risk markers. Increasing knowledge about the role of inflammation in ASCVD gives credence to the use of inflammatory markers to indicate the presence of atherosclerosis in asymptomatic individuals or the extent of atherosclerosis in patients with symptoms. Several markers have been suggested (Box 32.3), and research continues to look at the effects of diet on these biomarkers. Plasma levels of omega-3 fatty acids are inversely associated with the inflammatory markers C-reactive protein (hs-CRP), interleukin-6 (IL-6), fibrinogen, and homocysteine (Kalogeropoulos et al, 2010). An inflammatory marker specific to vascular inflammation has become available. The PLACTM test measures Lp-PLA2 (Jellinger et al, 2012). Lp-PLA2 levels indicate ASCVD risk independent from other markers and provides information on the relationship between inflammation and atherosclerosis (see Chapters 5 and 7).

Fibrinogen. Most MIs are the result of an intracoronary thrombosis. Prospective studies have shown that plasma fibrinogen is an independent predictor of ASCVD risk. Factors associated with an elevated fibrinogen are smoking, diabetes, hypertension, obesity, sedentary lifestyle, elevated triglycerides, and genetic factors. More clinical trials are needed to determine whether fibrinogen is involved in atherogenesis or is just a marker of vascular damage. Blood thrombogenicity increases with high LDL cholesterol and in diabetes.

C-reactive protein. C-reactive protein (hs-CRP) is synthesized in the liver as the acute-phase response to inflammation. The *hs* refers to human serum. In a normal individual without infection or inflammation, hs-CRP levels are very low, less than 0.6 mg/dL. Because atherogenesis is an inflammatory process, hs-CRP has been shown to be elevated (>3 mg/dL) in people with angina, MI, stroke, and peripheral vascular disease; the elevated levels are independent of other risk factors (see Chapter 5). Despite a lack of specificity for the cause of the inflammation, data from more than 30 epidemiologic studies have shown significant association between elevated blood levels of hs-CRP and the prevalence of atherosclerosis (Morrow and Crea, 2014).

BOX 32.3 Inflammatory Markers for Cardiovascular Risk

Genetic markers: angiotensin II receptor type-1 polymorphism
 Oxidized low-density lipoprotein cholesterol
 Adhesion molecules
 Selectins
 Free fatty acids
 Cytokines
 Interleukin-1
 Interleukin-6
 Tumor necrosis factor-alpha
 Acute-phase reactants
 Fibrinogen
 C-reactive protein
 Serum amyloid A
 White blood cell count
 Erythrocyte sedimentation rate
 Trimethylamine N-oxide (TMAO)

Derived from Fung MM, et al: Early inflammatory and metabolic changes in association with AGTR1 polymorphisms in prehypertensive subjects, *Am J Hypertens* 24:225, 2011; Pearson TA, et al: Markers of inflammation and cardiovascular disease: application to clinical and public health practice: a statement for healthcare professionals from the Centers for Disease Control and Prevention and the American Heart Association, *Circulation* 107:499, 2003.

HS-CRP levels are categorized for risk as low (<1 mg/L), average (2 to 3 mg/L), and high (>3 mg/L) after the average of two measurements are taken at least 2 weeks apart. The Mediterranean diet pattern (Appendix 23) is most effective in inhibiting inflammation. The Dietary Approaches to Stop Hypertension model (described later in the chapter and in Appendix 17) and the plant nutrition model also have proven to be beneficial. The data on low-fat and low-carbohydrate diets are inconclusive (Lee et al, 2014; Smidowicz and Regula, 2015).

Homocysteine. Homocysteine is an amino acid metabolite of methionine. Elevated circulating total homocysteine (tHcy) concentrations have been regarded as an independent risk factor for CVD. However, several large clinical trials to correct hyperhomocysteinemia using B-vitamin supplements (particularly folic acid) have largely failed to reduce the risk of CVD (Baggot and Tamura, 2015).

Although some evidence suggests that homocysteine may promote atherosclerosis, no causal link has been established. And it appears more likely that increased homocysteine levels are markers rather than causes of CVD. Giving supplemental vitamins folate, B₆ and B₁₂, have been shown to lower homocysteine levels in some individuals and is being investigated actively as a treatment for CVD but as of now is not widely recommended.

Trimethylamine-N-oxide. Trimethylamine-N-oxide (TMAO) is a gut microbiota-dependent metabolite that contributes to heart disease (Tang et al, 2013). It is produced by the liver after intestinal bacteria have digested animal protein. TMAO has been shown to predict cardiac risk in individuals not identified by traditional risk factors and blood tests. This is speculated to be a factor in the emerging evidence that a plant-based diet is cardioprotective compared with one that includes animal sources (Tuso, 2015).

Lifestyle Guidelines

Lifestyle modification remains the backbone of CVD prevention and treatment. Adhering to a heart-healthy diet, regular exercising, avoidance of tobacco products, and maintenance of a healthy weight are

BOX 32.4 Summary of American College of Cardiology (ACC)/ American Heart Association (AHA) Recommendations for Lifestyle Management

DIET

LDL-C

Advise adults who would benefit from LDL-C lowering to

1. Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils and nuts; and limits intake of sweets, sugar-sweetened beverages, and red meats.
 - a. Adapt this dietary pattern to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes mellitus).
 - b. Achieve this pattern by following plans such as the DASH dietary pattern, the USDA Food Pattern, or the AHA Diet.
2. Aim for a dietary pattern that achieves 5%-6% of calories from saturated fat.
3. Reduce percent of calories from saturated fat.
4. Reduce percent of calories from trans fat.

Blood Pressure

Advise adults who would benefit from blood pressure lowering to

1. Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils and nuts; and limits intake of sweets, sugar-sweetened beverages, and red meats.
 - a. Adapt this dietary pattern to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes mellitus).

- b. Achieve this pattern by following plans such as the DASH dietary pattern, the USDA Food Pattern, or the AHA Diet.
2. Lower sodium intake.
 3. a. Consume no more than 2400 mg of sodium/day.
 - b. Further reduction of sodium intake to 1500 mg/day is desirable because it is associated with even greater reduction in blood pressure.
 - c. Reduce intake by at least 1000 mg/day because that will lower blood pressure, even without meeting the desired daily sodium goal.
 4. Combine the DASH dietary pattern with lower sodium intake.

PHYSICAL ACTIVITY

Lipids

In general, advise adults to engage in aerobic physical activity to reduce LDL-C and non-HDL-C: 3-4 sessions a week, lasting on average 40 minutes per session, and involving moderate-to-vigorous-intensity physical activity.

Blood Pressure

In general, advise adults to engage in aerobic physical activity to lower blood pressure: 3-4 sessions a week, lasting on average 40 minutes per session, and involving moderate-to-vigorous-intensity physical activity.

Eckel RH, Jakicic JM, Ard JD, et al. 2013 AHA/ACC guideline on lifestyle management to reduce cardiovascular risk: A report of the American College of Cardiology /American Heart Association Task Force on Practice Guidelines. *Circulation* 129: S76-S99, 2014.

known lifestyle factors that, along with genetics, determine CVD risk. Three critical questions (CQs) were addressed in the 2013 ACC/AHA lifestyle modification guidelines. CQ1 presents evidence on dietary patterns and macronutrients and their effect on blood pressure and lipids, CQ2 presents evidence on the effect of dietary sodium and potassium intake on blood pressure and CVD outcomes, and CQ3 presents the evidence on the effect of physical activity on lipids and blood pressure. The recommendations are summarized in [Box 32.4](#).

Diet

The importance of diet and nutrition in modifying the risk of CVD has been known for some time. However, in general, individual dietary components have been the predominant focus. Because foods are consumed typically in combinations rather than individually and because of the possibility of synergist relationships between nutrients, there has been increasing attention to dietary patterns and their relationship to health outcomes such as CVD.

The Mediterranean Diet

There is no uniform definition of the **Mediterranean diet (MeD)** in the published studies, which makes it difficult to pool data. There are common features of the diet, such as greater number of servings of fruits and vegetables (mostly fresh) with an emphasis on root vegetables and greens, whole grains, fatty fish (rich in omega-3 fatty acids), lower amounts of red meat and with an emphasis on lean meats, lower fat dairy products, abundant nuts and legumes, and use of olive oil, canola oil, nut oil, or margarine blended with rapeseed oil or flaxseed oil (see Appendix 23). The MeD dietary patterns that have been studied were moderate in total fat (32% to 35%), relatively low in saturated fat (9% to 10%), high in polyunsaturated fatty acids (especially omega-3), and high in fiber (27 to 37 g per day). The Prevención con

Dieta Mediterránea (PREDIMED) trial was a randomized controlled trial (RCT) looking at the effect of a MeD on CVD outcomes. Those patients randomized to the MeD had a 30% reduced risk of CVD events ([Estruch et al, 2013](#)).

The Dietary Approaches to Stop Hypertension (DASH) Diet

The DASH dietary pattern is high in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts and low in animal protein and sugar. Two DASH variations were studied in the Optimal Macronutrient Intake Trial for Heart Health (OmniHeart) trial, one that replaced 10% of total daily energy from carbohydrate with protein; the other that replaced the same amount of carbohydrate with unsaturated fat. The former showed better results than the latter in lowering CVD risk ([Swain et al, 2008](#); see Appendix 17). The 2013 ACC/AHA lifestyle guidelines recommend the DASH diet as best for prevention of CVD, but also suggest that a MeD pattern is cardioprotective.

Vegan Diet

A vegan diet is a strict vegetarian diet that includes no dietary sources from animal origins (see Appendix 30). There is ongoing research to suggest only this type of very restricted diet can actually reverse ASCVD ([Esselstyn and Goulubić, 2014](#); [Tuso, 2015](#)).

Physical Inactivity

Physical inactivity and a low level of fitness are independent risk factors for ASCVD. Physical activity is associated with ASCVD, independent of the common cardiometabolic risk factors of obesity, serum lipids, serum glucose, and hypertension, in men and women. With the high prevalence of obesity, physical activity is a high priority. Physical activity lessens ASCVD risk by reducing atherogenesis,

increasing vascularity of the myocardium, increasing fibrinolysis, increasing HDL cholesterol, improving glucose tolerance and insulin sensitivity, aiding in weight management, and reducing blood pressure.

The most recent AHA recommendations for exercise for adults are the following:

- Get at least 150 minutes per week of moderate-intensity aerobic activity or 75 minutes per week of vigorous aerobic activity, or a combination of both, preferably spread throughout the week.
- Add moderate- to high-intensity muscle-strengthening activity (such as resistance or weights) on at least 2 days per week.
- Spend less time sitting. Even light-intensity activity can offset some of the risks of being sedentary.
- Gain even more benefits by being active at least 300 minutes (5 hours) per week.
- Increase amount and intensity gradually over time.

The AHA recommendations for children are the following:

- Children 3 to 5 years old should be physically active and have plenty of opportunities to move throughout the day.
- Kids 6 to 17 years old should get at least 60 minutes per day of moderate- to vigorous-intensity physical activity, mostly aerobic.
- Include vigorous-intensity activity on at least 3 days per week.
- Include muscle- and bone-strengthening (weight-bearing) activities on at least 3 days per week.
- Increase amount and intensity gradually over time.

Stress

Stress activates a neurohormonal response in the body that results in increased heart rate, blood pressure, and cardiac excitability. The stress hormone angiotensin II is released after stimulation of the sympathetic nervous system (SNS); exogenous infusion of angiotensin II accelerates the formation of plaque. The INTERHEART study found that the effect of stress on CVD risk is comparable to that of hypertension. Stress management was not part of the 2013 ACC/AHA lifestyle modification guidelines.

Diabetes

Diabetes is a disease that is an independent risk factor. The prevalence of diabetes mirrors that of obesity in the United States. Type 2 diabetes has continued to increase in incidence (see Chapter 29). Any form of diabetes increases the risk for ASCVD, with occurrence at younger ages. Most people with diabetes actually die of CVD. Some of the increased risk seen in patients with diabetes is attributable to the concurrent presence of other risk factors, such as dyslipidemia, hypertension, and obesity. Thus diabetes is now considered an ASCVD risk factor (see Chapter 29).

The Look AHEAD (Action for Health in Diabetes) study, conducted from 2001 to 2012, provided extensive longitudinal data on the effect of an intensive lifestyle intervention, targeting weight reduction through caloric restriction and increased physical activity, on CVD rates (the primary outcome) and CVD risk factors among adults with type 2 diabetes mellitus. Conclusions from the study were that increased physical activity and improvements in diet based on a MeD or DASH pattern can safely lead to weight loss and reduced requirement for medication to control CVD risk factors without a concomitant increase in the risk of cardiovascular events (Fox et al, 2015).

Metabolic Syndrome

Since the early findings of the Framingham Heart Study, it has been known that a clustering of risk factors markedly increases the risk of CVD (see Chapter 20 for an in-depth discussion of metabolic syndrome).

Obesity

Obesity has now reached epidemic levels in children and adults in many developed countries. Body mass index (BMI) and CVD are positively related; as BMI goes up, the risk of CVD also increases. The prevalence of overweight and obesity is the highest that it has ever been in the United States (see Chapter 20). Obesity rates vary by race and ethnicity in women. Non-Hispanic black women have the highest prevalence, followed by Mexican American women, American Indians, Alaskan natives, and non-Hispanic whites.

An obese-years metric was developed using more than 5000 participants of the Framingham Heart Study that captures the cumulative damage of obesity over years. The obese-years metric is calculated by multiplying the number of BMI units above 29 kg/m² by the number of years lived at that BMI. Higher obese years were associated with higher CVD risk in the study. The metric was found to provide a slightly more accurate measure of CVD risk than obesity alone (Abdullah et al, 2014).

Carrying excess adipose tissue greatly affects the heart through the many risk factors that are often present: hypertension, glucose intolerance, inflammatory markers (IL-6, tumor necrosis factor alpha [TNF- α], hs-CRP), obstructive sleep apnea, prothrombotic state, endothelial dysfunction, and dyslipidemia (small dense LDL, increased apo B, low HDL, high triglyceride levels). Many inflammatory proteins are now known to come from the adipocyte (see Chapters 7 and 20). These concurrent risk factors may help to explain the high morbidity and mortality rates observed in people who are obese.

Weight distribution (abdominal versus gynoid) is also predictive of CVD risk, glucose tolerance, and serum lipid levels. Central or abdominal length of adiposity also has been strongly related to markers of inflammation, especially hs-CRP. Therefore a waist circumference of less than 35 inches for women and 40 inches for men is recommended (see Chapter 20).

Small weight losses (10 to 20 lb) can improve LDL cholesterol, HDL cholesterol, triglycerides, high blood pressure, glucose tolerance, and hs-CRP levels, even if an ideal BMI is not achieved. Weight loss also has been correlated with lower hs-CRP levels. However, to restore vascular function, the amount of weight that must be lost, the time of weight maintenance, or the amount of improvement in endothelial function that lessens cardiovascular events is still unknown.

Nonmodifiable Risk Factors

Age and Sex

With increasing age, higher mortality rates from CVD are seen in both genders. However, gender is a factor for the assessment of risk. The incidence of premature disease in men 35 to 44 years of age is three times as high as the incidence in women of the same age. Therefore being older than 45 years of age is considered a risk factor for men. For women the increased risk comes after the age of 55 years, which is after menopause for most women. Overall the increased risk for CVD parallels age.

Family History and Genetics

A family history of premature disease is a strong risk factor, even when other risk factors are considered. A family history is considered to be positive when MI or sudden death occurs before the age of 55 years in a male first-degree relative or the age of 65 in a female first-degree relative (parents, siblings, or children). The presence of a positive family history, although not modifiable, influences the intensity of risk factor management.

Menopausal Status

Endogenous estrogen confers protection against ASCVD in premenopausal women, probably by preventing vascular injury. Loss of estrogen after natural or surgical menopause is associated with increased

ASCVD risk. Rates of ASCVD in premenopausal women are low except in women with multiple risk factors. During the menopausal period total cholesterol, LDL cholesterol, and triglyceride levels increase; HDL cholesterol level decreases, especially in women who gain weight.

Medical Nutrition Therapy

Medical nutrition therapy (MNT), which includes discussion of physical activity, is the primary intervention for patients with elevated LDL cholesterol (see Box 32.4). Physicians are encouraged to refer patients to registered dietitian nutritionists (RDNs) to help patients meet goals for therapy based on LDL cholesterol levels.

With diet, exercise, and weight reduction, patients can decrease LDL cholesterol and reduce body inflammation. The complexity of changes, number of changes, and motivation of the patient will dictate how many patient visits it will take for the adherent to be successful. An initial visit of 45 to 90 minutes followed by two to six visits of 30 to 60 minutes each with the RDN is recommended (Academy of Nutrition and Dietetics Evidence Analysis Library [EAL], 2011). Consequently these interventions are tried before drug therapy and also continue during pharmacologic treatment to enhance effectiveness of the medication (see *Pathophysiology and Care Management Algorithm: Atherosclerosis*).

Lifestyle Recommendations

The ACC/AHA recommends diet and lifestyle changes to reduce ASCVD risk in all people older than the age of 2 (Eckel et al, 2014). The ACC/AHA recommendations are for a diet high in vegetables, fruits, whole grains, low-fat poultry, fish, nontropical vegetable oils, nuts, and low-fat dairy and low in sweets, sugar-sweetened beverages, and red meat. The DASH diet pattern or U.S. Department of Agriculture (USDA) food pattern (MyPlate) is recommended to achieve this diet. The MeD was not specifically recommended because in the evidence evaluated the diet was not specific or consistent enough to draw conclusions. In general, the MeD pattern (Fig. 32.5) fits the recommendations. A study recently presented at the ACC supports the MeD pattern for CVD risk reduction (ACC, 2015). The study included more than 2500 Greek adults over more than 10 years. Nearly 20% of men and 12% of women in the study developed or died from heart disease. People who closely followed the MeD were 47% less likely to develop heart disease than those who did not follow the diet. The MeD Score Tool was used (see Fig. 32.5) to validate the dietary pattern. A MeD may also reduce recurrent CVD by 50% to 70% and has been shown to affect lipoprotein levels positively in high-risk populations (Carter et al, 2010).

Saturated fatty acids. Currently in the United States the average intake of saturated fat is 11% of calories. The recommendation for decreasing LDL cholesterol is 5% to 6%. The guidelines have no specific recommendation for trans fatty acid intake but recommend it be decreased with the saturated fat. Saturated fat is generally found in animal proteins. It is recommended that intake of animal protein, especially red meat and high-fat dairy, be decreased.

Trans fatty acids. **Trans fatty acids** (stereoisomers of the naturally occurring cis-linoleic acid) are produced in the hydrogenation process used in the food industry to increase shelf life of foods and to make margarines, made from oil, firmer. Most trans fatty acids intake comes from these partially hydrogenated oils (PHOs). In 2013 the FDA made a decision to remove PHOs from the “generally recognized as safe” list. This was based on the mounting evidence that trans fats contributed to ASCVD and was associated with increased LDL cholesterol levels. Trans fat intake is inversely associated with HDL levels (Yanai et al, 2015).

Monounsaturated fatty acids. Oleic acid (C18:1) is the most prevalent monounsaturated fatty acid (MUFA) in the American diet. Substituting oleic acid for carbohydrate has almost no appreciable effect on blood lipids. However, replacing saturated fatty acids (SFAs) with MUFAs (as would happen when substituting olive oil for butter) lowers serum cholesterol levels, LDL cholesterol levels, and triglyceride levels. Oleic acid as part of the MeD (Fig. 32.6) has been shown to have antiinflammatory effects.

Polyunsaturated fatty acids. The essential fatty acid linoleic acid (LA) is the predominant PUFA consumed in the American diet; its effect depends on the total fatty acid profile of the diet. When added to study diets, large amounts of LA decrease HDL serum cholesterol levels. High intakes of omega-6 PUFAs may exert adverse effects on the function of vascular endothelium or stimulate production of proinflammatory cytokines (Harris et al, 2009). The AHA does not support concern for omega-6 PUFAs as proinflammatory. However, this position has been challenged by researchers in the field. A recent review of the evidence on the role of omega-6 PUFAs found limited conclusive evidence of an association between n-6 and CVD. Intervention trials were identified but they generally had a small sample size and varied in terms of the study subject characteristics and timing, duration, and dosage of the intervention (Khandelwal et al, 2013).

Omega-3 fatty acids. The main omega-3 fatty acids (eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) are high in fish oils, fish oil capsules, and ocean fish. Some studies have shown that eating fish is associated with a decreased ASCVD risk. The AHA recommendation for the general population is to increase fish consumption specifically of fish high in omega-3 fatty acids (salmon, tuna, mackerel, sardines) and eat a 3.5-ounce serving twice a week. Consumption of omega-3 fat in the form of fish oil has been associated with higher levels of HDL cholesterol and lower levels of serum triglycerides (Yanai et al, 2015; see Appendix 26). The AHA recommends a discussion with a physician before taking fish oil supplements.

An omega-3 fatty acid from vegetables, alpha-linolenic acid (ALA), has antiinflammatory effects (see Chapter 7). Omega-3 fatty acids are thought to be cardioprotective because they interfere with blood clotting and alter prostaglandin synthesis. Omega-3 fat stimulates production of NO, a substance that stimulates relaxation of the blood vessel wall (vasodilation). Unfortunately, high intakes (above 3 g EPA/DHA) prolong bleeding time, a common condition among Arctic Native populations with high omega-3 fat dietary intakes and low incidence of ASCVD.
